Primary care management of older people with mental health problems

Chapter:

Primary care management of older people with mental health problems

Author(s): Louise Robinson and Carolyn A Chew-Graham

DOI: 10.1093/med/9780198807292.003.0022

Introduction

This chapter discusses the presentation and primary care management of the commonest mental health problems in older people. It presents cases drawn from the authors' real-life practice to represent clinical presentations and management within primary care and liaison with secondary care and the wider team. It discusses the management of patients largely within reference to UK primary care systems and policy, but the international readership should find parallels within their own healthcare systems.

Primary care management of older people with mental health problems

Primary care in the UK

In the UK, primary care services are an integral part of the National Health Service (NHS) in which general practitioners (GPs) work as independent contractors. People are required to register as patients with a general practice; currently, a practice determines its boundaries and only accepts patients who reside within this area. The GP works as a generalist and a provider of personal, primary, and continuing care to individuals, families, and a practice population, irrespective of age, gender, ethnicity, and problem. In England, the Health and Social Care Act 2012 requires GPs to undertake a commissioning role with greater involvement in the purchasing of local services for their patients in addition to their service provider role.

GPs increasingly work with a range of healthcare professionals in a multi-disciplinary primary healthcare team. The team includes a practice manager and administrative staff, practice nurses, and nurse practitioners or specialist nurses. Community nurses, such as district nurses, active case managers, Macmillan nurses, and health visitors may be co-located or linked with a group of practices. Team working is essential in order to manage the complex demands placed on general practice, which are partly due to caring for an increasingly ageing population with chronic and multiple health problems. The greater emphasis on preventative care, the transfer of clinical responsibility for some chronic diseases from secondary to primary care, and the shift in service provision in order to deliver care closer to patients' homes has contributed to these demands.

The implementation of a new General Medical Services (GMS) contract in 2004 fundamentally changed the way in which GPs work in the UK. The contract defines essential primary care services and optional enhanced services that are additionally remunerated. The contract links achievements in clinical and nonclinical care quality to financial rewards, through a Quality and Outcomes Framework (QOF) derived from evidence-based care (Gillam et al., 2012). The system encourages the delivery of optimum care in clinical domains, with emphasis on chronic disease management.

Common mental health problems in older people in primary care

Primary care is on the front line in dealing with older people's mental health, supporting families and managing people with complex comorbidities. Older people consult almost twice as often as other age groups: 22% of older people will have attended their GP within the last two weeks and 40% may have a mental health problem (NHS Digital, 2007). This chapter now considers in detail the initial management of the most common mental health problems encountered in older people in primary care. These include delirium, delusions, depression and anxiety, and dementia. These topics are considered from a primary care perspective but are also covered in other chapters throughout the book

Primary care management of older people with mental health problems

(delirium, Chapter 37; psychosis, Chapter 43; depression and anxiety, Chapter 38, 39, and 42; dementia, Chapters 28–36).

Delirium

Delirium is common in hospital patients (10–20% in all medical patients but up to 40% in people with cancer), but it is becoming increasingly common in older people in the community (Young et al., 2010).

Clinical presentation

Delirium is a syndrome comprising disturbance of consciousness (often manifest as impaired attention or concentration), cognitive deficits (such as memory, orientation, and language problems), and disturbed sleep–wake cycle; perceptual problems such as visual and auditory hallucinations and delusions; behavioural disturbance (such as restlessness, agitation, and apathy) and alterations in affect (such as fear), in addition to alterations in social behaviour (e.g. lack of cooperation with reasonable requests, withdrawal, and alterations in communication) (Table 22.1).

Table 22.1 How to differentiate between delirium, depression, and dementia.			
	Delirium	Depression	Dementia
<i>Onset</i>	Acute	Variable	Insidious
<i>Duration</i>	Days	Variable	Months to years
<i>Course</i>	Fluctuates	Possible diurnal variation (worse in morning)	Slowly progressive (though may be stepwise)
<i>Consciousness</i>	Impaired and fluctuating	Unimpaired	Clear at onset
<i>Attention and memory</i>	Inattentive; Poor memory	Poor concentration, sometimes complaining of poor memory	Poor memory but without inattention
<i>Affect</i>	Variable	Depressed;	Variable

Primary care management of older people with mental health problems

		Loss of interest and pleasure in usual activities	

The term delirium is synonymous with 'acute confusional state'. Onset is often sudden (hours or days) and fluctuation is a hallmark; a useful mnemonic is the four 'T's (Crausman, 2004):

1. Intermittent impairment of cognition
2. Inattention
3. Incoherent thought
4. Impaired consciousness.

The differential diagnosis includes depression, which can be associated with agitation or withdrawal, and dementia (Table 22.1).

Three main subtypes are recognized:

1. *Hyperactive delirium* (hallucinations, delusions, agitation, and disorientation).
2. *Hypoactive delirium* (cognitive impairment with apathy or withdrawal, less often accompanied by hallucinations and delusions).
3. *Mixed delirium* (displays both hypoactive and hyperactive features).

The third form can easily be overlooked in older patients.

Delirium can be triggered by a wide range of factors (Box 22.1), but those with pre-existing cognitive impairment or dementia are at increased risk. Age is a risk factor, and people in nursing and residential homes are also at increased risk. Factors frequently combine, e.g. a person with dementia who becomes constipated or develops a urinary tract infection. Delirium is common in end-of-life care and poor management will contribute to a poor-quality death and distress for carers.

Box 22.1 Risk factors and precipitants of delirium

Socio-economic

- Age (>65 years)
- male gender
- little contact with relatives
- institutional care

Physical

- Parkinson's disease
- Pain

Primary care management of older people with mental health problems

- Previous stroke
- Constipation
- Cancer
- Anaemia
- Metabolic (e.g. thyroid disorders, diabetes)

Acute physical event

- Any infection but particularly urinary tract infection (UTI) or lower respiratory tract infection (LRTI)
- Myocardial infarction
- Fracture
- Dehydration
- Organ failure

Mental health

Pre-existing dementia

Medications

- Hypnotics, analgesics
- Anti-Parkinson's disease drugs
- Drug interactions and polypharmacy
- Side-effects causing electrolyte disturbances

Sensory impairment

- Visual impairment
- Hearing impairment (can be as simple as a lost hearing aid)

Functional impairment and disability

- Malnutrition
- Dehydration

Environmental change

House move

Other:

- Shock
- Sepsis

Primary care management of older people with mental health problems

- Surgery
- Sleep deprivation

Assessment

Delirium is a symptom of underlying problems, and not a diagnosis in itself. The diagnosis is made on the history from the patient and a collateral history from informed observers (e.g. family member or caregiver), plus a physical examination to look for physical cause. Investigations in primary care should include: mid-stream specimen of urine (MSU), full blood count (FBC), urea and electrolytes (U&Es), liver function tests (LFTs), C-reactive protein (CRP), thyroid function tests (TFTs), and glycosylated haemoglobin (HbA1C). The practitioner should consider the need for other investigations, such as electrocardiogram (ECG) and chest X-ray (CXR). If more intensive investigation is thought necessary or the patient is at risk, then admission to hospital should be considered.

It is important to assess cognitive function, both as a baseline and to assess fluctuation. If the person is in hospital, use of the Confusion Assessment Method (CAM) (Inouye 1990) or Observational Scale of Arousal (OSLA) (Tieges, 2013) may help to distinguish between delirium, or delirium imposed on underlying dementia (NICE, 2010).

Principles of management

Treatment principles in the management of a patient with delirium focus on the identification and treatment of any underlying disorder, keeping the patient safe and amelioration of symptoms (NICE, 2010). The latter can be subdivided into nonpharmacological strategies and medical management.

Nonpharmacological approaches help keep the patient in touch with reality and therefore less likely to become distressed and agitated:

- Ensure effective communication and reorientation (e.g. explaining where the person is, who he/she is, and what your role is) and provide reassurance for people diagnosed with delirium. Consider involving family, friends, and carers to help with this.
- Managing the environment by avoiding sensory deprivation (e.g. a windowless room) or sensory overload (e.g. noisy environment); ensuring day-night variation in the environment is preserved; providing a large clock; avoiding unnecessary room changes; and trying to have some familiar objects around the patient.
- Maintaining physiological status, e.g. adequate hydration, nutrition, and avoiding hypoxia, constipation.

Primary care management of older people with mental health problems

- Ensure the patient's safety by anticipating and taking steps to prevent complications such as pressure sores, falls, further infections, constipation, and reduction in mobility.

Pharmacological (medical) interventions aim to reduce symptoms that distress the patient or add to risk. They are targeted at specific symptoms, e.g. pain, psychotic phenomena, agitation. Psychotropic medications should be reserved for older persons in distress or with psychotic symptoms, to prevent them endangering themselves or others. The use of psychotropic medication to manage wandering is *not* advocated.

Short term (<1 week), low-dose antipsychotic medications ('major tranquillizers') are often the pharmacological treatment of choice but are reserved for patients with severe agitation or psychotic symptoms and should be avoided in those with Parkinson's disease and dementia with Lewy bodies. Haloperidol, or olanzapine, are recommended as they have fewer anticholinergic side effects, few active metabolites, and only a small chance of causing sedation and hypotension. For haloperidol, the initial dose should be low, 0.5–1 mg, repeated if necessary, every two to four hours, with careful titration of the dose against symptoms. For patients in whom anti-psychotic drugs are contraindicated, lorazepam 0.5–1 mg orally (which can be given up to two hourly; maximum 3 mg in 24 hours) is an alternative.

Assessment of capacity and best interest decision-making

When a patient has delirium, their cognition will fluctuate. The clinician needs to assess whether the patient has the capacity to consent to treatment. In the UK, the Mental Capacity Act 2005 enshrines in statute current best practice and common-law principles concerning people who lack mental capacity and those who take decisions on their behalf. It sets out a single clear test for assessing whether a person lacks capacity to take a particular decision at a particular time (see section 'Legal and ethical issues in dementia', and also Chapter 58). It is a 'decision-specific' test, in this case whether to accept either treatment for a medical condition underlying delirium or a drug to treat its effects. Everything that is done for or on behalf of a person who lacks capacity must be in that person's *best interests*. The Act provides a checklist of factors that decision-makers must work through in deciding what is in a person's best interests, such as known prior wishes, prior verbal or written statements, and the views of those caring for them.

Referral and liaison

Patients admitted to a care home or hospital should be assessed for their risk of delirium (NICE, 2010). Patients with delirium should, where possible, be treated in their usual environment, but if the cause of the delirium is unknown, if confusion and wandering are not controlled, or if the patient is at risk of developing dehydration, then admission to

Primary care management of older people with mental health problems

hospital may be needed. Intermediate care may be an alternative if available. This system of care allows for either an increase in nursing care support for patients who are acutely ill but can be managed at home, or a brief admission to a facility that is intermediate between hospital and home, that offers intensive nursing and physiotherapy support, with a view to early discharge home.

Case study 1 An older Person becomes Confused

Mrs S is an 83-year-old lady who lives in a care home and who became confused overnight. She was reported by the staff to be wandering around the corridors in the night. She was reported to be irritable and argumentative when staff tried to get her up and dressed the next morning. The staff member in charge rang the practice to request a home visit for Mrs S. The GP noted that Mrs S has diabetes, treated hypothyroidism, hypertension, osteoarthritis, hiatus hernia, and recurrent urinary tract infections, and her medications are metformin, levothyroxine, ramipril, simvastatin, omeprazole, and paracetamol.

The GP visited Mrs S and established with the care home staff that she had become suddenly unwell the previous evening. Mrs S was reported to have eaten breakfast and was drinking plenty. She had been incontinent of urine, which was unusual for her. On examination, she was disoriented in time and place and more confused than usual. She was reluctant to be examined. She was afebrile and her pulse and BP were stable (compared to usual readings), her chest was clear, and there were no focal neurological signs. The staff had been unable to collect a urine specimen.

A provisional diagnosis of urinary tract infection was made and she was commenced on trimethoprim, with a request made to collect a urine specimen before and after treatment if possible. The GP also took blood for FBC, U&Es, and blood glucose (recent HbA1C and thyroid function tests had been satisfactory), and requested that the staff monitor Mrs S carefully and discussed how to manage the situation should Mrs S wander about during the night. The GP suggested that the staff should contact the practice again if Mrs S did not improve.

The GP also arranged to return to the care home to review the patient and her medication, particularly to discuss the need for simvastatin and regular omeprazole.

Delusions and other psychotic symptoms

Primary care management of older people with mental health problems

Psychotic symptoms are not uncommon in the older population and prevalence figures in community samples range from 0.2–4.7% (Targum and Abbott, 1999). In nursing homes, prevalence rates from 10% to as high as 63% have been reported (Zayas and Grossberg, 1998).

Among older patients, psychotic symptoms can be seen in a wide range of conditions. The causes and clinical manifestations of the symptoms usually vary with the underlying condition. Psychotic symptoms of acute onset are usually seen in delirium secondary to a medical condition (see Delirium), drug misuse, and drug-induced psychosis (including of prescribed drugs). Chronic and persistent psychotic symptoms may be due to a primary psychotic disorder (chronic schizophrenia, late-onset schizophrenia, delusional disorders, affective disorders), psychosis due to neurodegenerative disorders (Alzheimer's disease, vascular dementia, dementia with Lewy bodies, Parkinson's disease), or chronic medical conditions.

Delusional disorders in older people range from highly circumscribed persecutory delusions, through the presence of both delusions and hallucinations, to a full-blown schizophrenia-like presentation (Table 22.2). Whether these conditions are distinct from schizophrenia is unresolved. Aetiological factors include a genetic component, sensory deprivation (particularly deafness), and long-standing social isolation. Psychotic symptoms can be associated with aggressive or disruptive behaviour (Gilley et al., 1997) and are often a source of distress to caregivers. They can result in neglect and abuse of older patients (Steele et al., 1990) and persistent symptoms often result in admission to a residential or nursing home, which imposes a heavy financial burden (Stern et al., 1997).

Table 22.2 Symptoms of psychosis.

Core symptoms	Delusions, hallucinations
Behavioural changes	Apathy, aimlessness, self-absorbed attitude
Mood symptoms	Depression, anxiety
Vegetative changes	Changes in energy, sleep, appetite
Motor changes	Excitement, posturing, stupor
Cognitive symptoms	Deficits in planning, reasoning, problem solving, working memory

Primary care management of older people with mental health problems

Psychiatrists refer to 'positive' and 'negative' psychotic symptoms especially in relation to schizophrenia. 'Positive' symptoms refer to the core psychotic features, i.e. delusions and hallucinations, whereas negative symptoms are marked apathy, social withdrawal, and blunting of affect.

Assessment

In principle, the assessment of psychotic symptoms in older people is the same as in younger adults, but there are some nuances; the differential diagnosis, especially where onset is new, should always include consideration of an organic (medical) cause, delirium, side effect of a drug, or an early dementia. Physical conditions can produce psychotic symptoms, e.g. in delirium. Therefore, a thorough medical assessment is required that includes a collateral history from a carer or family member, in addition to a full physical examination to rule out and treat any underlying causative medical pathology. A thorough physical examination and full set of blood tests (to exclude metabolic causes for symptoms) are considered essential. This assessment should be carried out in primary care, the Emergency Department (if a patient has presented acutely and been taken there), on a medical ward (if the patient has been admitted), or by the old age psychiatrist.

Management

It is important to consider whether isolated psychotic symptoms not distressing or adversely affecting the patient require treatment with medication (Kidder, 2003); certainly, if the person is distressed or at risk, pharmacological treatment is required.

As older people are at particular risk of tardive dyskinesia, atypical antipsychotics may be more appropriate, although recent evidence (Douglas and Smeeth, 2008) suggests that the side effects from atypical antipsychotics might have been underestimated, and there is an increased risk of cardiovascular disease, including stroke, and metabolic side effects (impaired glycaemic control and raised cholesterol). A careful assessment of potentially remediable environmental causes such as sensory deprivation, poor lighting, and social isolation improve symptoms. Simple practical measures can reduce stimulations that produce psychotic symptoms, e.g. removing mirrors if reflections cause the delusion of having ghosts in the house, or drawing curtains over windows if the patient has a delusion of being spied upon. Addressing other contributory and causal factors such as physical illness and side effects of medication (particularly benzodiazepines, antiparkinson's drugs, some cardiac drugs, nonsteroidal anti-inflammatory drugs) is equally important. Treatment of older people with schizophrenia can be difficult because of lack of insight and capacity, but response to antipsychotics is usually good (Howard et al., 2018), especially if

Primary care management of older people with mental health problems

treatment can be prolonged, e.g. by close monitoring or use of depot injections.

The current UK guidance on schizophrenia and psychosis from NICE (2014) addresses the management and treatment of psychotic disorders in adults with onset before the age of 60 years, though clearly many patients will have lived beyond that age. The general principles of management certainly can be applied to the over 60 years age group. The NICE guideline recommends working in partnership with the service user and their carers in an 'atmosphere of hope and optimism' (NICE, 2014). There is a strong emphasis on the management of both mental and physical health, the role and needs of carers, and the recovery model leading to optimal social functioning.

The NICE guidance recommends a prompt referral to mental health services if a distressed person, with an associated decline in social functioning, has transient or attenuated psychotic symptoms, other experiences or behaviour suggestive of possible psychosis, or a first-degree relative with psychosis or schizophrenia. The assessment should be carried out by a consultant psychiatrist or a trained specialist with experience in managing at-risk mental states.

Mental health services should now be offering carers an assessment of their needs forming the basis of an annually reviewed care plan, which should be received by their GPs. Carers should also be advised about their statutory rights to a formal carer's assessment from social care services and how to access it. With the service user's permission, carers are to be included in decision-making and be offered a 'carer-focused education and support programme' (NICE, 2014), which has a positive message about recovery.

Oral antipsychotic medication and psychological input—namely, family intervention and cognitive behavioural therapy—are the mainstays of treatment. Psychological interventions are not recommended on their own.

The management of psychosis in older people requires special consideration not only (and especially) with respect to prescribing medication, but also to the legal framework under which treatment is administered. It is not uncommon for treatment decisions to be made in a patient's best interests under the Mental Capacity Act 2007 when they lack capacity to consent for themselves, for example, when managing behavioural and psychological symptoms in dementia (BPSD), or to use the Mental Health Act 2007 when assessment and treatment are necessary to manage risk to the patient or others.

Referral and liaison

If psychotic symptoms are suspected, an assessment of the risk to the patient (and others) is required, and whether the patient can remain at home. Referral for specialist opinion from old age psychiatry will be

Primary care management of older people with mental health problems

indicated for new-onset symptoms, the urgency depending on risk, and the availability of family and social support. With the population ageing, more people with psychosis diagnosed in earlier adult life are entering old age and may require ongoing input from specialist services.

Case study 2 A difficult hospital discharge

A patient, Deirdre R, was discharged from hospital to a local nursing home and is newly registered with the practice. Her discharge letter stated that she was admitted to hospital from a residential home with a chest infection and that the previous home refused to take her back because of 'difficult behaviour'. The discharge letter mentioned 'chronic schizophrenia'. Discharge medication was risperidone, temazepam, lansoprazole, ramipril, and bendroflumethiazide.

The day after discharge, the nurse in charge of the home rang the practice and asked for an urgent visit because Deirdre was reported to be aggressive, had urinated in another person's room, and was talking to herself.

The GP agreed to visit Deirdre, but first contacted the hospital ward to ask for further information about Deirdre's usual behaviour. Deirdre had been seen by the old age psychiatry team while she was on the ward and they were arranging follow-up, although it was unclear when this might be. At the visit, the staff complained that they had not been made aware of how difficult they were going to find managing Deirdre and asked if she could be prescribed night sedation. The GP examined Deirdre to ensure that there were no acute physical conditions to account for her increased confusion and arranged for an MSU to be sent.

The GP suggested that a joint visit with the old age psychiatrist might be useful so that her care and management within the care home can be planned, collaboratively with the staff, and arranged for this to be held later in the week. This seemed to be acceptable to the care home staff.

Depression

Depression is projected to be the leading cause of disease burden in middle- and higher-income countries by the year 2030 (Mathers and Loncar, 2006). Depression is a major contributor to burden on the individual, the family, and healthcare costs. Older adults face adversity in areas of ill-health, bereavement, isolation, loneliness, and loss, all of which are associated with depression. The experience of loss is central to

Primary care management of older people with mental health problems

feelings of anxiety and depression among community-dwelling older people (Kingstone et al., 2017).

Depression in older adults, traditionally defined as age older than 65 years, is associated with disability, increased mortality, poorer outcomes from physical illness, and increased use of primary and secondary care resources (Pearson et al., 1999). Population studies have demonstrated that depression severe enough to warrant intervention is one of the commonest mental health problems facing older people, affecting around one in ten older people in the community (Copeland et al., 1999). Major depression is a recurring disorder and older people are more at risk of recurrence than the younger population (Mitchell and Subramaniam, 2005).

According to WHO data, proportionately more people aged over 65 take their own lives by suicide than any other age group, and most will have suffered from major depression. Older people who attempt suicide are more likely to die than younger people, while, in those who survive, prognosis is worse for older adults (Manthorpe and Iliffe, 2010). A meta-analysis using studies with moderate to high methodological quality showed that the point prevalence of major depression in those over the age of 75 ranged from 4.6–9.3%, whereas rates for sub-threshold depressive symptoms (those failing to reach diagnostic criteria) ranged from 4.5–37.4% (Meeks et al., 2011). Most depressive episodes in late life will be a recurrence rather than a first-ever episode, and the increased women-to-men ratio is in line with that in younger adults. Prevalence rates of depression are increased in brain disorders, including dementia, Parkinson's disease, and stroke, and in people with long-term conditions, e.g. diabetes mellitus, cardiovascular disease (Moussavi et al., 2007).

Why does depression in older people go undetected and under-treated?

Older people consult their primary care practitioner more frequently than younger people, yet depression is diagnosed less often in older people (Chew-Graham et al., 2004). Older people can present with nonspecific symptoms such as malaise, tiredness, and insomnia, rather than disclosing depressive symptoms (Unützer et al., 1999), and these symptoms fit poorly with current classifications of mood disorders. Such classifications have been generated to reflect symptoms observed in younger people and have inherent limitations for diagnosis of depression in older people, whose presentation may differ because of ageing, physical illness, or both (Chew-Graham et al., 2004). In addition, physical symptoms, in particular pain, are common and the primary care clinician may feel they represent organic disease. Similarly, forgetfulness may lead health professionals to be concerned that the patient has cognitive impairment and early dementia, rather than depression (Unützer et al., 1999).

Primary care management of older people with mental health problems

Older people experiencing or at risk of loneliness may not consider that primary care has a role in alleviating loneliness because it is not an illness (Kharicha et al., 2017). In that study, older people tended to think that primary care practitioners tend to lack understanding of non-physical problems and that a good relationship was necessary to discuss sensitive issues like loneliness.

Older adults may have beliefs that prevent them from seeking help for depression, such as a fear of stigmatization and that antidepressant medication is addictive (Givens et al., 2006), or may not consider themselves candidates for care because of previous experience of help-seeking (Chew-Graham et al., 2012). In addition, older people are reluctant to recognize and name 'depression' as a set of symptoms that legitimizes attending their GP (Chew-Graham et al., 2012), or they may misattribute symptoms of major depression as being due to old age, ill-health, or grief (Burroughs et al., 2006; Overend et al., 2015), and they may use normalizing attributional styles that see depression as a normal consequence of ill health.

Primary care practitioners may lack the necessary consultation skills and confidence to correctly diagnose late-life depression. They may be wary of opening a 'Pandora's box' in time-limited consultations and instead collude with the patient in what has been called 'therapeutic nihilism' (Burroughs et al., 2006). In addition, due to the time-limited nature of primary care consultations, clinical decision-making is often centred around prioritizing competing patient demands that may focus on medical comorbidities. This is especially true in health settings like the NHS where the management of people with long-term conditions is driven by guidelines and treatment algorithms that focus on single diseases. In these time-limited and highly structured environments, competing demands on health professionals' time often lead to prioritization of physical health problems (Rost et al., 2000; Coventry et al., 2011). Additionally, a lack of congruence between patients' and professionals' conceptual language about depression, along with deficits in communication skills on the part of both patients and professionals, can lead to uncertainty about the nature of the problem and reduce opportunities to develop appropriate treatment strategies (Coventry et al., 2011).

Case-finding for depression in older people

Box 22.2 shows the risk factors for depression in older people, identified from large community studies (Colasanti et al., 2010). Thus, case-finding for depression in patients with such risk factors has been advocated using the Whooley questions (Box 22.3) (Whooley et al., 2000), which enquire as to whether over the past month, a person has often: i) felt down or depressed, and ii) experienced little interest or pleasure in doing things. This approach was incentivized under the GMS Contract between 2007 and 2013 to encourage detection of cases of depression.

Primary care management of older people with mental health problems

Box 22.2 Risk factors for depression in older people

Physical factors

Chronic disease:

Diabetes

Ischaemic heart disease

Heart failure

Chronic obstructive pulmonary disease

Organic brain disease:

Dementia

Parkinson's disease

Cerebrovascular disease

Endocrine/metabolic disorders:

Thyroid disease

Hypercalcaemia

B₁₂ and folate deficiency

Malignancy

Chronic pain and disability

Psychosocial factors

Social isolation

Change in financial circumstances

Being a carer

Change of role and loss of social status

Bereavement and loss

Difficulty in adapting to illness/pain/disability

History of depression

Being in institutional care

Box 22.3 Case-finding questions for depression

Primary care management of older people with mental health problems

1 During the past month, have you often been bothered by feeling down, depressed, or hopeless?

2 During the past month, have you often been bothered by having little interest or pleasure in doing things?

A 'yes' to either question is considered a positive test.

A 'no' response to both questions makes depression highly unlikely.

Source: data from Whooley, M., Stone, B., and Sogikian, K. (2000). Randomized trial of case-finding for depression in elderly primary care patients. *Journal of General Internal Medicine*, 15, 293-300.

There is some evidence (Arroll et al., 2005) that the further question, 'Is this something you want help with?' increases the usefulness of the screening questions in practice. This may help the flow of the conversation and the negotiation of discussion of distress (Coventry et al., 2011). An assessment of severity of the depression should be made by the GP using a schedule such as Patient Health Questionnaire-9 (PHQ-9) (Kroenke et al., 2001). In addition, it is vital that the GP explores with the patient ideas and plans for self-harm, and factors preventing the patient from acting on such ideas or plans.

In terms of screening for depression in later life, the Geriatric Depression Scale (GDS) (Yesavage et al., 1983) is widely used. False positives mean that the use of the GDS in entire practice populations of older people is not justified, but opportunistic screening or screening of at-risk groups may be useful, although there is little evidence to support this. The GDS has the advantage of having a comprehensive website that lists short and long versions in a variety of languages, many of which have cross-cultural validity (Rait et al., 1999). Other authors question the usefulness of such reductionist approaches (Dowrick, 2009) and emphasize the value of professional judgment over the narrow use of schedules (Van Weel et al., 2009).

Symptoms of depression in older people

The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) summarizes the common symptoms often present in depression and which the GP should explore in the consultation; five of more of these should be present for the depression to be classed as major (American Psychiatric Association, 2013). When taking a background history, it is important to identify factors that may precipitate and maintain depression (Box 22.2).

The key symptoms about which the practitioners should enquire include: low mood, reduced interest or pleasure in usual activities, changes in appetite or weight (up or down), too much or too little sleep, poor concentration, fatigue, and feelings of guilt or hopelessness.

Primary care management of older people with mental health problems

The following nuances are important in older people: somatic preoccupation, hypochondriasis, and the morbid fear of illness, which are more common presentations than the complaint of low mood or sadness. This can cause problems for the GP, as a depressed patient's hypochondriacal complaints can be quite different from the bodily symptoms expected from a knowledge of the patient's medical history. Subjective memory disturbance may be a prominent symptom and lead to a differential diagnosis of dementia, but true cognitive disturbance is also common in late-life depression. This usually takes the form of executive dysfunction, meaning difficulty in initiating and persevering with mental tasks. Anxiety is a common presenting or accompanying symptom and may mask the underlying depression. Dementia may alter the presentation of depression, and primary care clinicians should be aware that sustained irritable disruptive outbursts in patients with dementia may signify co-existent depression. Apathy and withdrawal are not uncommon symptoms and it is thought that apathetic presentations in later life with executive dysfunction may be due to vascular disease of the brain, to which older people are prone. Alcohol misuse is often linked to depression. Lastly, a persistent complaint of loneliness in an older person not usually prone to such remarks, often accompanied by a request to be rehoused, should prompt enquiry into mood, feelings, views on the future, and assessment of risk, and a more systematic enquiry about biological symptoms of depression, along with a formal assessment.

Assessment

Diagnosis is based on clinical interview, observation of the patient's behaviour, and, if possible, a collateral history from relatives and caregivers. The GP should cover five areas in the primary care consultation when depression is suspected in an older person: history, mental state, risk assessment, focused physical examination, and appropriate investigations, including FBC, U&Es, LFT, TFT, vitamin B₁₂ and folate, HbA1C, bone profile, and any further tests dictated by clinical presentation. The risk of self-harm must be established. Even seemingly medically trivial attempts at self-harm in older people cannot be ignored (Manthorpe and Iliffe, 2010) and should be assumed to be due to depression unless proven otherwise. It is important to check carefully for delusional ideas, as assessment and treatment of such patients require early referral for specialist opinion.

Severity of depression can be assessed using a validated assessment schedule such as PHQ-9 (Kroenke et al., 2001) and this is included in the QOF of the GMS contract in England and Wales.

Management of depression in older people

Most patients with depression are managed in primary care settings; however, a substantial number of patients are not recognized, and those who are diagnosed often do not receive effective treatment (Chew-Graham et al., 2004). There is a good evidence base for the management

Primary care management of older people with mental health problems

of depression in older people (Baldwin et al., 2003). The treatment goals are to treat the whole person, reduce risk, and achieve remission of depressive symptoms (because partial recovery is associated with later risk of relapse and chronicity). A longitudinal primary care cohort study in the Netherlands reported that the median duration of a major depressive episode in late life was 18 months, with two-thirds of patients taking three years to recover (Licht-Strunk et al., 2009).

There are effective treatments for the management of late-life depression (Wilson et al., 2001); however, only one in four depressed older people receive effective pharmacological treatment and fewer than 10% a talking therapy (Singleton et al., 2001; Prina et al., 2014; Pettit et al., 2017), despite the fact that many people express a preference for such treatments (Givens et al., 2006).

It is important that the GP explores the patient's views of their problem and the options that might be available to them. So, for example, a patient's views on antidepressants and talking through treatments or psychosocial interventions, what to expect, and waiting times are vital. In addition, the GP has a role in signposting to third-sector agencies (if acceptable to the patient) and thus should be familiar with groups and local networks in his or her area. Exercise and activity are important. Behavioural activation is a technique that can overcome the withdrawal and apathy that so often exists in late-life depression. It works by helping the patient develop a schedule of activities (which the patient used to enjoy doing but has stopped due to low motivation and apathy), agreed with the patient, with or without a written diary to support implementation. The GP can use some of these techniques within the primary care consultation, particularly advising about diet, exercise, and alcohol, encouraging behaviour change and goal setting, challenging negative thinking, and teaching relaxation techniques. GPs can give self-help leaflets to patients that reinforce the content of their discussion within consultations. Regular follow-up and support are important and is called 'active monitoring' in the NICE guideline for depression (NICE, 2009a).

Psychosocial interventions

Cognitive behavioural therapy (CBT), interpersonal psychotherapy (IPT), problem-solving treatment (PST), and psychodynamic psychotherapy are the most widely researched forms of psychotherapy in later-life depression (Gatz et al., 1998; Pinquart and Sörensen, 2001). In moderate to severe (nonpsychotic) depressive episodes, combining antidepressant medication with a psychological intervention such as CBT or IPT can improve outcomes further (Reynolds et al., 1999).

Behavioural activation has been shown to be an effective treatment for depression (Cuijpers et al., 2007) and results from a 2009 meta-regression analysis suggest that psychological therapy, particularly CBT, IPT, and PST, is equally effective in older and younger adults with

Primary care management of older people with mental health problems

depression (Cuijpers et al., 2009b). Combined psychological therapy and pharmacological therapy is more effective than psychological treatment alone for older people with depression (Cuijpers et al., 2009a). Anxiety management can be a highly effective adjunctive treatment for depressed patients, especially where patients who are recovering from depression are left with residual anxiety, low confidence, or phobic avoidance, which can undermine functional improvement.

Family work is important: the patient may unconsciously use the family to foster invalidism, which the family may then unwittingly reinforce. The unconscious goal may be to live under the same roof as one's children. More positively, the family is often critical in ensuring a successful outcome in treatment, e.g. reinforcing messages about treatment concordance, exercise and activity, and goal-setting, and the primary care team should work with the family as well as the individual patient.

The UK NHS has invested significant resources to improve access to routine, evidence-based, first-line treatment of common mental health problems for adults of working age by rolling out the Improving Access to Psychological Therapies (IAPT) programme across England. Initial evaluation from the demonstration sites suggested that older people are not referred as readily as those under the age of 65 (Clark et al., 2008).

Stepped care and NICE guidelines

Stepped care for common mental health problems is recommended in the primary mental healthcare setting within the UK (NICE, 2011a). The basic principle of stepped care is that patients presenting with a common mental health disorder will 'step through' progressive levels of treatment as necessary (Bower and Gilbody, 2005). There is limited evidence for this approach, particularly in older people, and it is suggested (Unützer, 2002) that systematic models of care dedicated to proactively managing depression as a chronic illness are required.

Initial management by the GP should include information about depression and referral to third-sector resources such as Age UK. Exercise is recommended by the NICE guidelines as a treatment for mild to moderate depression (NICE, 2009a), but there is only limited evidence for this approach in older people (Singh et al., 1997). Training in the use of the Internet to increase social support has been shown to reduce complaints of loneliness and depression (White et al., 2002) and there is recent evidence that befriending has a useful function in the management of mild depression in older people. Interventions offered need to encourage social engagement, such as befriending, and enhancement of creative, physical, and social activity (Chew-Graham et al., 2012).

Primary care management of older people with mental health problems

Collaborative care is recommended by NICE (2009a) in step 3 for people with depression and long-term conditions. There is evidence that this approach is effective (Katon et al., 2010). The intervention should involve (Gunn et al., 2006):

- a multiprofessional approach to patient care delivered by a GP and at least one other health professional (e.g. a nurse, psychologist, psychiatrist, or pharmacist);
- a structured patient management plan that facilitates delivery of evidence-based interventions (either pharmacological or nonpharmacological);
- scheduled patient follow-ups on one or more occasion, either face-to-face or by remote communication (e.g. telephone);
- enhanced interprofessional communication between the multiprofessional team who share responsibility for the care of the depressed patient (e.g. team meetings, case conferences, supervision).

A key component of collaborative care is the introduction of a care (or case manager) in primary care. The case manager acts as the conduit between patients and professionals in primary and specialist care and works as the patient's support or advocate to jointly determine problems, set goals and action plans, and offer education and problem-solving skills as ways to promote better patient self-care. The PROSPECT study (PRevention Of Suicide in Primary care Elderly: Collaborative Trial) studied the effect of a depression care manager offering recommendations to GPs according to a guideline and helping patients with adherence to medication (Bogner et al., 2007). The IMPACT study (Improving Mood: Promoting Access to Collaborative care Treatment) utilized a case manager coordinating care and delivering a specific psychosocial intervention (behavioural activation or problem-solving treatment) with or without medication management, and liaising with both the GP and the specialist mental health services (Unützer et al., 2002). Both studies suggest the effectiveness of such a collaborative care approach that has been shown to be acceptable to family physicians (Levine et al., 2005), and evidence from the UK (Chew-Graham et al., 2007; Bosanquet et al., 2017) is promising.

Treatment with antidepressants

Selective serotonin reuptake inhibitors (SSRIs) are well established as first-line treatment for moderate to severe depression in older adults. A Cochrane review included 32 randomized controlled trials of antidepressant treatment in people aged 55 or over and reported that SSRIs and tricyclic antidepressants (TCAs) had similar efficacy, but that TCAs were associated with more side effects and withdrawal from treatment (Mottram et al., 2006). Consideration of a patient's other medication is required when initiating treatment with antidepressants, although an SSRI will usually be first line. If antidepressants are considered, it is vital that the GP explores the patient's views and

Primary care management of older people with mental health problems

concerns about such medication, and a full discussion about these drugs, the time taken to work, and the possible side effects are covered.

Ongoing support and review from the GP, accompanied by written information, particularly when antidepressants are prescribed, is important. The patient should be warned about common side effects that can occur when tablets are started (such as nausea, fatigue, headache, and increased anxiety), including longer-term side effects (such as reduced libido and weight gain), and doctors should be aware of the risk of GI bleeding (particularly if the patient is taking aspirin) and hyponatraemia. The patient should be warned about the side effects of stopping an antidepressant abruptly and that it is vital to continue the antidepressant for at least nine months (longer if this is an episode of recurrent depression) to achieve remission of symptoms (National Collaborating Centre for Mental Health, 2011). For further details of antidepressant prescribing, see Chapter 39.

The NICE guideline (2009a) suggests that an SSRI should be tried for at least two weeks, possibly up to six weeks in older people, before considering a change in antidepressant. It is appropriate to start at the therapeutic dose of an SSRI for older people (care being taken to ensure there are no drug interactions). An increase in dose can be tried before an alternative SSRI is prescribed. Alternatively, mirtazapine could be prescribed, particularly if the patient has chronic pain or sleep problems. The GP should attempt to tailor the drug to the patient's symptoms. If there is no improvement in depressive symptoms, it is vital that the GP considers comorbidities, concurrent prescribing, alcohol excess, continuing loss and loneliness, or a diagnosis of vascular depression. In addition, risk of suicide should always be assessed.

Referral and liaison

The role of specialist care in the collaborative care model has been described in Stepped care and NICE guidelines. Referral to an old age psychiatrist is necessary if the patient is at risk of self-harm or suicide, or neglect. Referral should also be considered when treatment with two antidepressants and talking treatment has not led to an improvement of the patient's symptoms. At this stage, discussion with and/or referral to an old age psychiatrist is indicated. Treatment resistance may require a second antidepressant or addition of a mood stabilizer, both of which should only be initiated in specialist care, or consideration of electroconvulsive therapy (ECT). Guidance is outlined in the NICE guideline for depression (NICE, 2009a).

Case study 3 An Multimorbidity and depression

Sirfraz Ali consults his GP to discuss the pain in his knees. He is reluctant to take painkillers as he says he is 'already taking so many

Primary care management of older people with mental health problems

tablets'. He admits that he feels his diabetes has not been well controlled since his wife died, and says he feels lonely even though his grown-up children all live nearby. He is tearful during the consultation and says he feels ashamed of how he feels. He says he is frightened of what his future holds. Sirfraz admits that he feels low but insists that this is understandable as his wife died and he feels a burden on his children. He says that he should be strong and feels angry with himself for being 'like this'. He denies thoughts of harming himself, although admits reluctantly that he wishes every night that he won't wake up in the morning. He has had recent blood tests which confirm a high HbA1C, but all other tests are normal. A PHQ-9 is 18 and the GP suggests that Sirfraz may be depressed. He is not happy to use this word and says that he 'shouldn't have mental problems'. The GP acknowledges his feelings about the word 'depression' and suggests that there are ways of improving how he feels and that he might wish to attend a local support group (the GP is aware of two groups in a local community centre that are for South Asians, and one group in a local church for people with diabetes), but also gives Sirfraz some written information about depression. They discuss things that Sirfraz used to like doing and established that he likes cricket and photography, so the GP asked him to think about how he might get back to these hobbies.

On review two weeks later, Sirfraz is no better; he hadn't felt able to contact the support groups, and said most days he was just sitting at home, was not answering the telephone, and had stopped his family coming around to see him on two occasions. The GP asked if he wished to talk more about how he felt and how this was affecting his life. Sirfraz said that talking wasn't something he felt comfortable with, so the GP suggested that antidepressants might help, and discussed how it is thought they work, how long they would take to work, and what the potential side effects might be. Although reluctant, Sirfraz agreed to take a prescription, but also agreed that he could be referred to the local IAPT (Improving Access to Psychological Services) service, saying that he would be willing to be seen, although he did not want to participate in a group. The GP asked Sirfraz if he would return in a further two weeks. The GP contacted the local IAPT service to see if they had therapists who work with people with long-term conditions (LTCs) and depression, and also talked to the practice nurse about how the practice could better offer support to people with depression and LTCs.

Anxiety

Primary care management of older people with mental health problems

Epidemiology

Anxiety disorders are more common than depression in all age groups and as common in older people, and are accompanied by significant morbidity; the 2007 UK household survey reported a 9% prevalence of mixed anxiety and depression (McManus et al., 2009). 'Anxiety' covers the terms generalized anxiety disorder (GAD), panic disorder, obsessive-compulsive disorder, and phobia (National Collaborating Centre for Mental Health, 2011). GAD is a common disorder, of which the central feature is excessive worry about different events associated with heightened tension. A formal diagnosis using the DSM-IV classification system requires two major symptoms (excessive anxiety and worry about a number of events and activities, and difficulty controlling the worry) and three or more additional symptoms from a list of six (feeling wound-up, tense, or restless; becoming easily fatigued; concentration problems; irritability; tension in muscles; and difficulty with sleep). Symptoms should be present for at least six months and should cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Symptoms of anxiety

Patients complain of worry, irritability, tension, tiredness, or 'nerves', but older people may complain of somatic symptoms that may cause difficulty for the GP and may result in unnecessary investigations for the patient. Anxiety often co-exists with depression, and the GP also needs to be aware of the link with alcohol misuse and should always explore alcohol consumption in older people who present with symptoms of anxiety.

Assessment

Some clinicians consider anxiety and depression to be part of a continuum, and labelling the patient as having one disorder or the other may be less important than assessing the severity and impact on the patient's life. This may be a valid perspective in primary care, where people often present with mixed or comorbid problems, but it is important to distinguish which symptoms are most prominent in order to focus explanations, identify appropriate management and resources, and ensure referrals are made (Buszewicz and Chew-Graham, 2011). Thus, the use of the GAD-7 has been advocated as a useful instrument to assess severity of anxiety and thus direct management (Spitzer et al., 2006). The need to assess risk to the patient is often overlooked when the predominant symptom is anxiety, but patients are at risk of self-harm and self-neglect, and the GP should be aware of this.

Management of a patient with anxiety

Anxiety and depression are often comorbid conditions. The NICE guideline for anxiety (NICE, 2011c) advocates a stepped care model for the management of people with anxiety and this approach is appropriate for older people with anxiety symptoms, with or without depression. Thus,

Primary care management of older people with mental health problems

discussion with the patient about the symptoms and their meaning should occur, followed by negotiation of a management plan acceptable to the patient. When physical symptoms are the presenting problem, appropriate physical examination may help to reassure the patient that their symptoms are being taken seriously, but repeated investigations should be avoided. Initial management should involve verbal and written information about anxiety and signposting to age-appropriate support groups (e.g. Age UK) or self-help groups (Anxiety UK), and discussion of behavioural activation techniques, with an arrangement to follow the patient up. This constitutes 'active monitoring' in the NICE guideline for anxiety (NICE, 2011c). As in the management of depression, appropriate advice about alcohol and activity should be given.

If there is no improvement of symptoms, then discussion with the patient about the acceptability of referral for 'low-intensity psychological interventions' should take place. If this is unacceptable to the patient, then the GP should discuss with the patient how the patient would feel about taking antidepressants (SSRIs) and the rationale for this suggestion. Management of anxiety in older people should be no different from management in younger adults (see Chapter 42), although the link with chronic physical health problems means that a collaborative care approach (see Stepped care and NICE guidelines) may be indicated, although there is limited evidence for this and further research is advocated (Buszewicz and Chew-Graham, 2011).

Referral and liaison

Occasionally, patients with GAD suffer severe functional impairment, or are at risk of self-neglect or self-harm (NICE, 2011c). In such cases, urgent referral for a specialist opinion is required. Persistence of symptoms should also lead to discussion with a specialist, and research is required to assess the place of a collaborative care model for the management of people with anxiety.

Case study 4 A frequent attender

Miss Peters is 67 years old and has presented at the desk asking to be seen. The receptionist asks the GP on duty what she should do as Miss Peters seems quite agitated. She informs the GP that Miss Peters has already been seen in the practice once this week, and the GP sees from the computer records that she was complaining of abdominal pain and nausea. Today she is apparently complaining of chest discomfort and shortness of breath. The GP notes she is taking mirtazapine, ramipril, bisoprolol, calcium and vitamin D tablets, and paracetamol.

The GP asks Miss Peters to take a seat in the waiting room and tells her that she will be seen at the end of surgery. Miss Peters is calm

Primary care management of older people with mental health problems

when she enters the consulting room, but soon becomes agitated and tearful and talks about her constant fear that 'something awful is going to happen'. She is distressed and clutches her chest. The GP establishes that her chest pain is not exertional and does not sound cardiac. The GP reflects to Miss Peters about her repeated attendances and her symptoms and asks her what she thinks might be wrong. Miss Peters insists that she must have a heart problem and thinks she needs to go to hospital.

The GP acknowledges her worries and suggests that there might be other ways of managing her problems and asks her if she would complete a GAD-7. She agrees and scores 16. The GP suggests she might be suffering from anxiety and that there is help available. Miss Peters does not seem sure about this and insists that it is her body that has the problem and she says she has 'nothing to be anxious about'. Initially, the GP gives Miss P some reading material about anxiety and provides a relaxation CD, along with the suggestion that setting herself a goal to achieve each day might be helpful. The GP also mentions referral to the local primary care mental health service and antidepressants as options, and asks Miss P to consider both these before the next appointment, which they arrange in two weeks.

The GP is careful to document this consultation in detail in the records, so that if Miss Peters contacts the practice again before the next scheduled appointment, the consulting GP is aware of the plan negotiated at this consultation.

Dementia

In 2015, there were around 47 million people worldwide living with dementia and this number is projected to triple by 2050 (Livingston et al., 2017). In the UK, about two-thirds of people with dementia live in private households, with the majority of their care provided by primary and community care teams (Prince et al., 2014). With age the strongest risk factor for dementia, the illness is currently one of the major causes of care burden and disability in later life; costs of care are estimated to be around £28 million and rising (Prince et al, 2014). However, recent findings from large epidemiological studies have shown that both the incidence and prevalence rates of people with dementia is almost 20% less than predicted 20 years ago (Matthews et al., 2013; Matthews et al., 2016) despite ageing populations. Thus, numbers of people with dementia will continue to rise but perhaps at a slower rate than was anticipated. This is thought to be due to better vascular risk control and chronic illness care as well as better education.

Primary care management of older people with mental health problems

As a consequence of these findings, many high-income countries have introduced public health strategies, such as national dementia awareness campaigns, to help improve awareness of dementia and thus facilitate earlier diagnosis. In the UK, a national dementia strategy was introduced in 2009, and since this date, dementia diagnosis rates have increased from less than 40% in 2009 to 67.5% in 2018 (NHS England, 2018).

Symptoms and initial presentation

The diagnosis of dementia can be delayed by the insidiousness of the symptoms and the perceptions of both lay and professional people that these may be due to normal ageing (Bamford et al., 2007). General practice is often the first point of contact for patients with memory problems or other suspicious symptoms. Individual GPs will have different abilities and confidence in diagnosing and managing dementia, although professional confidence in this area appears to be increasing in the last decade (Tang et al., 2018).

Initially, the patient may present with memory problems, communication difficulties, behavioural issues, and/or personality changes; they are often accompanied by a concerned family carer (Bamford et al., 2007). As the illness moves into the moderate stages, memory and communication difficulties worsen and there may be concerns around personal care and/or safety issues, such as non-concordance with treatment in a previously compliant patient, hoarding of medication, missed appointments, difficulty managing money, and poor coping at home. Suspicions of family carers recorded in patients' notes help prompt further evaluation at subsequent contacts, and aid earlier diagnosis (Bamford et al., 2007).

Indirect presentation of a patient with possible dementia to other members of the primary care team or other community professionals is common. Practice receptionists or community pharmacists may report missed appointments, difficulties in patients' management of repeat prescribing, or obvious confusion or distress over medication. The community nurse or social worker may observe disorientation of a patient visited for other needs, or a health visitor may report a family crisis precipitated by failure to cope with a person affected by undiagnosed dementia.

Assessment

The initial assessment should include a careful history from the patient and their main carer, with relevant information from the patient's notes; a physical examination with baseline investigations and an objective cognitive assessment should be also carried out by the GP (NICE, 2018). The first step for the GP is to exclude a potentially treatable illness or reversible cause of the dementia, as in Case study 5. A history of a recent fall suggests the possibility of a subdural haematoma and, if suspected, immediate referral to a geriatrician or neurologist should be made for an urgent CT brain scan. A review of medication may identify incorrect

Primary care management of older people with mental health problems

dosage or drug interactions that are causing intellectual impairment. These may include sedatives, tranquillizers, antiparkinsonian agents, and hypotensives; adjustment or withdrawal of these will clarify the diagnosis. Normal pressure hydrocephalus, hypothyroidism, syphilis, hypercalcaemia, and vitamin deficiencies as the cause of, rather than result of, dementia are rarities in practice. For GPs, depression masquerading as dementia ('pseudodementia') is probably the most common differential diagnosis and should always be considered; if suspected, a trial of antidepressants may be indicated.

Case study 5 A patient with memory loss

The warden of a sheltered housing unit requested a GP to visit Mrs W, a 78-year-old female resident who had been 'going downhill' mentally for the past few months with memory loss, intermittent confusion, incontinence, and difficulty with self-care. The patient had a past history of atrial fibrillation and transient ischaemic episodes from cerebral emboli, and had been commenced on warfarin. The warden recalled a fall six weeks earlier, after which the patient had been examined at hospital and reassured that no injury had occurred. Rereferral for further investigation resulted in the detection of chronic bilateral subdural haematomas on CT scan, with no cerebral atrophy. Following surgery, her confusion cleared. Despite only partial recovery of memory, she was again able to cope alone.

A physical examination of the patient, particularly to look for anaemia, cardiac disorders, neurological evidence of previous stroke, and undiagnosed malignancy, is essential. Baseline investigations in primary care should include full blood count (FBC), erythrocyte sedimentation rate (ESR), biochemistry, and thyroid function tests, although results are more likely to detect co-existent medical pathology than to aid the differential diagnosis of dementia. The correction of iron- or vitamin-deficient anaemias, the control of cardiac arrhythmias, and treatment of hypothyroidism are good medical practices, but there is a risk of the GP diverting clinical interest into 'medicalization of the patient', rather than confronting the management of the underlying dementia.

Use of cognitive assessment tools in primary care

A number of simple tools are available for use in the community to make an initial assessment of a person's cognitive function; no single brief cognitive assessment tool performs better than any other (NICE, 2018). Until issues with copyright, the most commonly used cognitive assessment tool was the Mini-Mental State Examination (MMSE) (Folstein et al., 1975). It is scored out of 30 with a score of less than 25 being suggestive of dementia. However, this can take up to 20 minutes to

Primary care management of older people with mental health problems

complete and may not be practical for use within a primary care consultation, which is usually seven to ten minutes in length. The General Practitioner Assessment of Cognition (GPCOG) (Brodaty et al., 2002), and two other cognitive screening tests, the Mini-Cog Assessment Instrument (Borson et al., 2000) and the Memory Impairment Screen (MIS) (Buschke et al., 1999), have been found to be as clinically and psychometrically robust and more appropriate for use in primary care than the MMSE (Milne et al., 2008). The GPCOG is estimated to take five to seven minutes to complete, with questions for both the patient and family carer, and thus may be more relevant for primary care physicians (Brodaty et al., 2002). Another alternative, developed in primary care, is the six-item Cognitive Impairment Test (6CIT), which performs as well as the MMSE and is easier to use (Brooke and Bullock, 1999). Addition of a clock-drawing test may also be a useful quick and simple test for the GP to use (Shulman, 2000).

Specialist assessment and confirmation of the diagnosis

If the GP is highly suspicious of a possible diagnosis of dementia, he/she should refer the patient for a specialist multi-disciplinary assessment preferably to old age psychiatry or, if locally available, a memory clinic (NICE, 2018). Increasingly, old age psychiatry and memory clinics have access to specialist scanning facilities to enable not only a diagnosis of dementia to be made but also a specialist subtype of dementia to be confirmed (NICE, 2018). Case study 6 illustrates the advantages of early referral, including relief at acquiring an explanation for distressing symptoms; access to anticholinesterase inhibitor drugs and specialist cognitive rehabilitation and/or psychological interventions; advice on appropriate information and support services, including day care; carer assessment and support; and the ability to undertake advance care planning (Robinson et al., 2015).

Case study 6 A patient with dementia

George P, a 77-year-old man with a history of hypertension, hyperlipidaemia, and polycythaemia, presented to his GP with concerns about his memory but no disturbance of function. An initial MMSE score was 27/30. The GP arranged to review him at six-monthly intervals. One year later, he attended with his wife who was very concerned. She stated he was becoming confused and disorientated when outside; his MMSE was now 24. He was referred to the memory clinic, where a scan revealed changes consistent with vascular dementia. He and his wife chose to complete a Lasting Power of Attorney for finance and to visit the local dementia café for peer group support.

Primary care management of older people with mental health problems

If patients are in the moderate to severe stages of the illness, it may be less distressing for them to have an initial specialist assessment in their home in the presence of relatives; this can also facilitate a joint assessment with the local authority social services care coordinator to discuss both diagnosis and a future care plan. Despite the need to inform patients and their families sensitively and accurately of a diagnosis of dementia, disclosure rates vary considerably; often, family carers are told the diagnosis more frequently than patients and that there is still considerable use of euphemistic terms by health professionals (Robinson et al., 2011).

Long-term management in the community

People with dementia live an average of five years from the emergence of symptoms (Rait et al., 2010). Together with their old age psychiatry colleagues and/or community mental health teams, the GP and the primary healthcare team are responsible for coordinating and directing the long-term clinical management of patients with dementia; local authority social services are responsible for the social care and support of the patient (Robinson et al., 2015). Treatment of medical conditions co-existing with dementia should be continued, if supervision is available, until a decision is made for palliative care. Prescribing of cholinesterase inhibitors to people with mild/moderate dementia is recommended (NICE, 2018) in order to slow the rate of deterioration. Shared care protocols provide a framework for GPs to continue prescribing such drugs once a specialist decision to initiate treatment has been made (NICE, 2018).

In the UK, national guidance (NICE, 2018) and the National Dementia Strategy (Department of Health, 2009) both propose a systematic approach to the long-term support of people with dementia in the community, with care plans tailored to the needs and circumstances of individual patients and carers and, more recently, the specific allocation of a named care coordinator (NICE, 2018). Such an approach should include: the provision of psychosocial interventions to help reframe dementia and reduce the rate of cognitive decline; the provision of relevant information on prognosis; care options and financial and legal issues; the recognition of personal and social needs; the assessment and support of key carers (Cameron et al., 2011); the treatment of underlying medical conditions or disability; the management of behavioural problems and relationship difficulties; and ensuring where possible, that the patient remains in their preferred place of care for as long as is feasibly possible (Livingston et al., 2017).

Nonpharmacological interventions for the person with dementia

There is increasing evidence that some non-drug interventions can improve short-term performance or reduce the rate of cognitive decline, especially if combined with anticholinesterase medication (Alzheimer's Disease International, 2011; NICE, 2018). Such interventions include cognitive rehabilitation (a more individualized approach to help people

Primary care management of older people with mental health problems

focus on residual cognitive skills and improve their coping strategies); cognitive stimulation (an approach that targets cognitive and social functioning through reality orientation and other activities); reminiscence therapy (discussion of past activities, events, and experiences); and occupational therapy. Unfortunately, often due to a shortage of specialist services, such psychological therapies may not be easily and readily accessible to people with dementia, despite their being recommended in national clinical guidance on dementia (NICE, 2018).

Management of behavioural problems in the community

Most people with moderate to severe dementia will experience behavioural and psychological symptoms (BPSD) at some time, particularly in the middle and later stages (Savva et al., 2009). However, while the risks, such as wandering and getting lost, from such behaviour are often not as high as carers fear (Robinson et al., 2007), BPSD can lead to high levels of carer stress or curtailment of the person with dementia's activities, and they may be the crucial factor that leads to care home moves (Balestreri et al., 2000).

National guidance in the UK recommends non-drug approaches as the first-line management of such symptoms (NICE, 2018), but in the community this can be very difficult to achieve due to i) a lack of access to specialist nursing and psychological services to enable an individualized assessment of patients and their environment, to determine the antecedents, behaviours, and possible causes ('ABC' approach); and ii) the limited high quality evidence for the clinical and cost effectiveness of nonpharmacological treatments (NICE, 2018).

The UK has recently developed a multi-disciplinary pathway for the optimized management of BPSD. This pathway provides evidence-based guidance to primary, secondary, and community care professionals, including care home staff, on the holistic management of these challenging behaviours (Alzheimer's Society, 2011). If the behaviour persists and becomes more severe despite the use of non-drug approaches, the GP can prescribe a short course of an antipsychotic drug, such as risperidone (0.5–1mg); however, prescribing of these drugs should be time limited and only reserved for severe and distressing symptoms after careful assessment of the risks and benefits of their use and consideration of the type of dementia (O'Brien, 2008; Burns and Iliffe, 2009). There is some evidence that antidepressants, such as citalopram, may help behavioural symptoms including agitation and psychosis (Pollock et al., 2002). Cholinesterase inhibitors do not seem to be effective (Howard et al., 2007) and stopping them should be considered if a person is agitated.

Providing information in dementia

There is some evidence that information provision to families living with dementia can improve quality of life (Corbett et al., 2011). Family

Primary care management of older people with mental health problems

members and other supporters should have access to information and advice from sources that are accurate and allow them to address their individual concerns, which may be different to those anticipated by clinicians (Livingston et al., 2017; Wald et al., 2003; van der Roest et al., 2009). Accurate and up-to-date information should be available in primary and secondary care, social care, and voluntary and community settings (Robinson et al., 2015). Voluntary or third sector organizations are a major source of information for people with dementia and their families; in the UK, organizations such as the Alzheimer's Society (<http://www.alzheimers.org.uk>), Age Concern (<http://www.ageuk.org>), and Dementia Services Development Centres offer a wide range of information and practical advice, such as the *10 Helpful Hints* series of books (see <http://dementia.stir.ac.uk>). People with financial problems may find caregiving particularly difficult and may benefit from early signposting to financial or debt advice agencies (Robinson 2015). Welfare benefits provide some financial remuneration for people with a chronic illness and their family carers. The Disability Parking Scheme allows people with severe mobility impairment or their carers to park close to the places they want to reach, and is available also to those with severe memory impairment.

Legal and ethical issues in dementia

The GP is well placed to provide sensitive and timely discussion of legal and financial matters (Robinson et al., 2015), including information and advice about seeking Power of Attorney (POA) and advance care planning (ACP) for future health or care preferences (see Chapter 58). In England, the introduction of the Mental Capacity Act 2005 has provided a statutory framework for acting and making decisions on behalf of adults who lack the mental capacity to do so for themselves. The code of practice associated with the Act provides guidance on good practice for those acting under the terms of the Act. It contains i) guidance on how to assess capacity; ii) a statutory framework for an advance directive; and iii) advice on how to manage patient decisions, once the advance directive is applied (Department of Constitutional Affairs, 2007). The Act has also established an Independent Mental Capacity Advocate (IMCA) service; this provides representation and support for individuals who lack capacity but who have no one else to support them when major decisions are being made about their lives.

The Act has also seen the introduction of a new formal POA, the Lasting Power of Attorney (LPA), which has replaced the provision for existing Enduring Powers of Attorney (EPA), although the latter remain valid if executed before the implementation of the 2005 Act. LPAs extend the areas in which donors can authorize others to make decisions on their behalf to include personal care and medical treatment, i.e. any matter of personal welfare, in addition to LPA for property and financial affairs.

Primary care management of older people with mental health problems

ACP is a term used to refer to a series of discussions between patients, their families, and care professionals about their future wishes for their care should they lose capacity. There is some evidence that ACP can improve patient and carer outcomes in dementia (Robinson et al., 2012; NICE, 2018). Following these discussions, patients can formally record their wishes in a number of ways, including the completion of an advance directive, or living will, as it was previously known (see Box 22.4). In the UK, NICE (2011b) has provided quality standards on end-of-life care for adults, and there is a current debate about the choices that should be offered to people as they near death.

Box 22.4 Outcomes of advance care planning discussions: International and national terminology

- Statement of wishes and preferences:
 - Documents an individual's wishes and preferences for future care and is not legally binding.
 - In the UK, this is known as an advance statement.
- An advance directive for refusal of treatment (originally known as a 'living will'):
 - Comprises a statement of an individual's refusal to receive specific medical treatment in a predefined potential future situation.
 - It is legally binding and comes into effect when a person loses mental capacity.
 - In the UK, this is known as an advance decision to refuse treatment (ADRT).
- A proxy decision-maker or Power of Attorney (POA):
 - A legally binding document whereby the person nominates another ('attorney') to make decisions on his or her behalf should he/she lose capacity.
 - In England, following the introduction of the Mental Capacity Act, this is now known as a Lasting Power of Attorney (LPA); there are two separate aspects to LPA, one in relation to a person's health and welfare and another in relation to property and affairs.

Primary care management of older people with mental health problems

Caring for the caregivers: The role of the GP

Carers of people with dementia are more likely to experience depressed mood, to report a higher burden, and to have worse general health compared with carers of people with other long-term conditions (Brodaty et al., 2002; World Alzheimer Report, 2011; see also Chapter 54). In dementia, carers may grieve or experience loss as their relative loses functional and cognitive abilities and the tangible benefits of companionship, affection, and intimacy (Zarit and Zarit, 2008); this experience has been likened to 'coping with a living death' (Woods, 1989). Depressed mood in the carer is one of the factors that determine the move of the person with dementia to residential care (Gallagher et al., 2011) and may lead to abuse of this person with dementia. In view of the evidence, primary care physicians should endeavour to provide proactive carer support and to monitor their health and wellbeing, in addition to caring for the person with dementia (Cameron et al., 2011; NICE, 2018).

There has been a considerable increase in research in the area of specialist multicomponent interventions for family carers of people with dementia, which have been shown positively to influence both carers' health and care home admission rates (NICE, 2018). At a personal level, carers expect realistic information about dementia, the implications of the diagnosis, and its prognosis, and how to make best use of available facilities. Services should be adapted to the individual circumstances of the carer and the patient, and be culturally sensitive to differing racial, cultural, and religious backgrounds. The carer should be accepted as a contributing member of the care team, and effective communication with carers should be encouraged through discussion and the keeping of clear, concise records. For housebound patients, a shared care record, held in the patient's home, will maintain continuity and improve communication between the different professionals involved.

The carer may or may not be registered with the same practice as the patient. Overall, the evidence suggests that clinicians need to tailor interventions to the specific needs of individual carers and systematically assess carer needs (Pinquart and Sörensen, 2006; Sörensen et al., 2006). As it is the family that bears the major burden of caring for older people, the GP is the pivotal support for the family unit. The GP's role should include offering advice to carers on their personal health, acknowledging the carers' crucial contributions and the problems they experience, and giving emotional support by counselling the carer on their attitudes and expectations (Cameron et al., 2011). Vigilance by the GP in detecting early signs of strain or poor coping will help to avert crises; high rates of carer abusive behaviours towards care recipients have been recently reported in the UK (Cooper et al., 2009).

The community nurse team may also have a valuable supporting role, teaching carers the practical skills needed for home nursing and providing emotional support.

Primary care management of older people with mental health problems

Some areas of England have access to an Admiral Nursing Service; these are specialist nurses with expertise in dementia care and, in particular, carer support (Bunn, 2013). However, to date, evidence shows little difference in patient or carer outcomes between families receiving this specialist service and those supported by existing community teams (Woods et al., 2003). Although respite or short-break care is often offered as a means of providing support to the carer, and is positively received by them, the long-term benefits remain unclear (Mason et al., 2007).

Ensuring preferred place of care and care at home

The success of maintaining the patient at home depends on the carer's reason for caring, the quality of the relationship with carers, and identifying and addressing the carers' needs. Regular visits by the community psychiatric nurse, the community nurse, and a named GP, regardless of whether the patient lives alone or with carers, provides support and a coordinated, multi-disciplinary approach between primary and secondary care. Support services from local authority social services can include home care assistants, delivery of ready prepared meals, advice on financial benefits, and respite care. In the UK, voluntary organizations such as Age UK and the Alzheimer's Society can provide a wide range of support, including information and advice (legal and financial) as well as practical support via peer support groups, dementia cafes, carer support groups, sitting services, and respite care.

In addition to behavioural disturbances, other distressing problems arise with the progression of dementia and include sleep disturbance, swallowing difficulties, food and drink refusal, incontinence, and immobility. Advice can be offered on regular toileting to encourage continence and, if incontinence is a problem, aids such as pads, pants, and protective mattress sheets are available through the community nursing services. Referral to appropriate allied health professionals, such as the community physiotherapist, speech therapist, and occupational therapist, for their specialist assessment should be considered to enhance a patient's functional health and also facilitate access to aids and adaptation to help the family cope at home.

The patient with dementia who lives alone

Providing primary care services for older, demented patients who live alone poses special problems, and may only be possible through the goodwill of neighbours and external social care support. If access to the home is unreliable, arrangements should be made with neighbours to hold emergency keys. Neighbours are reassured by contact with the GP and by discussion about when to request help. If there is no available supervision from family carers or the community nurse team, the taking of medication can be simplified by use of a dosette box in which medication is placed into daily dosage compartments dispensed on a weekly basis by a pharmacist. Single patients with dementia may cause concern over security, and personal road and home safety. The local

Primary care management of older people with mental health problems

police welcome information about these vulnerable residents and this is particularly encouraged if there is a local neighbourhood security scheme. When eventually these patients require admission to a protected environment, a residential care or nursing care home is more appropriate than a sheltered housing unit, where the need to become familiar with new surroundings whilst still living independently is liable to accentuate confusion, as illustrated in Case study 7.

Case study 7 A Person with Dementia who Lives Alone

An 84-year-old woman with dementia who had no relatives lived alone with difficulty. The social services arranged admission to a nearby sheltered housing unit. Within a short time, she appeared more confused, her room became squalid, and she roamed the streets and was frequently returned by the police. She developed paranoid behaviour, attacked several residents, and was formally admitted to hospital under Section 2 of the Mental Health Act. Following assessment and treatment, she was stable enough to be transferred to a nursing home for people with dementia.

Social care for people with mental health problems

Social care covers a range of services and support to help people maintain their health and independence in the community (see also Chapter 25). Such services include home care (personal care, meals, laundry, shopping), day services, respite care, and, if available, residential and/or nursing care. In the UK, recent policy and legislation has aimed to improve the current provision of community care through increasing the choices available to users of these services and creating more integrated services. Initiatives include the inclusion of a Personal Health and Social Care plan in a patient's records to integrate health and social care provision, the establishment of joint health and social care teams, and the introduction of personal budgets, whereby people who require social care can opt to receive payments directly and purchase services themselves, potentially enabling greater choice and control. Evidence has revealed that personal budgets have the potential to achieve greater efficiency while giving people greater control and satisfaction (Alakeson, 2007; Carr, 2010). In dementia care, social care also has a safeguarding role in terms of the increased vulnerability of people who may not have the mental capacity to make their own decisions. There is increasing support for integrated health and social care models as a means of providing more integrated and person-centred dementia care (NICE, 2018).

Primary care management of older people with mental health problems

Respite care

Carers are at risk of increasing isolation and exhaustion through the intensity of their 24-hour responsibilities. To prevent this, and to delay institutionalization, the GP should emphasize the value of relief care, which can be organized on a daily basis, through day centres or sitting services, or on a longer-term basis through rotation of care with other family members, or planned regular admissions to respite beds in residential care or hospitals. The GP should be prepared to advise carers and families on respite care, and offer information on the range of options and the referral process appropriate to the patient's level of dependency.

For support in the home, domiciliary care may be offered by voluntary organizations or home care agencies such as Age UK, the Alzheimer's Society, and local authority social services. Families and carers are reassured to know that voluntary organizations are regulated and required to work to specific care standards. Short-term care can be arranged in residential care homes for patients who are mobile and only mildly confused; short-term care in nursing homes or hospitals should be arranged if the patient needs more intensive nursing care, is seriously confused, or doubly incontinent. If the patient is self-funding, private care arrangements are made, but if financial assistance is needed, referral for a community care assessment should be made to the local authority social services by the carer or GP well before the planned admission date (see Chapter 26). Patients are assessed against eligibility criteria for funded care. When a patient requires nursing care or supervision, or needs multi-disciplinary assessment and rehabilitation, admission to hospital or a nursing home is the responsibility of the NHS. Since April 2004, the NHS and local authority councils have been required to identify people who are likely to require short-stay respite care, and to agree arrangements for their management.

Although respite admission provides an opportunity for multi-disciplinary assessment of the patient, and may delay institutionalization, it may not reduce the overall burden on the carer. Heavily dependent patients may need regular admissions, e.g. for two out of every eight weeks, to ease the strain on carers. Relatives appreciate the opportunity of visiting the home or hospital beforehand to gain confidence in the staff and the surroundings, as the family may have reservations about delegating care to staff who are less familiar with the patient's condition than they are. Disadvantages of respite care for the carer include the difficulties of visiting patients in hospital or nursing homes, feelings of sadness, loneliness, and guilt on being separated from their relative, and the possibility of institutional cross infections. Some carers, however, refuse offers of help or indeed any support; others may stoically underplay the strain of caring, and deny the seriousness of the illness in their relative.

Primary care management of older people with mental health problems

Situations requiring hospital admission

A point may be reached when the carer is no longer willing, or able, to cope. Increasing disability of the patient outstrips the tolerance of the carer and is particularly likely to occur when sleep disturbance, wandering, incontinence, and immobility are problems. The patient then requires long-term care. It is important to be aware of the abuse of older people, which may be a symptom of strain in the carer (see Chapter 55). If this is suspected, the GP should refer the patient to social services for an assessment, and perhaps for transfer to a place of safety in hospital or residential care.

Acute admissions mostly occur when there is unexpected illness in the carer, or when a mildly demented patient who lives alone suffers a self-limiting illness that, under normal circumstances, would not require admission. In some areas, local schemes such as 'Hospital at Home' initiatives and rapid response nursing teams are available; these provide comprehensive 24-hour nursing at home for people who would traditionally have been cared for in hospital. Out-of-hours emergency calls by relatives who infrequently visit a mildly demented patient living alone, and insist that 'something must be done' before their return home, is not an uncommon crisis, and may express their own guilt.

It is vitally important to provide adequate and timely information between hospital staff and primary care teams involved in caring for older people with dementia or other mental health conditions, as their needs are often multiple and complex. In the UK, the current dementia commissioning guidance for GPs recommends that they are immediately notified of the diagnosis to improve communication and allow the GP to provide immediate support and further discussion with the family (Department of Health, 2011). However, the reality of the situation in practice is somewhat different and GPs may not be aware that a diagnosis has been made until they receive a clinic letter.

For older people with mental health issues who have been admitted to hospital, prompt discharge letters should include information on the patient's care needs, particularly in relation to community services and carer support, medication, general condition, and follow-up requirements. Sending discharge letters with patients to be handed to the GP is unreliable, especially when patients have poor mobility, live alone, or suffer memory loss. First attendances, hospital discharges, and a change in the treatment or condition of a patient should be reported, as should annual progress of patients attending for long-term care. Letters should summarize the findings at consultation, an assessment and management plan, and have educational value for the GP.

When patients are discharged or managed in outpatients, effective liaison between hospital staff and GPs is essential, especially when patient medication is initiated or changed; the consultant should give the GP timely notification of the patient's diagnosis and details of the drug

Primary care management of older people with mental health problems

therapy. The doctor who signs the prescription has legal responsibility for the consequences of drug treatment, and must not prescribe without adequate clinical information; it is therefore unacceptable for hospital staff to expect GPs to do so. For patients under consultant supervision, medication should normally be prescribed in hospital and dispensed in the hospital pharmacy for not less than 14 days at discharge, or after initiating treatment in outpatients, to ensure they have enough medication.

Intermediate care

The development of rehabilitation and care schemes that are intermediate between acute hospital care and long-term institutional care has led to a range of alternative provision termed *intermediate care*. Such services are designed to maximize independence and prevent unnecessary hospital admissions. Most schemes offer short-term interventions (one to six weeks) and involve cooperative working with other agencies including primary care teams, local authority social services, and the voluntary and private sectors. For acute care, recent developments aim to bridge the divide between hospital trusts and local authorities. Examples include innovative services such as 'hospital at home' or 'supported discharge' schemes in which the patient is discharged early from hospital and supported by intensive home nursing; these are acceptable to both patients and carers and provide care as effectively as hospital admission (Wilson et al., 1999). However, the cost effectiveness of intermediate care schemes in general remains uncertain and the availability of hospital at home schemes is variable (Robinson, 2014).

An alternative to acute hospital admission is the use of small community hospitals or nursing homes, in which inpatient care is provided by GPs and their multi-disciplinary teams who usually have recourse to specialist advice. This is a useful option when insufficient home care or community support makes continuing home care untenable, particularly when mentally impaired patients require acute generalist care or rehabilitation. Continuing care schemes, rehabilitation, and palliative care may be provided by community outreach teams, or by domiciliary and outpatient therapy services as alternatives to day hospital or inpatient care.

Home care services and residential care

Home care provision by local authority social services and independent voluntary sector organizations has allowed people to remain in their own homes for longer than was previously possible before admission to a residential care home or nursing care facility. Intensive home care services and increased contact hours by care staff have contributed to improvements in the quality of life and independence of older people (NHS Health and Social Care Information Centre, 2006). The GP has a coordinating role and acts as a point of contact for community care staff. The decision to transfer a patient into residential care is difficult and

Primary care management of older people with mental health problems

should only be taken after all possible community support services in the home have been explored with the patient's relatives and the community planning team. The latter consists of community nurses, social services, and, in patients with complex needs, the community matron employed by the local primary care team. Patients or their relatives seeking admission to a home are advised to discuss the situation with the community nurses caring for the patient and with the patient's GP before requesting assessment for a nursing home placement.

Nursing homes lie predominantly within the independent sector and are subject to registration with the NHS (see Chapter 26). Medical care in nursing homes may be provided by an attending medical officer appointed by the home, or more usually by a local general practice under contract for the provision of general medical care. Patients in residential care homes register with a local GP and have access to general medical care in the same way as the general population. Studies have shown that, in the population living in residential care, there is a high prevalence of physical dependency and depression (McDougall et al., 2007; Seitz et al., 2010) and even higher prevalence rates for dementia (Matthews et al., 2013). This results in high rates of consultation, prescribing, and referral for the attending GP, with the workload for patients in nursing homes being double that for other patients over the age of 74 years (Carlisle, 1999).

Managing people with terminal illness at home

In England, dementia is now the leading cause of death in older women. In the UK, over 40% of people with dementia die in the community; however, around one-third of people with dementia die in acute hospitals (Houttekier et al., 2010; Public Health England, 2018). It is the GP who coordinates their care, both for those who die at home and, in the time preceding admission, for those who die in hospital or hospice care. About 70% of older people with dementia die from bronchopneumonia, a finding confirmed on post-mortem (Burns et al., 1990), while cardiovascular disease, pulmonary embolus, septicaemia, and renal failure account for the remainder of deaths.

Prognostic tools have been developed for use in dementia but there is little evidence for their effectiveness or that they change key outcomes such as comfort (van der Steen et al., 2011). Although evidence is limited, there is general consensus that a palliative care approach is appropriate in dementia (NICE, 2018) and best practice recommendations have been made (van der Steen et al., 2014). The principles of maximizing comfort and quality of life should therefore take precedence and the benefits of potentially unnecessary interventions carefully considered. When patients with dementia become ill with a respiratory infection, the GP should discuss the poor prognosis with relatives and discover their preferences and their knowledge of their relative's wishes for the preferred place of care. Wherever the patient is cared for and whatever the mental status, the principles of good terminal care apply (NICE, 2018). These include:

Primary care management of older people with mental health problems

mouth care; the control of distressing symptoms such as pain and constipation; the involvement of community nurses and specialist palliative care services; and attention to the need for emotional, practical, and spiritual support for both patients and their families.

People with dementia and their families require more input from healthcare and social services prior to death than do people with terminal cancer (McCarthy et al., 1997). More recently, a variety of interventions and new service models to improve the quality of end-of-life care in dementia have been developed and evaluated; however, most studies to date have been small scale (Livingston et al., 2017). In some countries, assisted dying for people with dementia is legally permissible but in others this approach still raises considerable ethical and legal issues (Livingston et al., 2017).

Primary care: Opportunities for research in older people's mental health

General practice provides a wealth of opportunities for research in the area of older people's mental health. To achieve a whole-population approach in epidemiological surveys or in studies of community care-based interventions, it is worth considering the potential of general practice; a successful example is the Cognitive Function and Ageing Study (CFAS), which has recruited a cohort of 13,000 people aged 65 years and over to explore their cognitive, physical, and psychological health (Matthews et al., 2013; Matthews et al., 2016). Advantages of recruitment of patients from primary care include: the possibility of a more accurate database compared to the electoral register; a personal approach to the patient through the GP, which may lead to higher response rates; access to the patient's medical records and up-to-date chronic disease registers; and the GP's personal knowledge and contact with patients, which facilitates data collection and interpretation of results.

The question of whether to involve multiple small practices or one large group practice should be considered, along with the demographic balance of the practice populations; this avoids the use of skewed population samples and ensures the recruitment of sufficient patient numbers. In the UK, the introduction of national research networks, including for primary care, dementia and mental health, within the National Institute of Health Research (NIHR), has been successful in facilitating primary care-based research.

Having enlisted the cooperation of an interested general practice, it is essential to gain consent from participating GPs and, at the outset, to visit the practice to explain the project to all staff. The acceptability of protocols, letters, questionnaires, and pilot studies should be confirmed with staff, before seeking approval from a local research ethics committee. Establishing a link with a key practice administrator and a GP from each practice facilitates effective organization. It is recommended

Primary care management of older people with mental health problems

practice, according to the requirements of the Data Protection Act 2018, that researchers should obtain the consent of the patients or subjects before the practice is able to release their contact details to the research team.

In communicating with patients, it is essential to provide information on the research project and its potential benefits. The identity of the research clinician and his/her relationship with the practice should be explained. Patients appreciate a choice of venue for an interview, and usually the preferences range between home, the surgery, and the hospital. The researcher should provide a photo identity card, a letter of introduction from the link GP, and a contact telephone number, for security reasons and to reassure patients, relatives, and neighbours. Where door-to-door surveys are being carried out, it is essential to inform the local police, because neighbours will rightly be highly suspicious. There is usually a long lead-in time when setting up research and the actual interviewing, so a check on a patient's health status should be made by practice staff prior to visiting so as to avoid the distress of including acutely ill or recently deceased subjects. A common problem when interviewing in the community is how to respond to patients' requests for medical advice. As the interviewer is not providing general medical care, any difficulties with the patient's consent should be referred to the patient's doctor.

On completion of the research, feedback to the general practices involved helps to integrate the results with the clinical needs of patients, and to foster a sense of purpose and satisfaction. It is courteous to acknowledge the contributions of participating practices in papers submitted for publication. Indeed, if a GP has personally collected research data, joint authorship should be considered. This will provide a sense of goodwill that may lead to further fruitful collaboration with general practice.

Conclusion

Recognition by the primary care physician or GP of early changes, use of clinical intuition, and acting on family worries are vital in the earlier detection of mental health problems in older people. An awareness of the increased risk of depression in older people with comorbid physical conditions is vital. Members of the primary care team should provide holistic care for older people with mental health problems, and their carers, both at the point of diagnosis and in the longer term. Appropriate referral to secondary care and good liaison and collaboration between primary and secondary care are vital in the management of older people with mental health problems. Knowledge of third-sector services and appropriate referral can improve the support available to older people and their carers.

Memory assessment services

Chapter: Memory assessment services

Author(s): Sube Banerjee and Nicolas Farina

DOI: 10.1093/med/9780198807292.003.0023

Of clinics and services

Memory clinics were first established in the US in the 1970s in specialist centres interested in research into Alzheimer's disease (AD) and dementia. These clinics offered outpatient diagnostic, treatment, and advice services for people concerned about their memory. In addition to general research into dementia, Fraser (1992), describing these early services, identified four core functions:

1. To forestall deterioration in dementia by early diagnosis and treatment
2. To identify and treat disorders other than dementia that might be contributing to the patient's problems
3. To evaluate new therapeutic agents in the treatment of dementia
4. To reassure people who are worried that they might be losing their memory, when no morbid deficits are found.

Memory assessment services

The thing that set these memory clinics apart from normal neurological, neuropsychiatric, and old age psychiatric clinics was their specific focus on dementia. None was a full-time operation; most were exactly what they said they were—a clinic, a room in a specific hospital where once or twice a week or month there was a specific focus. The term ‘memory’ seems to have been used in order to avoid the negative connotations of the word ‘dementia’ and to denote a broader interest in cognition. The first memory clinic in the UK was probably that opened at St Pancras Hospital in London in 1983. The numbers of such clinics grew, so that it was possible to identify 20 clinics in 1995 (Wright et al., 1995), 102 in 2002 (Lindesay et al., 2002), and an estimated 222 in 2014 (Hodge and Hailey, 2015), with the orientation of these clinics moving from being research bases to ways of providing a diagnostic service for dementia.

The term ‘memory service’ appears to have first been used in naming the Croydon Memory Service (Banerjee et al., 2007), when SB, together with David Matthews, the team’s leader, coined the term to describe a new team, working out of a dilapidated 1970s psychiatric day hospital in the grounds of the former Croydon Workhouse. Our intentions were twofold when using the term in drafting the National Dementia Strategy (NDS) for England. First, we wanted to indicate that this should be a service whose job was to *serve* people with dementia and their carers, rather than a clinic organized for the convenience of service providers to meet their interests and needs (e.g. to recruit research participants or to be something fun to do on a Tuesday afternoon). Second, we wanted to stress that such services were not about ‘the clinic’ itself, but were instead about what they did (for people with dementia and their carers) —‘the service’.

This chapter is not about how to run a memory service or what tests to use. This book is full of information on how best diagnoses can be made and what constitutes best treatment and care. Instead, this chapter is about how such knowledge can become action that is of use to all those who would benefit from help: how we can deliver care to those with dementia that need it.

So, here we consider who memory services are for and what they should aim to achieve. We consider the evidence base and discuss ‘what good looks like’. But, before considering what we need to do, we need to understand the specific problem that such services are designed to address. We therefore first refresh the rationale for considering the establishment of such services.

Diagnosis rates for dementia

The numbers of people diagnosed with dementia and the proportion of those with dementia diagnosed in the UK has doubled to around two-thirds in the ten years since the publication of the National Dementia Strategy for England (<http://archive.today/spuZP>, Donegan et al., 2017); this has been achieved partly by better coding, but also by real increases

Memory assessment services

in the numbers and scope of memory services. This progress is very positive but there is still a way to go. Worldwide, underdiagnosis and late diagnosis remain a major issue. The World Alzheimer's Report 2011 (Alzheimer's Disease International (ADI), 2011) concludes that most people in the world with dementia have not received a formal diagnosis. In most high-income countries, between 20 and 50% of dementia cases are recognized. This 'treatment gap' is even greater in low- and middle-income countries, with 90% unidentified in India. If these data are extrapolated worldwide, 28 million (78%) of the 36 million people with dementia have not received a diagnosis, and therefore do not have access to treatment, care, and organized support that a formal diagnosis can facilitate.

By diagnosing people late or not at all, opportunities for harm prevention at an individual and a societal level are missed. We consider the potential benefits of diagnosis and early diagnosis in more detail below; however, in summary, if dementia is diagnosed, then at the very least people with dementia and their family carers have the possibility of planning for their future and availing themselves of the help, support, and treatments (social and psychological, as well as pharmacological) that are available.

Early and/or timely diagnosis

It is remarkable, but there are still some who would wish to deny people with dementia an early and accurate diagnosis. This case is often made on the basis of an asserted lack of evidence or the lack of a disease-modifying treatment, rather than evidence of disbenefit. There are important principles, including that a diagnosis should never be forced on any family, and that it is reasonable for people with dementia to make a positive decision about when, if ever, they know. However, no one would advocate this sort of therapeutic nihilism in cancer, heart disease, or HIV/AIDS, and nobody should do so in dementia. ADI, in their 2011 World Alzheimer Report, reviewed in detail all the data available and generated a categorization of the rationale for early diagnosis into nine broad themes (Box 23.1).

Box 23.1 World Alzheimer Report 2011: Nine reasons for early identification and treatment of dementia

- 1 Optimizing current medical management
- 2 Relief gained from better understanding of symptoms
- 3 Maximizing decision-making autonomy
- 4 Access to services
- 5 Risk reduction
- 6 Planning for the future
- 7 Improving clinical outcomes
- 8 Avoiding or reducing future costs
- 9 Diagnosis as a human right

Memory assessment services

Reproduced from Alzheimer's Disease International (2011). World Alzheimer Report 2011.

This categorization is useful, and is worth reproducing; each element is considered briefly in order to articulate the points made. The statements italicized are those of the authors.

1. Optimizing current medical management— *It's bad medicine not to.* The diagnostic process allows for the identification of potentially treatable or reversible disorders, including infections, depression, medication side effects, and nutritional deficiencies. The diagnosis allows physicians to adjust treatment plans for other health conditions, including avoiding drugs with anticholinergic effects, and to factor in comprehension and compliance challenges. Cognitive health can be maximized by control of behavioural and psychological symptoms, vascular risk factors, nutrition, and social activity.

2. Relief gained from better understanding of symptoms— *On balance, it's better to know than not.* If we ourselves are to have any chance of managing any problem, we need to know what is going on. People with early dementia very often know something is going on but do not know what, and that is a powerful source of strain. Early diagnosis enables people with dementia and their families to understand and adapt to cognitive and behavioural changes in dementia, reducing blame and impatience. Thus, harm is reduced by knowledge. Knowing the causes of problems can resolve anxiety felt by people with dementia and their families.

3. Maximizing decision-making autonomy— *I need to know to decide what to do.* Early diagnosis and early intervention enable people with dementia and their families to plan their finances, lives, and care in the future by identifying the condition at a time when the person with dementia can fully participate in medical, legal, and financial decisions and make plans for future care.

4. Access to services— *without diagnosis I can't get any sort of treatment for dementia.* If you don't know you have it, you can't get the treatments for it. Early diagnosis allows access to treatments, programmes of care, and services for dementia.

5. Risk reduction— *Diagnosis allows for the prevention of harm.* We can act to make the person with dementia, their carers, and the world safer. Dementia places older adults at risk for relationship problems, delirium, motor vehicle accidents, medication errors, and financial difficulties and exploitation, just for a start. Knowing creates time to address safety issues before accidents or emergencies occur. Again, we are preventing harm.

6. Planning for the future— *I need to know to plan.* The early recognition and detection of dementia enables people with dementia, their families, and clinicians to plan more effectively for the future,

including withdrawing from work if still at work and ensuring child safety.

7. Improving clinical outcomes—*Everyone, me, carers, society, does better if I know.* Early diagnosis enables early intervention; early intervention enables improved outcomes for people with dementia and their family carers. Data suggest that interventions, be they drugs, psychological, social, or educational, are of most benefit if given early in the disease process (NICE/SCIE, 2007).

8. Avoiding or reducing future costs—*Early diagnosis delivers better value, saving money.* The driver of long-run costs in dementia is time spent as a resident of a care home, with acute hospital bed days determining medium-run costs. The data reviewed suggest that interventions aimed at people with dementia and also their carers can reduce total care expenditure by preventing acute hospital admission and delaying the time to care home admission. Better outcomes and lower cost equate to better value. This is the fundamental golden equation in health services development, and evaluation and early diagnosis and intervention delivers this.

9. Diagnosis as a human right—*Whose diagnosis is it anyway?* It is still possible to talk to clinicians, who do not specialize in dementia, who will aver that ‘it is better not to know the diagnosis of dementia than it is to be told’. What is striking is how very little support there is for such paternalism and unwanted protectionism. This is a shield that people with dementia and their families neither need nor want. In many cases, this unintentionally toxic position is a reaction in those clinicians of their being uncomfortable in making the diagnosis and communicating it to their patients. The last 25 years have seen increasing attention being paid to ensuring that people with dementia are treated as autonomous individuals with their rights respected. The Fairhill Guidelines (Post and Whitehouse, 1995) stated, ‘because individuals have a right to control their own lives, and because true control depends on knowing about oneself, individuals have a right to full disclosure regarding a dementia diagnosis’. This is a fundamental truth, and the medical profession needs to deal with it and design systems to enable it. A moment spent putting oneself in the position of a person with dementia makes this clear.

In recent years there has been a growing preference for the use of the term ‘timely’ rather than ‘early’ to describe when diagnoses should be made. The INTERDEM group (De Lepeleire et al., 2008) defined timely diagnosis as:

... the time when the patient or caregiver *and* the primary care physician recognize that a dementia syndrome may be developing. The preference for timely diagnosis implies that methodologies should concentrate not on population screening, but on speedy response to the first reported signs of changed behaviour and functioning in the patient.

Memory assessment services

Others have highlighted that timely diagnosis incorporates the needs of the patient about when they should receive the diagnosis (Dhedhi et al., 2014). As such, this minor semantic change appears to be preferable for many, as it removes the chronological emphasis of an *early* diagnosis. It also raises an important issue about choice, and irrespective of the benefits of an early and timely diagnosis, there should always be a choice for the patients.

Timely diagnosis and intervention in dementia—an established health policy priority

Responding to this, early diagnosis and early intervention have consistently emerged as key policy priorities in the recent series of National Dementia Strategies. The fourth objective of the French *Plan Alzheimer* was ‘improving access to diagnosis and care pathways’. In the US, early diagnosis of AD is one of the six main purposes of the US National Alzheimer’s Project Act (NAPA), which was passed with bipartisan support and signed into law by President Obama in January 2011. The Secretary of State for Health for England, launching the country’s first NDS (Department of Health, 2008), said:

Current best estimates are that only one-third of people with dementia ever receive a diagnosis of their illness. We can’t hope to address their needs fully, or those of their carers, without a diagnosis being made, appropriate information being given and effective intervention at an early stage. Some have argued in the past that it is best not to let people know. We have long accepted that this should not occur with cancer sufferers. The same should be true for those with dementia. This was one of the most consistent messages emerging from the consultation process from people with dementia.

There are now more than 30 countries with National Dementia Plans listed on the ADI website and all have a focus on early or timely diagnosis. Internationally the World Health Organization’s (WHO) Global Action Plan on the public health response to dementia (WHO, 2017) both have timely diagnosis feature as being a key priority globally.

Memory assessment services

What is a memory service?

As discussed, there is a lack of clarity of definition of what constitutes a memory assessment service, a memory service, or a memory clinic. In line with this, previous efforts to group memory services based on their characteristics have failed due to variability in the structure and the process characteristics (Chrysanthaki et al., 2017). What they all share is an interest and skill in the diagnosis of dementia and particularly in the early diagnosis of dementia. A simple statement of what a memory service is for (i.e. its primary aim) is that given in the NDS for England, namely 'Good-quality early diagnosis and intervention for all'; this requires the service to do three things:

1. to provide a good quality diagnosis early in the illness
2. to provide good quality early intervention in dementia
3. to provide this good quality service to all who might need it in a given population.

So, a service without the skills to identify the illness causing dementia (e.g. AD, vascular dementia, Lewy-Body dementia, etc.) and to have a high degree of clinical certainty both in assigning and excluding a dementia diagnosis, would not meet these criteria. Equally, the service needs to have the skill to identify that small group where there is real clinical uncertainty, even after a full multifaceted, multi-disciplinary assessment, and where a longitudinal approach to diagnosis is needed. Using these tests, a service that provides diagnosis but not treatment would also be seen to fail. The issues of what we do to make a diagnosis well and the effectiveness of intervention in terms of clinical outcomes are covered elsewhere in this book and are not considered further here.

Finally, there is the stipulation that the service should work for all in a population. This is based on equity and access; these should not be services for the lucky few, as many memory clinics have been in the past. They need to have the capacity to deal with all incident cases in the area they serve. An average UK Clinical Commissioning Group (CCG) population has 50,000 older people; this means that the service needs to be able to see around 1000 people a year. This would not be possible with the traditional once-a-week memory clinic that sees a couple of new cases per week. We need to have a grander and broader ambition for our memory services.

Memory services can be powerful local agents and engines for change. They are there to empower people with dementia and their carers by providing them with the benefits that come from good quality early diagnosis and treatment. They are also there to enable the whole health and social care system to work well for dementia. Memory services are therefore at the heart of a win-win-win scenario, where there is quality and value improvement for people with dementia and carers, for health services, and for social services.

Memory assessment services

More detail is given in the NDS of what a memory service would be expected to do. The full text of its objective 2 reads:

Objective 2: Good-quality early diagnosis and intervention for all. All people with dementia to have access to a pathway of care that delivers: a rapid and competent specialist assessment; an accurate diagnosis sensitively communicated to the person with dementia and their carers; and treatment, care and support provided as needed following diagnosis. The system needs to have the capacity to see all new cases of dementia in the area.

This partial operationalization gives us further information on what such services would be expected to do in order to be considered of 'good quality'. This requires:

- a rapid assessment
- a competent specialist assessment
- an accurate diagnosis to have been made
- the communication of the diagnosis in a sensitive manner to the person with dementia and their carer
- provision of treatment, care, and support needed following the diagnosis
- to do this for all incident cases in the area served.

Such functions have informed the creation of standards such as those set by the UK Royal College of Psychiatrist's Memory Services National Accreditation Programme (MSNAP; <http://archive.today/DonQ8>). These acknowledge that 'memory services differ widely in their organisation, funding, staffing and levels of service, even within the same Trust.' They therefore centre on 'function', rather than any particular model of service delivery, covering:

- Management systems for the service
- Resources available to support assessment and diagnosis
- Assessment and diagnosis
- Pharmacological interventions
- Signposting to ongoing care management and follow up
- Psychosocial interventions

Communicating the diagnosis well

Communicating the diagnosis to people with dementia and their families in a sensitive way that enables people to take on board this vital but challenging information is at the heart of what a memory service needs to be able to achieve (Banerjee, 2010).

Memory assessment services

It will always be possible to find specific cases where the person with dementia may not want to know, though in reality such individuals are unlikely to have cooperated with the diagnostic process in the first place. But basing practice on such hard cases makes for bad medicine. There is no substitute for a personalized and sensitive approach to the disclosure of the diagnosis, but there is also no avoiding this task.

It is natural that carers should feel protective to family members with dementia. The finding that 83% of carers from an Irish memory clinic did not wish the patient to be told of the diagnosis is often quoted. But the most salient fact from this study is that 71% of the same carers wanted to be told the diagnosis if they developed dementia (Maguire et al., 1996). It is also important to note that this snapshot was taken over two decades ago and public attitudes and understanding are changing. In a more recent study of 50 people with mild dementia, 74% of the carers were willing for patients to be informed of the diagnosis of dementia (Pinner et al., 2003), 98% of carers wanted to know themselves if they had it, and 92% of those with dementia wanted to be told their diagnosis.

A memory service needs to treat communication of the diagnosis as a process, not an event. It is common for patients to use denial and avoidance of a dementia diagnosis as it serves as a coping strategy (Milby et al., 2017), though this is typically followed by a period of reflection and adaptation. Research carried out in this later period suggests that there are often feelings of regret on the part of carers that they had not received the diagnosis earlier so that they could have been more patient, understanding, and less blameful of the person with dementia (Connell et al., 2004). Disclosure of the diagnosis is a necessary prerequisite for future care planning including (with sensitivity) end-of-life care decisions (Derksen et al., 2006; Lawrence et al., 2011). It is self-evident that response to the disclosure of a diagnosis of dementia will depend on the way that this is done. It is an absolute requirement that memory services should do this well from the perspectives of patients and carers. The consultation for the UK NDS found distressingly frequent instances when doctors, thinking that they were doing this well, were in fact doing this badly and potentially doing harm. The following are indicative quotes taken from the NDS (Department of Health, 2008):

I've just been told 'You've got Alzheimer's,' and they walk out; [it] is absolutely bloody disgusting—(person with dementia).

I got the diagnosis on the phone by somebody I had never met telling me, 'Your husband has Alzheimer's and vascular dementia'. That was probably the worst possible way. That was absolutely infuriating—(carer).

I think they need [to be] diagnosing much earlier and take notice of it because I think there are lots of channels that could be avoided if

Memory assessment services

the first time they saw you, they got down to business and meant it. Not just fob you off—(person with dementia).

They didn't give me enough information. I came away thinking, 'What do we do now, where do we go from here?' I have a prescription in one hand and a note for blood tests in the other and nobody has said what the CAT scan showed ... nobody has given me that information. I am the person who is going to deal with [my husband]—(carer).

All memory services need standard operating procedures for communicating the diagnosis well that are owned by the whole team and that are delivered consistently. Recommendations for good practice include the following elements (Lecouturier et al., 2008):

1. Preparation
2. Involving family members
3. Exploring the patient's perspective
4. Disclosing the diagnosis
5. Responding to patient reactions
6. Focusing on quality of life
7. Future planning
8. Effective communication

The patient benefits case for memory services

Until recently, little research had robustly evaluated the benefits of accessing memory services, particularly compared to other models. This is in part due to variability in the structures and processes that occurs in different memory services, making it methodologically difficult to disentangle potential effects. Longitudinally, quality of life has been found to improve six months following accessing memory services (Banerjee et al., 2007; Park et al., 2017). Further investigation has identified that, apart from the involvement of Allied Health Professionals, the structure or function of the service had no impact on patient or carer quality of life (Park et al., 2018). Irrespective of patient outcomes, patients and carers that have accessed memory services seem to have positive experiences (Hodge et al., 2013; Hailey et al., 2015), though they often have unmet information and communication needs (Abley et al., 2013).

Some who attend memory services do so only because they are prompted to do so by others, but many will have concerns about their cognitive health. They may have subjective memory complaints or be concerned by an existing family history of dementia. By accessing memory services, these people and their relatives will have the expectation that their concerns will be addressed. However, patient concerns do not always translate into symptoms that meet diagnostic criteria, leading to disappointment. Many of those that do not receive a diagnosis will be reassured that they do not have a dementia and are happy to be discharged from the clinic. But some find no diagnosis or a 'diagnosis' of

Memory assessment services

mild cognitive impairment (MCI) and the lack of offered advice and support dissatisfying (Willis et al., 2009). This can lead to people feeling shocked, helpless, and confused about the future (Samsi et al., 2014). Being given the label of MCI can lead relatives to feel disappointed about being discharged from memory services: 'What is quite difficult to take was that it was like "Yeah, there's a problem, it's not that bad. Off you go." ' (Dean et al., 2014). It is therefore essential that memory assessment services are aware of the potential impact of receiving (or not) a diagnosis of dementia, and remain sensitive in the needs of the patients. It also makes clear the need for services to have clear guidance and procedures for the sensitive communication of the absence of a diagnosis or of MCI should be as much of a part of the skill set of memory services as communicating the diagnosis of dementia. Equal consistency in the management of MCI in terms of programming routine reassessment at six to 12 months by the memory service or requiring a further referral would be very valuable.

What happens after diagnosis is of major importance. Post-diagnostic treatment and support is a key component of good quality dementia care. Another area where evidence is lacking but where there appear to be major differences in practice and opinion is the role of memory services in post-diagnosis follow-up. There is major variation in the role that memory services take in providing post-diagnostic care themselves. Many commissioned models require memory services to concentrate only on diagnosis and so to discharge people back to primary care immediately after diagnosis, or soon after, for those with uncomplicated dementia. There seems to be little consistency on the duration, content, and the providers of post-diagnostic support by memory services. In Scotland, the 'Five Pillars Model' of post-diagnostic care is promoted, which states that post-diagnostic support should include (<http://archive.today/XjFoQ>):

1. Understanding the illness and managing symptoms
2. Planning for future decision-making
3. Supporting community connections
4. Peer support
5. Planning for future care

The Scottish Government has guaranteed a minimum of one-year post-diagnostic support (The Scottish Government, 2013), with most individuals needing around eight follow-up meetings in addition to telephone support (Age UK, 2017). Comparatively, current post-diagnostic guidance in England states that follow-ups should be 'systematic' (Barrett and Burns, 2014), which is more open to interpretation. There are very few studies available which evaluate the effect of good quality follow-up and post-diagnostic care for people with dementia and their family carers and the proper role of memory services. However, it is clear that memory services are ideally placed after diagnosis to ensure that people with dementia and their carers start off on their journey of living with dementia equipped with the information and signposting that they need. A good quality system of diagnostic care would be akin to a relay race

Memory assessment services

with people with dementia passed safely and securely from one service to another seamlessly. Too often our current disjointed services seem designed to ensure that the baton is dropped, or even lost, for most they serve (Prince et al., 2016).

The economic case for memory services

We finish by addressing the issue of cost. Services must bring value to the people they serve. This value should be measured in terms of the improvements in outcomes that accrue from this service compared to another divided by the cost of the service. If we look at memory services, then it seems very likely that they meet this vital test.

A core aim of the NDS was to ensure that effective services for early diagnosis and intervention are available for all on a nationwide basis. The Strategy accepted that this would require local investment and stated its assessment, and that of HM Treasury, that such a 'spend to save' approach, as advocated by the NAO in its value for money report (2007), could both increase the quality of care and save hundreds of millions of pounds of expenditure over a ten-year period. This is an external validation and endorsement of the clinical and cost-effectiveness of such services.

Gomes and colleagues estimated the costs of memory assessment services six months following diagnosis was on average £1899 per patient (Gomes et al., 2017). However, the incremental net benefit based on the EQ-5D-3L was -£1724 per patient which suggests cost/benefit balance. Such a financial estimate was based on relatively short duration, and therefore did not consider the potential cost savings associated with reduced use of residential care. Banerjee and Wittenberg (2009) modelled the impact of national provision of memory services in preventing admissions to care homes. They estimated the overall savings to society, including savings accruing to public funds and private individuals. The savings increased as the numbers of people prevented from entering care homes increases over a ten-year period. Total annual savings to society from a 6%, 10%, and 20% reduction in the numbers of people with dementia entering care homes would amount to around £150, £245, and £490 million, respectively, by year ten from the nationwide introduction of the early diagnosis and intervention service.

In terms of cost-effectiveness, in the tenth year of the service's operation, its estimated cost would be around £265 million (in 2007/8 prices), taking account of real rises in care costs. If quality of life is factored in, the estimated Net Present Value (NPV) over ten years would be positive, with a gain of around 6250 quality-adjusted life years (QALYs) in the tenth year, where a QALY is valued at £40,000 or 12,500 QALYS if a QALY is valued at £20,000. A gain of 12,500 QALYS would amount to only around 0.02 QALYs per person year. These relatively small improvements seem very likely to be achievable with ease in view of the rise of 4% achieved in the pilot of the Croydon Memory Service (Banerjee et al., 2007). This

intervention would therefore meet stringent accepted definitions of cost-effectiveness (NICE, 2004; Rawlins and Culyer, 2004). Two other cost-benefit analyses provide confirmatory evidence of the potential economic benefits associated with earlier diagnosis and intervention. Both analyses are based on screening programmes in primary care, with savings estimated of a similar order of magnitude at US \$4,000 and \$7,700 per person, respectively (Weimer et al., 2009; Getsios et al., 2012).

Liaison old age psychiatry

Chapter: Liaison old age psychiatry

Author(s): Fiona Thompson and Elena Baker-Glenn

DOI: 10.1093/med/9780198807292.003.0024

Introduction

The word 'liaison' is defined as communication or cooperation that facilitates a close working relationship between people or organizations (Oxford English Dictionary, 2018). Liaison psychiatry is a sub-specialty of psychiatry that specializes in the interface between physical and mental health, and would typically involve treating patients who are attending general hospitals rather than those who are being cared for in the community or in mental health units. As such, liaison psychiatry involves working closely with staff in general hospital settings. The presence of liaison psychiatry results in a greater recognition of integrated care, and it is now considered a critical service that should exist in all acute hospitals (Royal College of Psychiatrists, 2013a). Although the term *liaison psychiatry* is the most commonly used term, many services operate under the title of Psychological Medicine and it is felt by some that this

Liaison old age psychiatry

latter term is more representative of the work practised in the general hospitals (Lloyd and Mayou, 2003).

Early liaison psychiatry services focused on those of working age (those between the ages of 18 and 65); however, over time the number of old age liaison psychiatry services has grown due to increased recognition of the need for services aimed at those over 65 years of age, who make up the majority of in-patients in the general hospital settings. At the opposite end of the age spectrum, paediatric liaison psychiatry is also a growing area of interest.

This chapter outlines the development of old age liaison psychiatry, focusing particularly on the UK, including the relevant policies that have influenced this development, and considers current liaison psychiatry service models. It discusses common clinical conditions seen by old age liaison psychiatry services, in addition to other important roles that liaison psychiatrists have in working with general hospital staff, and it also looks at the future of old age liaison psychiatry.

Development of liaison psychiatry

Some consider that psychiatry's establishment as a specialty caring for the 'mentally ill' in the late 1800s resulted in psychiatry becoming increasingly separated from the rest of medicine. Initially, those patients in the general hospital who were referred to psychiatrists were psychotic, had self-harmed, or had disturbed behaviour, with the expectation from the medical teams that those individuals would be transferred to a psychiatric ward (Sharpe, 2014). Over time, a much greater awareness has developed of the benefits of integration and of the value of mental health input for people who primarily need acute hospital in-patient or outpatient care, and a wider range of referrals are now made to liaison psychiatry, including for medically unexplained symptoms.

In the early twentieth century, Barrett recognized the importance of liaison psychiatry, stating: when 'Psychiatry has gained the position of a liaison science between medicine and social problems ... general hospitals and dispensaries should have psychiatric services coordinated among their medical specialties' (Barrett, 1922). Later, in his seminal paper, George Henry (1929) proposed that all general hospitals should have a psychiatrist, and the paper outlined a series of clinical observations, including a number of cases of medically unexplained symptoms that resulted in inappropriate medical and surgical procedures. The term 'liaison psychiatry' itself was reportedly first used in the 1930s to describe the department at Colorado General Hospital in Denver, Colorado (Billings, 1936).

The establishment of liaison psychiatry services continued around the world, but dedicated services were rare in the UK until the 1970s. The founding of the Royal College of Psychiatrists in 1971 was a key step in the development of liaison psychiatry in the UK, as it brought together

Liaison old age psychiatry

psychiatrists who worked in asylums with those working in teaching hospitals. A special interest group in liaison psychiatry was established in the 1980s, and liaison psychiatry subsequently became a section of the Royal College of Psychiatrists in 1997 and then a Faculty in 2004 (Aitken et al., 2016).

Many liaison teams were originally set up with a focus on the emergency department and have been expanded over time to provide psychiatric input into other areas within the hospital. The rationale for the provision of liaison psychiatry services is to improve psychiatric and medical outcomes of patients, enhance patient experience of medical care, ensure patient safety, and contribute to greater overall cost effectiveness of medical services (Sharpe, 2014). In some areas, there is greater specialization within liaison psychiatry, for example neuropsychiatry, perinatal psychiatry, palliative care, chronic pain, and transplant psychiatry. These are all potentially valuable services that can help to ensure patients have access to the correct care; however, some argue that clinical teams could have more of an impact, and be more sustainable, if they remain flexible and retain their shared service provision (Sharpe, 2014).

Many old age psychiatrists previously worked with patients from a defined geographical area and would care for those patients across the in-patient wards, the community, and in the general hospital. In 2003, it was reported that dedicated liaison psychiatry nurses for older people were only present in 14% of services (Holmes, 2003). However, more hospitals now have a dedicated liaison psychiatry service, which allows key relationships to be developed with the general hospital teams and facilitates better response times.

In 2015, 179 emergency departments in England were surveyed, and 168 reported the existence of liaison psychiatry services. Of these, 150 reported that they worked with older adults, with only five services reporting that they did not see older adult patients; the remaining services did not explicitly report which age groups they worked with. Of the 150 services that saw older adults, only 39 had a separate older adult team within the service, and only 28 of those teams had a consultant old age liaison psychiatrist working within the team (Barrett et al., 2015). In a service evaluation in Newcastle, a 10% yearly increase of older people referred to the dedicated liaison psychiatry service for older people was observed, with the referral numbers to this service being similar to those seen by the local self-harm team (Mukaetova-Ladinska, 2013).

Commissioning and funding of services

In recent years, liaison psychiatry services in the UK have been expanded, especially those in old age liaison psychiatry. Indeed, in 2015 most services reported that they were better resourced than a year earlier (Barrett et al., 2015). As part of the implementation of the Five Year Forward View (NHS England, 2014) NHS England established crisis

Liaison old age psychiatry

and acute care work streams to support commissioning and provision of 24-hour mental health services, which included £249 million of new funding over a four-year period to expand liaison mental health services. As part of this plan, 50% of all acute hospitals should have a 'core 24' liaison team in place by 2020, meaning that liaison staff would be available 24 hours a day, seven days a week (NHS England, 2016). This document, and the subsequent funding, has resulted in an expansion of many teams across the country; however, the needs of older people are not explicitly stated within the document, and it is important to ensure that any expansion can meet their needs.

In most areas in England, mental health and acute services are provided by separate organizations, 'Trusts', with separate commissioning, and there is also often a physical separation between teams, with many mental health units being situated miles from their catchment general hospital. The funding of liaison services varies across the country, with some being funded via the acute trust, and others from the mental health trust. The services that are commissioned also vary from hospital to hospital—many liaison services continue to focus on the emergency department and self-harm presentations, but others are more integrated into the general hospital wards, with some services being commissioned to provide outpatient services. A number of liaison teams offer follow-up appointments to patients in an outpatient setting, including after self-harm presentations, while other services have subspecialist areas commissioned, such as substance misuse, or specific pathways of care where psychiatry is a core part of the treating multidisciplinary team, e.g. trauma, psycho-oncology, neuropsychiatry, or diabetes. While some hospitals employ psychologists—who are based in separate departments in the general hospital, and are thus separate from liaison psychiatry—many others employ psychologists as a core part of the liaison psychiatry team. A number of liaison teams conduct regular shared clinics with physicians, while Leeds General Infirmary have a National Inpatient Centre for Psychological Medicine, where the care is provided by a range of staff, including liaison psychiatrists and physical healthcare specialists.

The need for liaison psychiatry

The role of the liaison psychiatry team would normally include assessment, diagnosis, treatment, risk assessment, care planning, reviews, and liaison with the medical team, the community mental health team, and primary care. In addition, the liaison psychiatry services would provide relevant training for staff working in the general hospital and would raise awareness of mental health problems and their management.

Thirty per cent of patients with a long-term physical health problem also have a concurrent mental illness (Centre for Mental Health, 2015), which increases the risk of physical health complications and increases the costs of treating the physical illness. The presence of a mental disorder can result in an increased length of hospital stay, and raise morbidity and mortality. It was found that, compared with the general population, the

prevalence of depression is doubled in those with chronic physical illness such as diabetes, hypertension, coronary artery disease, heart failure, and increased threefold in those with stroke, end-stage renal failure, and COPD (Egede, 2007; NICE, 2009). The prevalence of depression is also seven times higher in people with two or more long-term conditions (Moussavi et al., 2007). Patients with COPD have been found to show higher rates of generalized anxiety disorder, panic, and depression, all of which may result in more admissions, longer stays when admitted, and higher relapse rates (Howard 2010).

In addition, it is also well documented that poor mental health can negatively impact on patients' physical health, with a reduction in life expectancy of between seven and ten years with depression, almost 15 years for those using drugs or alcohol, and between ten and 15 years for those suffering from schizophrenia (Chang et al., 2011). Schizophrenia has also been associated with both a threefold higher mortality rate from respiratory disease (Saha et al., 2007), and a twofold increased risk of obesity, diabetes, hypertension, metabolic syndrome, and smoking (De Hert et al., 2009; Foley, 2013), while depression has been demonstrated to have a negative impact on adherence to treatment, including treatment for physical illnesses (Martin, 2005). Liaison psychiatry can help to detect many of these difficulties and can provide support to physical healthcare teams in the management of these patients, with the aim of improving the quality of care received (Department of Health, 2001).

The Healthcare Quality Improvement Partnership (HQIP) has recently placed a significant focus on parity of esteem within their national audits, to ensure that mental health is always considered (Homayoun, 2017). In addition, the National Confidential Enquiry into Patient Outcomes and Deaths (2017) report revealed that there were a large number of patients who had both physical and mental health problems in the general hospital setting. It also suggested that there may be many more patients who had unrecognized mental and physical comorbidity, as not all patients will have had a mental health coding documented on the system. The report also investigated the provision and responsiveness of liaison psychiatry and found that just over 80% of hospitals had a liaison psychiatry service, with the remainder receiving their liaison input via a community mental health team. The report identified significant gaps in care and treatment, which require commitment from the whole organization to ensure that the patient journey is optimized and that seamless referrals to, and timely responses from, liaison psychiatry occur. Twenty-one recommendations were made within their report, including that liaison psychiatry should be fully integrated into general hospitals and be a core part of the multidisciplinary team (The National Confidential Enquiry into Patient Outcome and Death, 2017). As well as setting standards for liaison psychiatry clinical documentation, the report makes recommendations to improve acute hospital staff training and expertise, medication reconciliation, application of Mental Health legislation, and support with alcohol, substance misuse, and smoking cessation. The Care Quality

Liaison old age psychiatry

Commission (2016) specifically includes mental health in their key lines of enquiry in acute hospitals, including dementia care, use of Mental Health legislation, and access to specialist mental health care.

There has been some debate regarding ageless services, and a number of organizations have begun moving towards this approach. In many areas of liaison psychiatry, there is recognition that there are multiple benefits of having specialists in old age liaison psychiatry and of having access to specialist advice and support for patients with delirium and dementia. Indeed, guidance states that teams should have access to liaison services with recognized experience in treating dementia (NHS England et al., 2016). Eighty per cent of hospital bed days are occupied by someone with comorbid physical and mental illness, mainly the elderly (Parsonage et al., 2012).

In some areas an ageless liaison psychiatry service continues to function, with the same team seeing patients across the age spectrum. However, it is vital that such teams are able to access old age psychiatry experience and expertise if this resource is not available within the team. The National Dementia Strategy supported the commissioning of specialist liaison psychiatry for older people (Department of Health, 2009), and a number of areas have developed old age liaison psychiatry as a separate team from general adult liaison psychiatry, often with some cross cover between the teams.

The National Audit of Dementia in England and Wales is commissioned by HQIP and published by the Royal College of Psychiatrists. The audit programme, which measures acute hospitals against criteria of organizational policies and governance, individual care for the patient and carers, and discharge planning, has recently completed a third round in 2016 and a fourth round is planned in 2018 (Royal College of Psychiatrists, 2017). The second round specifically enquired about access to liaison psychiatry. Nearly all hospitals (94%, 198/210) reported having access to a liaison psychiatry service, and 85% (168/198) of these were able to provide emergency or urgent assessments. Of the hospitals with access to a liaison psychiatry service, 82% (162/198) had a named Consultant Psychiatrist lead, which was an improvement from 75% of hospitals in the first audit conducted in 2010. Sixty-eight per cent (135/198) had a Consultant Psychiatrist with older adult experience who had dedicated time for the liaison service, an improvement from 50% the previous year. Ninety-six per cent (189/198) reported the service to be provided by a specialist mental health team, but only 69% (130/189) of hospitals said that the liaison team would regularly provide routine mental health care to both adults and older adults services. Indeed, 28% (52/129) of hospitals stated that they only covered adult liaison psychiatry, while only a third of those with access to a liaison psychiatry service had access to older adults' expertise 24 hours a day (Royal College of Psychiatrists, 2013b).

Liaison old age psychiatry

Service models

Several different service models for liaison psychiatry have been developed over time, and the models are still rapidly changing and developing. Models and standards for old age liaison psychiatry have not been explicitly specified, but many services view old age liaison psychiatry as having to adopt the same standards as the corresponding working age liaison psychiatry services. Fig. 24.1 shows the structure of a fully integrated liaison psychiatry service.

Fig. 24.1
Example of fully integrated liaison psychiatry service.

A number of the models that have been developed can be categorized according to the approach that staff take regarding how rapid the response time is and how pro-active the liaison psychiatry team can be in the general hospital. National guidance in England is that patients referred as an emergency should be seen within one hour, urgent referrals should be seen within one working day, and routine referrals should be seen within two days of the referral (Royal College of Psychiatrists, 2013a). Services can also be categorized by the number of hospital beds and level of staffing.

There are five key approaches to liaison psychiatry, some of which overlap:

1. A consultation model, also known as consultation-liaison psychiatry
2. A liaison model, where the approach is much more integrated.
3. The Rapid Interface and Discharge (RAID) model
4. A proactive liaison psychiatry model
5. Mental Health Partnerships' Models for Liaison Psychiatry Services.

Liaison old age psychiatry

Consultation model

Consultation liaison psychiatry emerged in the United States, and developed throughout the 1970s. In the consultation model, the referring doctor, or other member of the referring team, would have to request a psychiatric assessment or advice. Following assessment, the psychiatry team would make recommendations on a case by case basis; however, the general hospital team would be responsible for the management of that intervention.

Liaison model

Benefits of a more integrated approach than that offered by a consultation liaison psychiatry model have been recognized for a number of years. The differences between the consultation model and a liaison psychiatry approach were described in 'Who Cares Wins' and the comparison has been adapted and updated in Table 24.1 (Royal College of Psychiatrists, 2005). The liaison approach is designed to integrate the assessment and treatment of patients with mental disorders into the routine practice in general hospitals, with liaison psychiatry staff having a greater presence in the hospital and routinely collaborating with colleagues across other specialties. Importantly, the model is not limited to direct patient contact, incorporating other tasks such as education and training, service development, and quality improvement into its remit (Fig. 24.1). The service is intended to be proactive, and a systematic review in 2000 demonstrated that this approach was associated with a number of advantages, including better diagnostic accuracy by those referring patients to the service, and increased adherence to recommendations made by the psychiatry team (Draper, 2000).

Table 24.1 Differences between consultation and liaison psychiatry.

Consultation	Liaison
Reactive	Proactive
Limited resources	Intensive resource use
Isolated working	Collaboration with colleagues
Hospital referrals are a low priority	Hospital referrals are a high priority
Limited impact of liaison service	Impact demonstrated of benefits
Slow response to referrals	Rapid response to referrals

Liaison old age psychiatry

Fewer referrals made	More referrals made
Limited review of patients	Frequent patient reviews
Poor-quality referrals	Better referral quality
Poor adherence of the treatment plan by the clinical team	Improved adherence to the treatment plan
Practice of hospital staff not altered	Changed practice of hospital staff
Mental health separate from general services	Mental health integrated with general services
No change on length of stay	Reduced length of stay in hospital
	Better patient satisfaction

Adapted with permission from Who cares wins: improving the outcome for older people admitted to the general hospital. Working Group of the Faculty of Old Age Psychiatrist, Royal College of Psychiatrists, London. The production of this document has been funded by the Faculty of the Psychiatry of Old Age, Royal College of Psychiatrists. Copyright © 2005 The Royal College of Psychiatrists.

Many organizations provide a service that would be considered to be somewhere between these two models, where services remain reactive and require referral, and many patients are only seen once. However, compared with when the 'Who Cares Wins' document was published, liaison services have developed considerably over the last decade. There is now more collaboration with colleagues in the general hospital and better teaching opportunities in mental health for the general hospital staff, and hospital referrals are a high priority in the presence of a dedicated service.

RAID model

The Rapid Assessment, Interface and Discharge (RAID) model was established in Birmingham in 2009 as a single point of access, multidisciplinary service, available 24 hours a day. This model was developed to have a greater focus on response times, with a one hour target response time to assess patients referred from A&E for emergencies, and a 24 hour response time for those referred from in-patient wards. An evaluation of the economics of this service was undertaken by the London School of Economics and the Centre for Mental Health in 2011 (Parsonage and Fossey, 2011; Tadros et al., 2013).

Liaison old age psychiatry

The service was shown to significantly reduce the rate of readmission, from 15 readmissions down to four readmissions for every 100 people. Combined with a reduction in the average length of stay, which was observed mainly in older patients, this decrease in readmission rate resulted in an estimated saving of 8,100 bed-days per year, enabling the hospital to close 60 of their 600 beds without cutting services. The study found that for every £1 invested in liaison psychiatry, there would be a £4 return, with most savings being for those over the age of 65, demonstrating the cost-savings that could result from the presence of a liaison psychiatry service (Tadros et al., 2013). The RAID study was not randomized, but the model has since been developed in a number of organizations.

Proactive liaison psychiatry model

Two studies in the US have shown promise in a proactive model to reduce length of stay. Desan and colleagues (2011) compared proactive care including brief review of all admissions, rapid consultation, and follow-up with usual practice of reactive consultations. The number of reviews and caseloads were predictably higher, but costs more than offset by savings in length of stay.

In 2015, Sledge and colleagues (2015) introduced a proactive behavioural intervention team in Yale-New Haven Hospital, where patients were discussed with the medical team, case reviews taking around three minutes for each patient. They found that over 50% of the patients that they screened within the timeframe had mental health needs, and 23% of patients received a psychiatric consultation, in comparison with only 11% of the control group. The introduction of the intervention team resulted in a reduced time between referral and consultation, and a decreased average length of stay in the general hospital.

In contrast to the findings described here, a randomized, double-controlled clinical trial of proactive consultation was conducted on the general medical in-patient services of a university hospital, with the main outcome measures being length of hospital stay and hospital costs. Hospital resource use decreased in the entire sample over 21 months and it was found that a single experimental psychiatric consultation did not reduce costs (Levenson, 1992).

HOME, a large multi-centre randomized controlled trial is currently being conducted in the UK in those aged 65 and over. In this trial, three Trusts in England will be randomizing patients to proactive liaison psychiatry or usual care, even when no mental illness is evident, to determine if there is an impact on discharge date from input from liaison psychiatry (see The HOME study: <https://oxfordpsychologicalmedicine.org/research/thehomestudy/>).

Liaison old age psychiatry

Mental Health Partnerships' models for liaison psychiatry services

Four models of liaison psychiatry were described in the Mental Health Partnerships' 'Guidance on Developing Models for Liaison Psychiatry Services', with the intention of setting the minimum service requirements needed to attain the cost and quality outcomes that the evaluation of RAID suggested were possible. The recommendations in the guidance resulted from adapting the RAID model and other services to provide models for hospitals of various sizes, with and without emergency departments and with varying demands across the 24-hour period (Aitken et al., 2014c):

- Core: Liaison Psychiatry Services that operate working or extended hours only, intended for services where there is variable demand across the week, including periods of no demand, and where a 24-hour staffed response would not be economical.
- Core 24: Liaison Psychiatry Services that operate 24 hours a day, seven days a week, intended for services where there is sufficient demand to warrant a full 24-hour service.
- Enhanced 24: Liaison Psychiatry Services that operate 24 hours a day, seven days a week with extensions to fill local gaps in service and some outpatient services, intended for services where enhancements to the minimum specification are required to fit in with gaps in existing pathways and services.
- Comprehensive: Liaison Psychiatry Services that operate 24 hours a day, seven days a week, enhanced with in-patient and outpatient services to specialties, which would tend to be found in large secondary care centres with regional and supra-regional services (Aitken et al., 2014a).

NHS England have stated that 50% of all acute hospitals should have a Core 24 liaison team in place by 2020, meaning that liaison staff would be available 24 hours a day, seven days a week.

Table 24.2 shows example staffing requirements and costs for each of the different service types. The setup of services will vary due to the local demand and circumstances; for example, some teams have larger consultant numbers and lower nursing numbers. There are also many hospitals whose bed numbers fall between the 500 and 2000 beds outlined in the example models (Aitken et al., 2014a).

Liaison old age psychiatry

Table 24.2 Example requirements for the different service models.

	Core	Core 24	Enhanced 24	Comprehensive
Example number of beds	500	500	500	2000
Consultants	2	2	4	5
Other medical	0.6	2	2	2
Nurses	2 band 7 (team leader), 6 band 6	6 band 7, 7 band 6	3 band 7, 7 band 6	2 band 8 17 band 6 10 band 5
Other therapists	0	4	2	16
Team manager	1 band 7	1	1	3
Admin—band 2, 3, 4	2.6	2	2	12
Clinical services manager	0.2 band 8	0.2–0.4	0.2–0.4	1
Business support band 5	0	1	1	1
Total WTE	14.4	25.2–25.4	22.2–24.4	69
Hours of service	9–5	24/7	24/7	24/7

Liaison old age psychiatry

Age	16+	16+	16+	16+
Older person	Yes	Yes	Yes	Yes
Drug and alcohol	No	Yes	Yes	Yes
Outpatient	No	No	Yes	Yes
Specialties	No	No	No	Yes
Cost	£0.7M	£1.1M	£1.4M	£4.5M

Liaison old age psychiatry

Clinical aspects of old age liaison psychiatry

In a general hospital setting, over two-thirds of beds are occupied by patients aged over 65 (Department of Health, 2009). In liaison psychiatry, referrals may come from any team in the hospital, which requires a flexible approach. There are a number of particular challenges associated with assessments in general hospital wards, including a lack of privacy to perform the assessment. Interruptions are also common, and it is not unusual for the patient to be unaware of the referral to the liaison psychiatry team. It is therefore important to check that the patient understands why the referral to liaison psychiatry was made prior to the assessment. Ideally, referrals will articulate the specific question to which the referring team would like an answer; however, it is often the case that such questions are not included in the referral, and it is also important to bear in mind that other useful information may come from the assessment that could influence the management plan.

There are a number of reasons why patients are referred to liaison psychiatry services from the acute hospital. Some patients have a pre-existing diagnosis of a mental disorder and require specialist input during an admission with a physical health problem. Others may develop or reveal a psychological illness during their time in hospital, for example, delirium, depression, anxiety, or psychosis. In some cases, these conditions may be related to their physical health or treatment. Emergency referrals to liaison psychiatry are often related to self-harm, suicide risk, or acute behavioural disturbance. Moreover, liaison psychiatry clinicians may be asked to assist with complex capacity decisions, or with discharge planning. It has been reported that 70–80% of referrals are from medical departments, and around 5% of patients referred require in-patient psychiatric treatment, with 10–20% being referred to community teams (Anderson and Ooman, 2012).

Some of the more common conditions seen by old age liaison teams are:

- Depression
- Dementia and cognitive impairment
- Delirium
- Alcohol problems
- Behavioural disturbance.

In addition, liaison psychiatrists are also called on to provide advice on relevant legal frameworks, especially in cases where capacity is lacking and the patient presents a risk of harm to themselves, or requires detention under the Mental Health Act.

Little information is currently available in the literature analysing referrals to old age liaison services, but it is likely that more data will become accessible over the coming years. In the local service at Addenbrookes Hospital, Cambridge, the total number of referrals to older

Liaison old age psychiatry

people's liaison psychiatry over a one-year period commencing 1 April 2016 was 1,487, which led to 1,300 face-to-face assessments, in addition to 187 cases where only advice was required.

There were a number of reasons for patients being referred to this old age liaison service. In many cases, the patient was not referred for a single reason, the referral arising from a combination of issues. The most common reason was for a mental health assessment (1,262 cases), followed by requests for a medication review (887 cases). Patients were also referred to the team for advice on placement or discharge plans (369 cases), Mental Capacity Act assessments (256), contribution to the multidisciplinary management and education (217), and carer's education and support (172). Table 24.3 summarizes the mental health diagnostic outcomes of patients assessed over this 1-year period in Addenbrookes Hospital (Wai, 2017).

Table 24.3 Number of patients seen by old age liaison psychiatry in Addenbrookes Hospital with particular psychiatric diagnosis over a one-year period.

Diagnosis	Number of patients
Delirium	428
Dementia	415
Depression	271
No active mental health problem	121
Anxiety	79
Alcohol-related disorder	33
Schizophrenia	31
Bipolar affective disorder	29
Adjustment disorder	13

These data contrast with those reported by Guthrie (2016) for referrals to a working age adult service, where the most common diagnosis was depression, followed by schizophrenia and bipolar affective disorder.

Some of the common conditions seen by old age liaison psychiatry teams are outlined in the next few subsections. More detailed information about each of the conditions can be found in other relevant chapters; the

Liaison old age psychiatry

objective here is to consider the assessment and management of these conditions in a liaison setting.

Depression

A systematic review of depression in general hospital settings revealed the median prevalence to be 10%, but there was a wide variation of 3–52%, which related to different diagnostic criteria being used and the different medical specialties being considered (Walker et al., 2016). There is thought to be a higher risk of the development of depression with neurological disorders, HIV, cancer, and chronic pain than for other diagnoses. Rayner and colleagues (2010) concluded that antidepressants were effective compared with placebo in seventeen studies that included patients with a range of physical illnesses, including cancer, diabetes, heart disease, lung disease, renal disease, HIV, head injury, multiple sclerosis, stroke, and mixed somatic diseases.

Shoar and colleagues' (2016) study in surgical patients showed that depression at the time of admission was significantly associated with longer hospital stay, a previous history of mood disorders, the need for surgery or reoperation, underlying diseases, surgical complication, and lack of familial support.

The assessment of depression in general hospital settings may be complex as it has to be differentiated from an acute stress reaction related to a serious concurrent health condition. Communication difficulties associated with disorders such as acute stroke, in addition to sensory impairment, may also present challenges for assessment.

Treatment options include pharmacotherapy and psychological treatments, and there may also be a number of social issues, which liaison psychiatry can help to resolve. Liaison psychiatrists may also be able to help to identify precipitants arising from the ward environment, for example, profound social isolation resulting from prolonged care in a side room. It is important to consider any risks of self-harm or suicide and to put in place a plan to mitigate any ongoing risks, for example, one-to-one nursing observations. Other risks of depression include the adverse outcomes of the patient's physical health conditions, for example, suboptimal rehabilitation following hip fracture due to reduced motivation and/or falls anxiety, reduced treatment adherence, or unwillingness to engage with discharge care planning. Due to tight timelines for rehabilitation decisions, there is often limited time available in liaison psychiatric practice to decide whether or not to instigate antidepressant treatment, and rapid decisions may be needed for patients with severe depression who are refusing food and fluids.

Dementia and cognitive impairment

Sampson and colleagues (2009) reported the prevalence of dementia in the general hospital to be 23.2% in those aged 70–79 and 65.5% in those over 90 years of age, but only half of these patients had been diagnosed

with dementia prior to admission, indicating significant unmet need in the community. The vast majority of acute hospital admissions for people with dementia occur in an emergency, and many emergency presentations in people with dementia are preventable (Aitken et al., 2014b). As the population ages, increasing numbers of people will die with dementia, many in an acute hospital. The rising prevalence of dementia is important, as additional resources will be required for intermediate and palliative care, and for the provision of mental health liaison services for patients with dementia. The most common cause of dementia is Alzheimer's disease followed by vascular dementia, mixed Alzheimer's and vascular dementia, and then Lewy body dementia.

Cognitive impairment is commonly found in older people over the age of 65 who are admitted to hospital as an emergency (Reynish et al., 2017). One study described 'cognitive spectrum disorder' (CSD) as a composite of delirium, dementia, or Abbreviated Mental Test (AMT) score < 8/10, in patients in the general hospital; CSD was present in almost 40% of those over the age of 65 and in over half of those over the age of 85, and resulted in an increased length of stay in hospital (Reynish et al., 2017). A superimposed delirium was reported in 46% of patients with dementia, and higher mortality rates have been reported in patients with severe cognitive impairment (Reynish et al., 2017; Sampson et al., 2009).

The most recent National Audit of Dementia showed that the majority of hospitals have dementia champions, but staff reported that they needed more support, especially out of hours. Recommendations from the audit included an initial screening or checks for delirium, better accessibility to key personal information related to care needs, closer attention to meeting nutritional needs, and higher-level support from dementia champions, ensuring the availability of a dementia champion to support staff at all times. It was also felt that the person with dementia needed to be more involved in decision-making, and so further training for staff on consent, best interest decision-making, lasting power of attorney, and advance decision-making was required (Royal College of Psychiatrists, 2017).

Delirium

Delirium is common in the general hospital setting, affecting around a fifth of adult in-patients, especially if the patient has an existing cognitive impairment (Ryan et al., 2013). However, it can affect as many as 60% of older adults (NHS Confederation, 2009). Despite its relatively high prevalence, delirium remains undetected in significant numbers of patients. Indeed, one study found that delirium was undetected in 72% of cases (Collins et al., 2010). Delirium is sometimes classified into hyperactive, hypoactive, and mixed. Multiple causes of delirium are well known, including infection, biochemical disturbance, acute organ failure, and medication. Prevention and recognition of this condition are important. Features of delirium may include: fluctuations of mental state; impaired cognitive function, especially attention and orientation; clouded

consciousness; psychosis especially visual hallucinations; altered sleep-wake cycle; and motor disturbance (Stern, 2010).

In some cases, the cause of the delirium is not clear. It is important for the liaison teams to ensure that a physical cause has not been missed and to work with the treating team to ensure that relevant investigations have been performed. The adjusted hazard ratio of a patient dying during an admission if they develop a delirium has been estimated to be 3.5, with raised mortality persisting for up to five years after an episode of delirium (Eeles et al., 2010). Other negative outcomes of delirium include increased length of stay and discharge to institutional care.

The acute hospital should have systems in place to identify those at risk of delirium and to prevent its development. Common predisposing factors for the development of delirium include older age, dementia, severity of medical illness, infection, multiple high-risk medication, catheterization, immobility, sensory impairment, urea and electrolyte disturbance, and malnutrition (Ahmed et al., 2014). The potential to prevent delirium is well established. Inouye and colleagues (1999) showed that the introduction of protocols for the management of six risk factors (cognitive function, sleep, mobility, visual impairment, hearing impairment, and hydration) reduced the incidence and duration of delirium.

Treatment of delirium should focus on the underlying cause, and nonpharmacological interventions to manage the patient's behaviour are essential. A safe environment without access to dangerous objects is crucial, and one-to-one nursing care, avoiding excessive sensory stimuli, providing natural daylight in the day, ensuring a working light source above the patient's bed to help reduce misperception, and a visible clock and calendar to facilitate orientation are also useful. Reducing ward moves and ensuring access to glasses and hearing aids can also help with the symptoms of delirium. If possible, it can be helpful to limit the changes in staff members caring for the patient and staff should be encouraged to introduce themselves to the patient and explain what they are doing each time they are interacting with the patient.

At times, pharmacological therapy is essential in the management of the behaviour. Unless contraindicated, a small dose of haloperidol or an atypical antipsychotic can be used first line. Antipsychotics should not be given to patients with a diagnosis of Lewy body dementia and, in those cases, benzodiazepines may be required.

Alcohol

Detection of alcohol problems in the general hospital setting is important, as early recognition can help to prevent delirium and reduce unnecessary investigations. Physical signs to look for include tremor of tongue and hands, excessive capillarization of facial skin and conjunctivae, bruising and other injuries, alcohol on breath, obesity, hypertension, and an enlarged liver. The CAGE screening questionnaire can be helpful to check

Liaison old age psychiatry

for features of dependence: this screening tool asks if people think that they should Cut down on their drinking, if people have Annoyed them by asking them to cut down on drinking, if they ever feel Guilty about their drinking, and if they have had an Eye-opener, i.e. a drink in the morning to steady their nerves (Ewing, 1984).

To identify those at greater risk of alcohol withdrawal, alerting features are alcohol on the patient's breath, the patient drinking over half a bottle of spirits or equivalent a day, morning tremor or relief drinking, previous withdrawal symptoms, elevated MCV and/or GGT, and co-dependence on other substances, e.g. benzodiazepines. In the first 24 hours, there is often apprehension, tremor, insomnia, nausea, vomiting, and tachycardia; however, clinical teams should also be alert to unexplained delirium or agitation during recovery periods following emergency admissions for people with unrecognized alcohol use disorder. The Clinical Institute Withdrawal Assessment for Alcohol—Revised (CIWA-Ar) is a ten-item tool that can be useful to monitor withdrawal. It is not a diagnostic tool, but it can be helpful in assessing withdrawal severity and for titrating pharmacotherapy (Kattimani and Bharadwaj, 2013). Chlordiazepoxide can be used to relieve withdrawal symptoms and is commonly prescribed as a reducing regime. Oral thiamine is poorly absorbed, and so systemic replacement of the thiamine is essential to help prevent Korsakoff's syndrome and Wernicke's encephalopathy. Pabrinex is therefore an essential treatment, and would normally be given intravenously in the general hospital setting. Signs of Wernicke's include disordered mental state, oculomotor abnormalities, gait ataxia, and polyneuropathy (Liow, 2017). The elderly population have an increased risk of delirium compared with younger patients, and it is also important to consider the misuse of illicit drugs, prescription drugs, or over the counter medication in the elderly.

Behavioural disturbance

Patients are frequently referred to liaison services because of concerns about their behaviour. It is important to gather information about a pattern of the behaviour and potential triggers, in addition to identifying the reason for the change in behaviour, for example, if the patient is in pain, intoxicated, depressed, psychotic, withdrawing from alcohol, experiencing a delirium, or are they exhibiting behavioural and psychological symptoms of dementia. For patients with dementia, it is helpful to obtain a clear history from ward staff about challenging behaviour, for example, wandering could be caused by agitation or forgetfulness, while aggressive behaviour may be spontaneous and random, occurring at particular times of day e.g. sundowning, or associated with nursing interventions. Information from the patient, family, or carers, in addition to ward staff, is essential in putting a care plan together to manage the behaviour. Nursing staff in the general hospital may need additional support to help them to manage the patient's behaviour and it is helpful if they can record a behaviour chart

Liaison old age psychiatry

to look at potential triggers and interventions that help with the behaviour.

Capacity/legal frameworks

Thousands of decisions about patient care are made every day in acute hospitals, and patients' ability to participate in decisions should be assumed. Mental capacity legislation is designed to protect people and to empower those who may lack capacity to be as involved in decision-making as possible, especially for serious or irreversible decisions.

The Mental Capacity Act 2005 in England and Wales is designed to empower those working in health and social care to assess capacity without reliance on mental health professionals. A two-stage capacity test can be used by anybody who cares for or treats a person who may lack capacity. The first stage of this test is to determine whether or not there is an impairment of, or disturbance in, the functioning of a person's mind or brain; the second stage is to determine if the impairment or disturbance is sufficient to impact on the capacity to make a decision by assessing whether the patient can understand the information, retain the information long enough to make a decision, weigh up the pros and cons, and communicate their decision (Department for Constitutional Affairs, 2013).

However, it is possible that an expert opinion will be required for particularly complex cases or for major decisions (SCIE, 2016). In such cases, a referral to liaison psychiatry may be made, and they should work alongside the treating team, the patient and their family or carers to assess capacity (Fig. 24.2). If the patient lacks capacity, a best interest decision should be made, which may also involve a psychiatric opinion to consider the impact of the various options on the person's psychological wellbeing.

Fig. 24.2

The contribution of liaison psychiatry in complex capacity assessments.

Liaison old age psychiatry

In addition, there may be patients on an older adult ward who do not wish to stay on the ward, but lack capacity to consent to the admission or to understand the reason for the admission. Consideration about whether there is a deprivation of liberty, which would result in a breach of Article 5 of the European Convention of Human Rights, is essential as well as deciding which legal framework to use. In England, the Mental Capacity Act 2005 and the Mental Health Act 1983 (amended 2007) are the statutes that are frequently referred to. The Deprivation of Liberty Safeguards is part of the Mental Capacity Act and would often be used in the general hospital when the patient was primarily there due to their physical illness in cases where they were being deprived of their liberty and lacked capacity to agree to the admission. In some cases, for example, where a patient has a severe depression but continues to require medical treatment, consideration for the Mental Health Act, or equivalent legislation, may also be required. Alternative legal frameworks exist in other jurisdictions.

Case examples

The following boxes highlight few case examples where old age liaison psychiatry may be involved.

Case study 1

Mary is a 68-year-old lady who was admitted to a respiratory ward with an acute exacerbation of COPD. She was receiving antibiotic treatment and the respiratory team optimized her COPD treatment. However, subjectively, she felt that her breathing was deteriorating despite the treatment that she was receiving. Mary was assessed by the liaison psychiatry team, and it was felt that she had an anxiety disorder that was impacting on her breathing. Based on the assessment, the liaison psychiatry team worked with her to identify thoughts and behaviours related to her breathlessness and delivered brief psychological therapy. Her breathing and the control of her COPD improved.

Case Study 2

Jack is a 70-year-old man who was in hospital after an attempt to end his life that occurred following the death of his wife. He had taken a large overdose of medication that belonged to him and his wife. He required treatment on the medical high dependency unit and was referred to liaison psychiatry who saw him when he was still requiring medical treatment. He had experienced symptoms of severe depression for several months, but had not wanted to seek help from his family or GP as he felt embarrassed. He had no

Liaison old age psychiatry

previous history of mental illness and did not want to admit how low and hopeless he had been feeling. During his time in hospital, the liaison psychiatry team were able to see him daily, which allowed them to develop a therapeutic relationship, encourage a helpful openness with his family network, consider psychosocial interventions for depression, and commence anti-depressant treatment. On discharge from hospital, Jack was referred to the crisis team who were able to work closely with his family to manage risk and monitor his response to antidepressants.

Case Study 3

Peter is a 66-year-old man who was on a rehabilitation ward following a cerebrovascular accident. He had previously been fit and well, was working and was an active member of the local community. During the first two weeks following his stroke, he had been low in mood, irritable and had not engaged in rehabilitation. He was referred to liaison psychiatry. A psychosocial formulation was used to highlight the personal difficulty he had in adjusting to uncertainty and a lack of control over his daily routine. The multidisciplinary team on the ward used this understanding to adapt his care to meet the needs of his personality and values. He regained a sense of control and hope, and subsequently his progress through rehabilitation improved.

An example of an integrated service in diabetes care

One example where liaison psychiatry has been shown to have a significant influence is in diabetes. It was reported that the prevalence of diabetes was 6.6% of the UK population aged 20-79 in 2013, and this prevalence was projected to increase to 7.4% by 2035, while worldwide age-standardized prevalences in 2014 were 9.0% for men and 7.9% for women (Guariguata, 2013). Twenty per cent of people aged over 75 are reported to have diabetes (Meneilly et al., 2001), and the vast majority of cases are reported to be due to Type 2 diabetes (NCD Risk Factor Collaboration, 2016). Poor diabetic control can lead to significant complications, including blindness, renal failure, or amputation (Hippisley-Cox and Coupland, 2016).

Depression is the most common psychiatric comorbidity with a prevalence of 10–30% (Doherty, 2016). Patients with diabetes may struggle to adapt to their condition, and there may be a fear, especially in type 1 diabetes, of hypoglycaemia. In addition, some diabetic patients experience needle phobia, and diabetes can complicate the management of an eating disorder as omitting insulin can promote glycosuria.

Liaison old age psychiatry

Interventions can include pharmacotherapy with antidepressants, and psychotherapy, including motivational interviewing.

King's College, London established a 3DFD scheme in 2010, which stands for three dimensions of care for diabetes. This scheme assesses 300 patients a year who have diabetes and a comorbid mental illness, including needle phobia, depression, or anxiety. Over half of these patients had a new diagnosis of a psychiatric disorder, which illustrates that there was a considerable unmet need prior to the establishment of the service. Introduction of the service resulted in a significant drop in attendances to the emergency department, fewer admissions to the general hospital, and was estimated to save £850 per patient over a one-year period—a saving that is anticipated to increase over time (Doherty et al., 2016).

A collaborative project between liaison psychiatry and the diabetes services in Cambridge incorporated a Psychological Wellbeing Practitioner into the diabetic service in order to promote psychological wellbeing. They were able to screen for common mental health problems, signpost, and provide a brief intervention. In cases where there were more complex problems, a stepped care pathway approach was used and a psychologist or psychiatrist from the liaison team was able to become involved. There were significant improvements reported in both physical and psychological outcomes and staff satisfaction also improved.

Use of rating scales or screening tools

There are a number of different screening tools available for use by staff in the general hospital to help them to identify patients who have symptoms that are suggestive of a psychological problem or a psychiatric illness, and who require referral to liaison psychiatry. These tools include ultra-short screening instruments, and their use varies between hospitals and between departments in each hospital.

Some of the tools, for example, those used for anxiety and depression, can be affected by the presence of some physical illnesses, as sleep and appetite disturbance accompany both physical and mental illnesses, particularly in a general hospital environment; caution is therefore needed when interpreting tools that incorporate these measures. The Hospital Anxiety and Depression scale is a self-rated scale developed with the aim of detecting anxiety and depression in patients who have physical health problems. Importantly, it does not include sleep or appetite disturbance, but instead focuses on cognitive symptoms of both disorders. It comprises a 21-point scale, and scores of 11 or more on either the anxiety or depression sub-scales are proposed as indicating the presence of an anxiety or depressive disorder (Zigmond and Snaith, 1983). The Geriatric Depression Scale is another tool that is available to clinicians. It is a 30-item questionnaire, which can take some time to complete, although a 15-item and four-item version are available (Yesavage, 1982).

Liaison old age psychiatry

Cognitive testing is often carried out in general hospital settings using the Mini-Mental State Examination (Folstein et al., 1975) or the Abbreviated Mental Test. More detailed assessment can be undertaken using the Addenbrookes Cognitive Examination or longer batteries of tests. However, physical illness, impaired vision or hearing, educational background, depression, or anxiety can affect the score, so it needs to be interpreted along with a history from the patient and collateral history in order to facilitate a diagnosis.

Screening for delirium is commonly done by The Confusion Assessment Method (CAM) which is based on DSM-III-R and takes around five minutes to administer. However, use of this tool requires training. An alternative is the Delirium Rating Scale, a ten-item scale based on the patient's behaviour over a 24-hour period, and the Delirium Rating Scale—Revised 98, a 16-item scale; however, these latter two tools should only be used by those with training. The 4AT test consists of four items, two brief cognitive tests, assessment of level of consciousness, and an acute change in mental state (4AT, 2011). Advantages of this test are that it can be used without specific training and it is easy to use with a good sensitivity and specificity (Bellilli et al., 2014).

Outcomes

As a result of the increased focus within healthcare on outcome measurements, the Framework for Routine Outcome Measurement in Liaison Psychiatry (FROM-LP) was developed. This framework aimed to solve the challenges in developing outcome measures in liaison psychiatry where services vary in content and quality, and also where a service operates in many clinical environments with different patient groups (Royal College of Psychiatrists, 2015). It includes clinician-rated clinical outcomes, patient-rated clinical outcomes, patient-rated satisfaction, and referrer-rated satisfaction (Royal College of Psychiatrists, 2015). The recommendation was that FROM-LP should be adopted across all liaison services to facilitate data collection and effective reporting of outcomes. Outcome measurement tools should assess performance, service quality, and cost-effectiveness. FROM-LP uses the Identify and Rate the Aim of the Contact model and it gathers information about response times of the liaison service; however, it does not consider time of referral to liaison psychiatry from the point of admission (Tadros, 2016).

Training in liaison psychiatry

Liaison psychiatry has developed significantly in recent years, particularly for older people. Higher trainees in general adult psychiatry in the United Kingdom have been able to receive an endorsement in their training in liaison psychiatry through the Royal College of Psychiatrists since the late 1990s, if they undertook a year of training in an accredited liaison psychiatry post. Since 2016, trainees in older adult psychiatry have also been able to gain a similar accreditation in liaison psychiatry, which is a demonstration of the increased importance of this area (Burn,

Liaison old age psychiatry

2016). There are also a number of paediatric liaison posts being developed in several areas, but there is currently no formal accreditation in child and adolescent mental health training.

Nursing staff working in liaison psychiatry teams are experienced mental health practitioners. It was previously recognized that there was a need for competencies for liaison nurses to be developed, and this task was undertaken by the London Wide Liaison Nurses Special Interest Group. The latest revision included competencies specific to different patient groups, including older adults (Eales et al., 2014).

Teaching and education

One of the key roles of a liaison psychiatry service is to provide training for the general hospital staff. This teaching or training can be undertaken in a variety of formats, depending on local demand and requirements. Formal teaching programmes can be established with key staff groups, for example, on dementia, delirium, self-harm, managing disturbed behaviour, legal frameworks, and recognizing psychiatric disorders. Informal teaching is also important on the wards when discussing referrals and when feeding back information about patients that have been seen. Attendance at the medical grand round is also useful, and several organizations run Schwartz rounds, where the focus is on the social and emotional issues in particular cases; these sessions can help facilitate joint learning across all staff working in the general hospital (see <http://www.theschwartzcenter.org/supporting-caregivers/schwartz-center-rounds/>).

Accreditation of services

The Royal College of Psychiatrists College Centre for Quality Improvement (CCQI) run a number of accreditation schemes across different services. The Psychiatric Liaison Accreditation Network (PLAN) accreditation is designed to assure and improve the quality of liaison psychiatry services. It also facilitates the networking of different teams through e-mail discussions and events. Services that meet the required standard are awarded accreditation for a three-year period, with an interim review (see <http://www.rcpsych.ac.uk/workinpsychiatry/qualityimprovement/qualitynetworks/liaisonpsychiatry/plan.aspx>). Examples of improvements that have been made by teams as a result of PLAN accreditation include the provision of better assessment rooms, better training for the liaison team, improved policies and procedures, and better information being provided to patients (Palmer et al., 2016).

Interfaces

Where liaison psychiatry services are embedded within the mental health Trust, it is important to consider the joint governance arrangements with the general hospital Trust as the liaison psychiatry team will work across both organizations. Liaison psychiatry teams often contribute to relevant

Liaison old age psychiatry

policies and guidance within the general hospital, and joint meetings between the relevant managers should be established.

In addition to good working relationships and collaboration with colleagues in the general hospital, another important role of liaison psychiatry is to ensure good interfaces with other mental health colleagues who work in the psychiatric in-patient units and in community care. Many of the patients will require ongoing support or review within psychiatric services once they leave the general hospital, and it is essential for the liaison psychiatrist to be able to facilitate that ongoing support. Collaboration with primary care is also essential, as GPs and general practice staff provide significant input into the care of patients once they leave the general hospital.

The future of liaison psychiatry and integrated care

Liaison psychiatry has shown significant expansion over recent years. However, there is further research underway investigating the benefits of more proactive models of liaison psychiatry, and the recognition of the importance of integrated care is increasing. Additional research is still needed into the benefits of liaison psychiatry and the potential input of liaison psychiatry into different specialist areas, e.g. as with diabetes.

Further development of a liaison model in primary care may be seen in the future and additional work may be done to promote admission avoidance in the general hospital. There are plans within the five year forward view to improve psychological therapy access and to integrate physical and mental health (NHS England, 2014). An example of improved integrated care is the involvement of Improving Access to Psychological Therapies (IAPT), which have now expanded into physical healthcare. The potential benefits of the integration of mental and physical health are increasingly recognized in patients with long-term conditions. For example, Cambridgeshire and Peterborough Clinical Commissioning Group estimated that introducing IAPT services to diabetes, cardiovascular, and respiratory pathways saved £193,000 between October 2016 and September 2017 due to reduced A&E attendances, fewer hospital admissions, and a reduction in the number of GP appointments used. Further evaluation and research into these services will clearly be beneficial (Gammie, 2017).

Conclusion

This chapter has provided an overview of the development of old age liaison psychiatry, including some of the current service models in liaison psychiatry, and common conditions seen by old age liaison teams. It has considered the advantages of having liaison psychiatry services integrated within the general hospital, the importance of detection of psychiatric illnesses, and the additional roles of the liaison team within the general hospital setting, e.g. teaching, training, and joint governance. Significant expansion of liaison services has occurred over recent years,

and the importance of liaison psychiatry is reported nationally. Much progress has been made towards recognizing old age liaison psychiatry as a subspecialty and it is increasingly recognized as being a key service as the majority of inpatients in the general hospital setting are over the age of 65. Moreover, much of the current evidence of cost savings relates to those over the age of 65.

Social care

Chapter: Social care

Author(s): Jo Moriarty

DOI: 10.1093/med/9780198807292.003.0025

Introduction

Social care is the personal care and support required by some people because of needs arising from their age, illness, disability, or other circumstances. Support is provided in residential and nursing homes, people's own homes, and in other community settings (Wenzel et al., 2018). Outside the United Kingdom (UK), it is more frequent to see this provision described as 'social services' or 'long-term care'. Another term, 'social protection', encompasses the totality of support for older people and working-age people with disabilities, including pensions and welfare benefits, health care, and social care.

Old age psychiatrists need to understand social care because so many of their patients and their families will also be in touch with social care services. The effects of dementia and depression, in particular, are such that the overwhelming majority of patients and carers need some social care support, especially when symptoms worsen. This is clearly

demonstrated by the over-representation of people with dementia and/or depression in home care services (Pickett et al., 2012; Bruce et al., 2015; O'Brien et al., 2017) and in care homes (Prince et al., 2014; Stewart et al., 2014). At the same time, it is often only through contact with old age psychiatry services that many patients and families become aware of what kinds of social care support are available. Old age psychiatrists are also, therefore, often the first point of call for patients and their families attempting to negotiate a complicated and diverse system of social care funding and support. This highlights the importance of their role as an important link between other health and social care services.

This chapter describes the key legislation underpinning publicly funded social care, explains how it is funded, summarizes key research on personal budgets, home care, day care, and care homes, and discusses some of the key current policy debates. Social care is what is termed a 'devolved matter', so the Scottish and Welsh governments and the Northern Ireland Assembly can make their own decisions about how social care services operate under their jurisdiction. Since devolution, social care policy has become increasingly divergent across the UK. However, the overwhelming majority of social care research emanates from England, so although this chapter refers to developments in Scotland, Wales, and Northern Ireland, most of the material included is about England. It should also be noted that the volume of social care research specifically about older people with mental health problems remains limited—indeed, it is only comparatively recently that local councils began reporting data on the number of people with dementia using their services to NHS Digital. The text will make it clear when reference is made specifically to older people with mental health problems, all people aged 65 and over, and people using adult social care services as a whole.

Social care legislation

Care Act 2014

The key piece of legislation in England is the Care Act 2014, which marks one of the most significant changes to social care law in England since the National Assistance Act 1948. It was enacted alongside accompanying guidance, which has since been updated to take account of regulatory changes and feedback from stakeholders and the care sector (Department of Health and Social Care, 2018).

As well as simplifying the complex and piecemeal arrangements by which older people and people with disabilities were deemed eligible (or not) for publicly funded social care, the Act has three key principles. The first is the duty it places on councils with social services responsibilities (known as CSSRS to distinguish them from district councils which are not responsible for social care) to promote the wellbeing of adults and carers and carers in need of support living in their area. Wellbeing is defined as

Social care

relating to any of the following, without any attempt to create a hierarchy within them:

- personal dignity (including treatment of the individual with respect);
- physical and mental health and emotional wellbeing;
- protection from abuse and neglect;
- control by the individual over day-to-day life (including over care and support, or support, provided to the individual and the way in which it is provided);
- participation in work, education, training, or recreation;
- social and economic wellbeing;
- domestic, family, and personal relationships;
- suitability of living accommodation;
- the individual's contribution to society.

Some commentators (e.g. Penfold, 2017) have suggested that this principle is the most important aspect of the Act as it underpins efforts to achieve more personalized care and support in line with the preferences of an individual, and not at the convenience of the system.

A second duty placed on local authorities is to contribute to the prevention or delay in the need for support. The increased emphasis on timely diagnosis in dementia (Dhedhi et al., 2014) and the risks of untreated depression (Briggs et al., 2018) highlight the potential for preventive support for older people and family carers. However, many carers and older people regularly report difficulties in finding out about what social care support is available and what are their entitlements (Mukadam et al., 2011; Moriarty et al., 2015). For this reason, the Care Act places a duty on local authorities to establish and maintain information and advice services in their area relating to care and support for adults and support for carers. The voluntary organization Independent Age commissioned research to see whether this new requirement had improved local councils' information and advice services, including undertaking a 'mystery shopping' exercise in which callers telephoned local councils using pre-scripted scenarios, such as asking about handrails. The report concluded that, although most information and advice services complied with the requirements of the Act, less than a third provided all the online information required by the legislation (Qa Research, 2016).

The Care Act 2014 guidance (Department of Health and Social Care, 2018) describes the assessment and eligibility process as one of the most important elements of the care and support system. People may approach a local authority for an assessment, or be referred by a third party. Local authorities then have a duty to provide assessments for any adult, including carers, appearing to have a need for care or support, regardless of the local authority's view of the level of that need or the individual's

Social care

financial resources. This may be carried out by a person working for the local authority—or, as is happening more frequently, responsibility is delegated to another organization—for instance, to a carers' organization. The emphasis on support for carers highlights another important intention behind the Act. In the words of Norman Lamb, Minister of State for Community and Social Care during the passage of the Care Act, it would put carers on a 'level footing with those for whom they care' (Lamb, 2013).

Where an adult refuses a needs assessment, the local authority concerned is not required to carry out the assessment. However, it must go ahead with the assessment if the adult lacks capacity to refuse the assessment and the authority is satisfied that carrying out the assessment would be in the adult's best interests, or the adult is experiencing, or is at risk of, abuse or neglect. In the same way, should an individual be unable to request an assessment or struggle to express their needs during an assessment, the local authority must use the principles outlined in the Mental Capacity Act 2005 to help people be as involved as possible in their assessment and to help them make decisions about their preferred options.

Authorities also have a duty to improve the quality of care and support for adults and support for carers (including the outcomes that are achieved from such provision). Since the 1990s, local authorities have contracted with private companies and voluntary organizations to provide social care services. However, many social care providers have become increasingly dissatisfied with the level of fees paid by local councils to provide services for their residents on their behalf. In some instances, this has led some companies to withdraw from contracts with councils (Asthana, 2016). In others, it has led to cost cutting. The health and social care regulator, the Care Quality Commission (CQC), produces an annual assessment of health and social care services in England. In 2016–2017, it reported that 19% of social care services were rated as 'requires improvement'. While 78% were rated as 'good', just 2% were outstanding. This compared with 6% of National Health Service (NHS) acute hospital and mental health care services and 4% of GP practices that received the same outstanding rating (Care Quality Commission, 2017).

Social care funding

Unlike the NHS, which is free at the point of delivery, social care is means tested. Local councils currently use a combination of central government grants, local taxation, and charging for services to pay for social care. At the time of writing, people in England and Northern Ireland with assets of over £23,250 are expected to pay the full costs of the social care they receive. If their assets are between £14,250–23,250, they will be eligible for maximum financial support from their local authority but are still likely to have to make contributions from their income until they have 'spent down' to £14,250. In Scotland, the equivalent amounts are £27,250 and £17,000 (Care Information Scotland, 2018). Another key difference is

Social care

that people in Scotland with assets of more than £27,250 who are assessed as needing personal care are not charged for this support, although they do pay for other aspects of their care, such as care home accommodation costs, day care, and meals services. In Wales, the Welsh Government has set a limit on the amount that local councils can charge for services (currently £80 per week) and has raised the amount of capital a person can keep without having to pay for their residential care to £40,000. Their intention is to eventually raise the limit to £50,000 (Welsh Government, 2018).

Crucially, across all four UK countries, housing assets are not currently included in financial assessments for social care services provided to people living in the community. Once a person moves into a care home, the situation is changed. However, councils must 'disregard' the value of a property if it is also the main residence of a carer or another close relative aged 60 and over or with a severe disability that incapacitates them. As old age psychiatrists will know, decisions about selling a family home to pay for care can lead to convoluted disputes, especially where a person is thought to have deliberately disposed (or has been deprived by others) of assets to increase eligibility for local authority funding or where families disagree about what is best for the person needing care.

Many older people are what is termed 'asset rich and income poor'. Local councils across England are expected to help those who own their own homes meet their care costs by allowing them to make 'deferred payments'. The system varies slightly across the UK but deferred payments are essentially a legal agreement whereby local councils make payments on people's behalf until they decide to sell their home or die. The proceeds from the sale are then used to repay the council. In practice, local authorities sometimes set limits on the percentage of a home's value that can be used for deferred payments. This is to prevent falls in house prices leading to a person's assets becoming less than the sum spent paying for their social care.

It has always proved difficult to get definitive figures on the proportion of people funding their own social care. Estimates suggest that about 20–25% of people using home care and 44% of residents in care homes in England are self-funding (Baxter and Glendinning, 2014) but only about a quarter of those in Welsh care homes are self-funding (Jones et al., 2016). As well as those who fully fund their own social care or whose care is fully funded by their local council, a third group consists of care home residents whose fees are partly or fully paid by their local council but who have family or friends or receive a charitable grant to pay top-up fees. These sums were originally intended to be voluntary payments for 'extras' such as a larger room or a nicer view but are increasingly used to cover the gap between the upper limit that a local council is prepared to pay for care and the actual fees charged by the care home itself (Passingham et al., 2013). Age UK estimates that about 50,000 of the 400,000 people (a figure which also includes those aged under 65) living in care homes in England are paying top-up fees. Age UK, along with other older persons

Social care

charities, e.g. Independent Age, has described these fees as a ‘stealth tax’ with relatives often feeling pressurized into accepting them without necessarily seeing evidence of an additional service being provided.

Old age psychiatrists will know from their conversations with patients and their families that the current system in which there is no limit to the amount of money an individual might pay to fund their own social care during their lifetime accounts for much of the unhappiness with current funding arrangements. While the majority of older people only move into a care home for the final few months of their lives, leaving their assets largely intact, people with severe dementia may spend several years living in a care home. Care home fees vary throughout the country, but a person living in a nursing home specializing in dementia care could easily pay over £1,000 per week at current prices. Should that person survive for several years, they may end up using all their assets to pay for care. This is sometimes called ‘catastrophic costs’. Families and people with dementia and organizations advocating on their behalf point out that older people with, for example, cancer but not dementia are unlikely to face similar costs. The striking figure produced for the Dementia UK Update report (Prince et al., 2014) is that, while local councils pay £4.4 billion a year on social care support for people with dementia, individuals with dementia and their families are paying £5.8 billion a year on privately funded social care. This sum excludes the costs needed to replace the unpaid care provided by family and friends.

Reforming social care funding in England

There is now much greater media and public interest in social care funding than in the past—as witnessed by the furore over the so-called ‘dementia tax’ in the 2017 General Election (Heaven, 2017)—but in reality, concern about the system dates back at least to the early 1990s. This occurred when a loophole in the benefits system allowed people to claim for the cost of residential care. The result was a rapid rise in the number of people living in care homes far in excess of the growth in the number of older people in the population (Lewis and Glennerster, 1996). Faced with spiralling increases in the social security budget, the government decided to make local councils responsible for assessing people’s needs for support and for funding the care costs of people they assessed as needing support whose assets were below the limit entitling them to receive publicly funded social care. Prior to this, local councils had exercised much greater discretion in deciding what social care services they would provide and how they would assess local residents’ entitlements to support.

Since the 1990s, the gap between demand for social care and social care funding has widened considerably. There are several reasons for this. The first is the growth in the number of people aged 80 and over in the population alongside an increase in the number of people of all ages living with complex conditions. As more people live with increasingly complex needs, they require more social care support in the form of help

Social care

with personal care, meal preparation, and other activities of daily living. In 2014–2015, approximately 578,000 people aged 65 and over were accessing long-term social care support in England, compared with 291,000 people aged 18–64. However, £6.675 billion was spent on the 18–64 age group compared with £6.927 billion on those aged 65 and over. Total expenditure on publicly funded adult social care in 2016/17 was £16.8 billion (NHS Digital, 2017). It is difficult to set this figure in an international context because countries take different approaches to defining and reporting social care expenditure (Robertson et al., 2014).

The second factor is reductions in central government grants to local authorities. For some years, councils sought to cover this gap by increasing efficiency costs and tightening eligibility criteria so that fewer people qualified for publicly funded social care support. However, between 2010 and 2020, core funding from national government will have reduced by £16 billion (Local Government Association, 2017). At one point, the 2015 Conservative government intended that these core grants would be phased out completely. Instead, councils would be allowed to retain almost of the money they raised through business rates. Many local councils argued that this change would benefit councils that raise large sums in business rates each year, e.g. Westminster, but that councils in poorer areas yielding low business rates would struggle unless there was some sort of redistribution. At the time of writing, it is not clear whether central government grants will be withdrawn completely, as originally intended (Hetherington, 2017). However, if they are withdrawn, the consequences for social care funding could be serious as adult social care constitutes the biggest area of discretionary spend for local authorities (Cromarty, 2018) and many councils report that they can only provide statutory social care services, with no leeway to develop preventative services or provide support to anyone but the most severely disabled.

The third, and final, reason for the social care funding gap is the increase in care costs. Social care is a labour-intensive but poorly remunerated service and increases in the number of people requiring intensive support mean that labour costs will also increase, even if individual earnings remain largely unchanged. As labour costs account for 50% of the cost of running a nursing home (Wanless, 2006), even comparatively small increases in wages overheads can have a considerable effect on running costs. For many years, local councils and social care providers achieved savings by controlling labour costs (Moriarty, 2015). This meant that social care was among the lowest-paid occupations. While social care workers have benefited from the introduction of the National Minimum Wage and the National Living Wage, some employers have become notorious for not paying home care workers for travel time between clients, meaning that they are illegally paid less than the National Living Wage (Gardiner and Hussein, 2015). It is also worth pointing out that although social care is a 24/7 service, enhanced payments for working unsocial hours are minimal or non-existent, which can make it especially difficult to recruit people to work in the evenings or at night. Low wages

Social care

are universally believed to be one of the main factors contributing to longstanding difficulties in social care recruitment and retention (Moriarty et al., 2018).

The social care sector argues that, despite the action it has taken to control expenditure, this is no longer enough to cover reductions in social care funding. The Health Foundation has estimated that the funding gap for social care in 2017/2018 was at least £2bn (Health Foundation, 2017). This is projected to rise to £6bn by 2031 (Wenzel et al., 2018). Commentators are increasingly concerned that more people who need care are not having their care needs met. There is also evidence that care providers are facing quality challenges and the care provider market is becoming increasingly precarious. Furthermore, in some areas a lack of suitable care provision is adding to pressures in the health service (Cromarty, 2018).

Successive governments would argue that they have not been oblivious to what is increasingly termed a social care crisis. As the health and social care policy analyst Richard Humphries has pointed out, there have been at least five independent reviews of social care funding and twelve white papers, green papers, and consultations of one kind or another under five governments over the past 20 years (Humphries, Undated). The nearest that any government came to reforming social care funding was a commitment in the Care Act 2014 to set a means tested cap on the costs that individuals might be expected to pay for social care over their lifetime, as recommended by the Dilnot Commission (Commission on Funding of Care and Support, 2011). However, successive delays in implementing the care cap mean that this proposal has almost certainly been abandoned.

At the time of writing, the 2017 Conservative government has promised a social care Green Paper to be published in late 2018. While it is not yet known what it will propose, it is likely to consider some, if not all, of the following options. These include:

- A 'social care premium', a dedicated fund paid by those aged over 40 to fund personal care free at the point of delivery (House of Commons Health and Social Care and Housing, 2018);
- 'Prefunded social care' whereby working-age people would contribute a percentage of their income into a privately managed fund (Vasilev, 2017);
- A National Care Service, along the lines of the NHS paid for through general taxation;
- A long-term care insurance system similar to systems in countries such as Germany, Austria, Japan, and Luxembourg (Glendinning and Wills, 2018);
- Hypothecation—the earmarking of a tax to be spent on health and social care (Murray, 2018).

Social care

In theory, private insurance products are another way of helping people insure themselves against future care costs. In practice, few are available and they are expensive. The average cost of an immediate needs annuity, usually taken out by people about to enter a care home, which pays all future fees in return for a lump sum payment, is £69,000 (Wenzel et al., 2018)—many older people are likely to decide that they are not worth the risk. Equity release is another mechanism that allows older home owners to release money from the value of their house but this is a better solution for people wanting to pay for care at home or make adaptations to their house because equity release policies usually stipulate that the sale of the house will be triggered if the policyholder(s) move into a care home. Either way, these two options are only available to a minority of older people and would not resolve the question of how to fund social care for people with severe disabilities aged 65 and under who are rarely able to build up substantial savings or housing assets.

Every proposal for reforming social care funding has its advocates and detractors. A further difficulty for policymakers is the low level of understanding among the general public about how social care is funded (Bottery et al., 2018) and a reluctance to interfere with what is seen as the 'right' to an inheritance. Sir David Behan, the Chief Executive of the CQC 2012–2018, has commented:

The future of the social care system is one of the greatest unresolved public policy issues of our time—a long-term sustainable solution is urgently required (Behan, cited in Marsh, 2017).

Only time will tell if wholesale reform to social care funding is enacted or if variants on the current system, with all its associated problems, will continue.

Personal budgets and direct payments

Personal budgets in social care are sums of money allocated by a local authority to people assessed as needing social care to be spent on services to meet their care needs. They can be managed on behalf of users by the authority, or a third party, or given to users as direct payments to spend themselves (House of Commons Committee of Public Accounts, 2017, p. 4). In Scotland, a direct payment is known as self-directed support while elsewhere in Europe, they are often term 'cash for care' payments. Direct payments in social care date back to 1997 when the Community Care (Direct Payments) Act 1996 came into force.

Until the last quarter of the twentieth century, the majority of social care services were directly provided by the state and choice was not an important factor in how they were organized. However, from the late 1970s, choice of provider has been the main way in which successive governments have sought to improve service quality (Stevens et al., 2011). In the UK, as in the majority of the more developed countries, the option for people using services to choose either social care services

Social care

directly provided to them or to receive cash to be used to purchase services themselves has become an important policy objective, with direct payments increasingly becoming successive governments' preferred method for supporting people eligible for publicly funded social care (Ettelt et al., 2018).

[Personal budgets] are all about making the financial aspect of ... care more explicit at the individual level. By specifying the individual's budget, and allowing the individual to decide how it should be spent, the personal budget (theoretically) offers more choice, control and flexibility to the budget holder. It also places a duty on the individual to identify and potentially source the most appropriate services, and to varying degrees, manage the budget and be accountable for how it is spent (Gadsby, 2013).

Adults eligible for NHS Continuing Healthcare and children in receipt of continuing care have had a right to have a personal health budget since October 2014. Both the 2015 and 2017 Conservative governments intend that the right to a personal health budget should become more widespread.

The introduction of direct payments was particularly welcomed by members of the disability movement, mainly consisting of people aged 18–65 with physical disabilities, for whom choice was an important way of achieving greater independence and autonomy (Stevens et al., 2011). More recently, a more critical discourse has emerged highlighting the anomalies in aspirations about choice and control in a system which is actually determined by eligibility (Slasberg and Beresford, 2017) or the practicalities in dismantling some of the professional and structural barriers that exist (Ettelt et al., 2018).

This more critical discourse is informed by results from studies carried out with different groups of service users, particularly those for whom concepts such as choice and control might be less important than other aspects of care or those who may lack capacity to exercise choice and control. A randomized multimethod comparison group study compared 510 direct payment recipients (termed individual budget holders) living in 13 pilot authorities with 449 people receiving conventional services in the same locality. Its overall conclusions were that individual budgets produced positive outcomes in terms of service users' quality of life and sense of control. Benefits could also be seen for carers, who reported a better quality of life and more opportunities for a social life. However, it also reported that older people were less likely than their younger counterparts to use innovative support and were more anxious about the process of planning and managing their individual budgets. It recommended that more work is needed on tailoring approaches to the needs of different groups of service users (Manthorpe et al., 2009; Moran et al., 2011; Stevens et al., 2011; Netten et al., 2012).

Social care

The uptake of direct payments among older people (Woolham and Benton, 2013) and among older people with mental health problems in particular, has lagged behind other groups and still remains relatively low. The original legislation excluded people with dementia but, where a person lacks capacity to manage a direct payment, it is now possible for the payment to be made to a 'suitable person' who purchases and manages care and support services on behalf of the person with dementia. A suitable person does not have to be related to the person with dementia, although in practice he or she is likely to be providing regular support. An alternative arrangement is for an Individual Service Fund (ISF), which is a managed account held by a third party who arranges for support to be provided in line with the person's wishes. They are sometimes seen as a middle way between direct payments and support arranged by the local council for people who do not have anyone who could act as a 'suitable person' or who do not want the responsibility of managing a direct payment.

Three qualitative studies (Kinnaird, 2010; Manthorpe and Samsi, 2013; Laybourne et al., 2014) have highlighted the barriers operating against direct payments for people with dementia, including practitioners' low expectations about what people with dementia would want other than conventional home care (Laybourne et al., 2014) and concerns about financial abuse (Manthorpe and Samsi, 2013). For people with dementia (Kinnaird, 2010) and 'suitable persons' (Laybourne et al., 2014), the most frequently reported problems were negotiating the social care system and practical problems such as delays in receiving the payments. At the same time, people with dementia (Kinnaird, 2010) and carers (Laybourne et al., 2014) spoke positively about the choices they were able to make, including booking a holiday cottage rather than a short break in a care home.

Home care

Home care is the main community care service supporting people with dementia living at home. It helps delay entry into long-term care for people with dementia (Andrew et al., 2000) and home care users experience better quality of life than those living in care homes (Nikmat et al., 2013). Unfortunately, there is also plenty of evidence that much home care provision is of poor quality and does not meet the needs of people with dementia. A good example of this is the practice of commissioning very short visits, sometimes as short as 15 minutes. Many people with dementia can continue to get up or prepare meals if they are given extra time and encouragement. However, this is not possible when workers need to leave quickly for their next visit. The end result is that workers may try to save time by, for example, dressing a person with dementia rather than encouraging him or her to do it independently.

Many home care workers have limited training and knowledge about dementia. Recruitment and retention problems are longstanding (Moriarty et al., 2018), which means people with dementia do not always

Social care

benefit from having regular workers, even though continuity of care is especially important for them. Finally, almost all home care is commercially provided and changes in ownership can mean that an agency that formerly provided reliable well-trained workers no longer does so. A solution to these problems has been to set up specialist dementia home care agencies, but these are not always available everywhere.

Day services

Day services are a long-established way of providing social activities for people with dementia at the same time as giving those people who have a family carer a break. They are also valued by many older people without dementia, particularly those experiencing social isolation and loneliness (Orellana, 2018). The advent of personalization has been accompanied by the closure of many day centres, leading Needham (2013) to argue that the personalization narrative has been much more effective in legitimizing their closure than in stimulating the emergence of new collective spaces.

Day care has been shown to improve quality of life for people with dementia and reduce distressing behaviours. It may also delay placement in a care home among those cared for by adult children, although for spouses, it may act as a transitional service between community settings and living in a care home. However, conflicting findings have also been reported, accentuated by methodological challenges such as lack of differentiation between a service used for a couple of hours a week and one used every day, or differences in the types of activities that are provided and whether or not any supplementary services, such as counselling for carers, are provided (Fields et al., 2012). An important factor in one comparative study of Norwegian and Scottish day services highlighted that many of the people with dementia and their carers described an initial reluctance to use the service which changed to enjoyment as they became used to the service. The authors (Rokstad et al., 2017) argued that practitioners needed to become better at introducing the service to people with dementia and their families and explaining that feelings of apprehension were frequent and might change.

Care homes

In the UK, the term 'care home' refers to all residential long-term care settings that provide communal living and personal and/or nursing care for older people and other adults. In the past a distinction was made between residential homes providing personal care and nursing homes providing nursing care. Homes now register as a care home only or care home with nursing. These slightly unwieldy terms reflect the reality in which residents have an average at least three or more conditions (Goodman, 2016). For many years, erratic and inequitable access to specialist health care meant that residents did not always receive optimal

treatment for these conditions but there is now greater emphasis on services working together to improve this (Goodman, 2016).

Homes can also choose to specialize in providing certain types of care, such as specialist dementia care or palliative/end-of-life care. In England, residential care is overwhelmingly provided by the independent sector, with voluntary organizations providing almost all the rest. There are proportionally slightly more local authority-run homes in Scotland, Wales, and Northern Ireland, especially in places where there are fewer self-funders and profit margins are likely to be lower.

Around three-quarters of people in care homes have dementia, while just over a quarter have depression. In specialist care homes for older people with mental health problems, these proportions rise to 91% and 29%, respectively (Stewart et al., 2014). There is also evidence of significant levels of comorbidity of depression and dementia (Sutcliffe et al., 2007).

The complex health conditions experienced by many care home residents mean that a well-trained work force is essential. Despite this, levels of training among care home staff are very variable (Denning and Milne, 2009). In particular, while there has been a considerable increase in training resources for care home staff on delivering more person-centred dementia care, comparatively little of this material has been systematically evaluated for its quality and accuracy (Fossey et al., 2014).

Most of the research interventions developed in care homes are addressed at the most common problems faced by care home staff and residents (Centre for Policy on Ageing, 2014), for example, dealing with depression and dementia (Kuske et al., 2007), distressing behaviour (Moniz-Cook et al., 2017), communication skills (Moriarty et al., 2010), end-of-life care (Moriarty et al., 2012), or are aimed at areas where deficits in care are often reported, such as a shortage of activities for residents (Mozley et al., 2007). These generally report positive findings—albeit usually more in terms of staff satisfaction than improved outcomes for residents—but a key problem continues to be maintaining this training in the ‘real world’ once the intervention is over.

Other social care support

For reasons of space, it is not possible to discuss other types of social care support in more detail beyond highlighting the increasing numbers of older people with mental health problems living in supported and extra care housing (Fendt-Newlin et al., 2016) and the potential (and barriers) to the use of assistive technology (Woolham et al., 2018).

It is also worth mentioning alternative forms of social care support that tend to be on a smaller scale and not available elsewhere. These include:

- Befriending (Greenwood et al., 2016);

Social care

- Shared Lives as an alternative to traditional day care or short breaks, whereby a person with dementia spends time in the family home of a paid worker, sometimes known as adult fostering (Shared Lives, 2017); and
- Homeshare, where a person provides low-level support and companionship to a person with dementia living at home in return for an affordable place to live (Macmillan et al., 2018).

All these services tend to be very positively evaluated by people with dementia and their carers, but it has proved difficult to ensure that they become 'standard' services available to all those who would like these forms of support.

Partnership working

Good support for older people with mental health problems requires good partnership working between health and social care. The differing origins of health and social care and different ways in which services have been organized and funded has created barriers to more effective working. However, there are policy pressures for greater integration between health and social care. The 8 Pillars of Integrated Community Support developed by Alzheimer Scotland aim to improve coordinated working for people with dementia living in the community (Blake Stevenson Ltd, 2012). The pillars are:

- A Dementia Practice Co-ordinator; (a named, skilled practitioner such as a community psychiatric nurse, social worker, or allied health professional;
- Therapeutic interventions to tackle the symptoms of the illness;
- General health care and treatment;
- Mental health care and treatment;
- Personalized support;
- Support for carers;
- Environment-adaptations and aids to support the independence of the person with dementia and assist the carer; and,
- Community connections-support to maintain social networks for both the person with dementia and the carer.

These eight pillars sum up what good social care for older people with mental health problems *should* involve, even if they are more aspirational than available across the country.

Conclusion

This chapter has tried to show the breadth of the different types of social care support available to older people with mental health problems. Many older people with mental health problems are living with other conditions and the range of challenges they face and the diversity among this group

mean that a range of social care support will be needed, especially as their growth in numbers has led to tightening eligibility criteria and reductions in the number of people who qualify for social care support (Fernandez et al., 2013).

Care homes for older people

Chapter: Care homes for older people

Author(s): Tom Dening and Alisoun Milne

DOI: 10.1093/med/9780198807292.003.0026

Introduction

This chapter is in three parts. First, we discuss the care home sector, looking at the changing nature of care homes and how care is provided, paid for, and regulated to achieve acceptable standards of quality. In the second part, we consider the people who live in care homes, with particular reference to their physical and mental health. Finally, we explore a positive care culture, its key dimensions, and what enhances quality of care; also, which external issues contribute to its promotion. Much of the following description of care home provision is based on the UK, but we draw from international research findings, as issues of long-term care are critical for many other countries, too.

The care home sector

Care homes in the UK

Care homes for older people

Care homes are an important sector of care provision and constitute a significant part of the general economy, with a total current value of around £15.9 billion. There are currently nearly 12,000 registered care homes for older people providing over 400,000 beds (Laing and Buisson, 2016). Of these, 261,000 beds (58%) were in establishments registered as 'care homes with nursing' (nursing homes) with the remaining 192,000 (42%) in residential care homes (without nursing). Residents receiving nursing care account for 45% of *all* care home places. Residential care homes provide 24-hour support and staff are available to help with personal care and activities of daily living, e.g. mealtimes, continence promotion, and the wellbeing, security, and safety of residents. Community nursing arrangements may be needed for individual residents (e.g. regular injections, treatment of leg ulcers). Nursing homes offer 24-hour medical care from qualified nurses. If a person's needs are best met in a nursing home and the person is eligible for NHS-funded nursing care, the costs of this are met by the relevant clinical commissioning group in England and in Wales by the local health board (Laing and Buisson, 2016).

Over the past 30 years, care home services have transformed from being a predominantly public sector activity to a predominantly private sector activity. In 2015, 90% of residential and nursing care services were delivered by independent, mainly for-profit, providers (Laing and Buisson, 2016). Until relatively recently, some NHS hospitals offered continuing care for a small proportion of very frail older people, including those with severe dementia. Now nearly all 'continuing care' patients are placed in nursing homes; a few of these are NHS run, although usually the NHS just commissions provision from private nursing homes (Lievesley et al., 2011).

Dementia is the largest specialist segment of the care home market. In 2014, an estimated 172,000 care home residents in the UK were receiving 'dementia care' whether in dedicated units or not. About 40% of all care home funding is spent on dementia care.

Currently, about 60% of capacity is operated by larger providers (with three or more care homes). The ten largest for-profit providers hold 25% of the market. Although occasionally large providers (e.g. Southern Cross) fail, it is likely that further consolidation of the market will continue. Care homes range in size from about ten beds to over 100 beds. The size of homes has approximately doubled in the last 25 years: the mean for nursing homes is now 51 places, compared to 28 for residential homes. There is a trend towards residential care homes re-registering as nursing homes where they can capture a wider pool of demand. The average occupancy rate across all homes is over 90%.

Standards of physical amenities in care homes have improved significantly in the last 20 years in response to self-pay market forces and demands from local authority commissioners. Most for-profit care homes provide single room accommodation with en suite facilities. Rooms are

Care homes for older people

larger too, with most being at least 12 square metres; many developers build rooms larger than this to 'future proof' their assets (Health and Social Care Information Centre, 2014).

Supply side issues

Care homes are distributed unevenly across the country: there is a larger supply of places in the north of England than in south east, especially London. This pattern reflects differences in the price of housing, wage costs and income levels; different local authority and NHS commissioning practices also contribute (Humphries et al., 2016). A shortage of specialist dementia care across the UK, particularly in south east England, is a persistent concern (MacDonald and Cooper, 2007).

At present, the care home sector is contracting somewhat, with independent care home closures outweighing new places opening (Laing and Buisson, 2016). Forty-seven care home operators became insolvent in 2014/15; up from 40 in 2013/14. Care home closures are apparently due to the combined impact of market uncertainty; cuts to adult social care spending; and changes in care delivery, with greater emphasis on community-based living for frail older people (Leyland et. al., 2016).

These trends conceal wide regional variations; for example, reduction in care home beds ranges from 18% in London to 2% in the east of England. As care markets are hyperlocal, this is a significant problem for affected local authorities, older people and their families. Most care homes serve a catchment area of less than 10 miles in diameter and often rely heavily for referrals from one local authority (Laing and Buisson, 2016). Another factor relates to who pays for the bed; the care home market is highly polarized. Providers with mainly self-funding residents are relatively financially secure, while those relying on public funding are vulnerable to cuts to local authority budgets, increased costs e.g. introduction of the National Living Wage (discussed below), and financial losses (Laing and Buisson, 2016).

There are significant concerns about the future supply of care homes. It is estimated that 42,000 additional beds are needed by 2022 across England to meet the predicted demand (Bone et al., 2018). However, 87% (130 out of 150) of local authorities will probably *not* have sufficient places to meet this demand, so any additional beds will be provided by care homes catering for self-funding residents, thus amplifying the existing inequities. Despite the policy emphasis on community-based living, the complex needs profile of care home residents limits the capacity of non-residential alternatives, such as extra care housing (see section **Extra care housing**), to prevent or delay the need for it.

Relocation

An alarming consequence of care home closure is the enforced relocation of residents. Evidence suggests that relocations that are approached in a thoughtful and organized way lead to better outcomes for residents.

Care homes for older people

Conversely, relocations which are rushed and unplanned, without actively involving residents and their families, are associated with negative outcomes including emotional distress, increased risk of depression and worsening of dementia symptoms (Jolley et al., 2011). Relocation may even increase the risk of death (Veale, 2012).

Leyland et al. (2016) found that an evidence-informed protocol on enforced relocations helped to reduce the risk of harm to residents. The protocol adopted several core principles: involving the resident and their families throughout; discussing their preferences at an early stage; and ensuring effective and timely communication about decisions, the timings of key events and the older person's rights. In addition to best practice protocols, there are several freely accessible, evidence-informed national resources (e.g. Social Care Institute for Excellence and Association of Directors of Adult Social Services, 2011). However, it appears that best practice is still not consistently applied by local authorities (Holder and Jolley, 2012). As care home closures will continue or even increase, effective management of the relocation of vulnerable older residents remains an important issue.

Extra care housing

Extra care housing (ECH) refers to accommodation with self-contained housing units, 24-hr staff on site, with domestic care and communal facilities available to residents (Evans, 2009). In 2014 there were approximately 40,000 Extra Care units in England mostly in the socially rented sector (Laing and Buisson, 2016).

Most ECH schemes offer a range of graduated support services titrated to meet dependency needs as they increase. As a model it appears to work well for those with physical disabilities and/or mild dementia (Callaghan and Towers, 2014). It is less clear how well ECH can support people with more advanced dementia and/or multiple needs and whether it delays admission to long term care for these groups (Bäumker et al., 2010). There is little development of co-housing schemes in the UK, a model of inter-generational 'shared' housing that is popular in other parts of Europe particularly Scandinavia.

Although limited in scope there is evidence that 'all forms' of retirement-related housing bring health and quality of life gains, including improvements in wellbeing following a move into the housing facility. It is also linked with reduced need for care services in the medium term and an enhanced sense of security (Netten et al., 2011; Westwood and Daly, 2016).

The hope, in the early 2000's, that ECH would offer a viable alternative to care homes, has not been realized. In a climate of financial austerity, investment in ECH provision is unlikely if decision-makers are focused on short term cost savings, and partners—housing, health, social services, and ECH providers—are not incentivized to work together. It remains to

Care homes for older people

be seen how effective private sector retirement housing schemes are in terms of extending community-based living for older people with complex needs and delaying, or even preventing, care home admission.

Funding and paying for care

The financing of long-term care is a major concern worldwide. In England, there is an historical distinction between ‘nursing care’—paid for by the NHS—and ‘personal care’—means tested and partially or wholly paid for by the individual. This division remains highly contested and a source of widespread confusion and geographical inequity. It is further complicated as a person may be deemed eligible for NHS funding if their needs are regarded as ‘primarily health related’. This distinction is not made in Scotland where, under the Community Care and Health (Scotland) Act 2002, all long-term care is state funded.

Supporting an individual in long-term care is expensive for both the individual and the state. In the UK, the average weekly charge is around £600 per week in residential care, rising to about £840 per week in nursing homes (Laing and Buisson, 2016). The highest rates, are in the southeast of England and the lowest are in the north of England and Wales (Featherstone and Whitham, 2010). The standard rate for NHS-funded nursing care (for residents who need nursing input but do not receive NHS continuing care funding) has recently been increased, in recognition of the complex needs and high levels of dependency of many residents.

Over half of care home residents are self-funded, either in whole or part; most of the rest are fully or partially funded by their local authority, and 7% by the NHS ((Baxter and Glendinning, 2015; Laing and Buisson, 2016). The number of self-funding residents is slowly increasing as larger numbers of older people are home owners, whilst the number of wholly local authority funded residents is decreasing. In 2013–14, local authorities spent £5 billion on care home placements for older people; about a third of their overall spend on adult social care (Health and Social Care Information Centre, 2014).

The number of residents who receive NHS continuing care funding has increased in recent years, from 14,000 older people in 2005 to 43,500 in 2014. This reflects the impact of three factors: the complex health profiles of those admitted to a care home, i.e. more people are deemed to have a ‘primary health care need’; relaxation of the eligibility criteria due to an Ombudsman’s ruling in 2007; and the adversarial activities of middle-aged sons and daughters to ensure their parent is assessed appropriately for NHS funding.

Self-funding

As might be expected, there is a greater proportion of self-funders in affluent areas of England, e.g. 54% in the southern home counties, compared to 16% in Northern Ireland (Bäumker and Netten, 2011). There

Care homes for older people

is also considerable regional variation in top-up fees, in terms both of the proportion of people being charged and the weekly amount paid. Top-up payments range from £25 pw to over £100 pw (Laing and Buisson, 2016). There is concern about when, and in what circumstances, top-ups are required (National Audit Office, 2011). Despite official guidance clearly stating that older people must have a choice of home that is ‘affordable within their budget’, independent investigations have revealed many situations where top-ups have been *expected* rather than *voluntary* (Passingham et al., 2013; Local Government Ombudsman, 2015). Such situations include: pressure placed on families at the point of hospital discharge; care home fees raised so it’s ‘pay up or move out’; and top-ups being demanded by the care home when self-funders run out of money, i.e. they reach the current threshold of £23,250¹ (in England) when they qualify for local authority funding (Ray and Sullivan, 2016).

The Local Government Ombudsman’s (2015) investigation referred to earlier also identified other relevant shortcomings. Local authorities offered inadequate information about care homes in their area to the public, and failed to take responsibility either for setting up top-up fee arrangements or to signpost relatives to independent advice about top-up fees. Care homes often charged top-up fees without notifying the local authority. Older people’s finances were sometimes assessed ahead of any assessment of their needs. Following the investigation, local authorities were told to comply with legislative guidance linked to the Care Act 2014 for England and the Social Services and Well Being Act 2015 for Wales. This includes ensuring that choice of an affordable care home is always offered and that comprehensive, accessible information—including about costs and fees—is provided to anyone who may need to place a relative in a care home.

Self-funders often pay significantly higher fees for similar services and amenities than those funded by the local authority. Self-funders are effectively cross-subsidizing publicly funded residents (Office of Fair Trading, 2005). The size of the gap between the two fee rates has been increasing over the last five years. Local authority negotiated rates are estimated to be at least £104 below the ‘floor level’ costs of keeping an older person in a care home (Laing and Buisson, 2016). Laing and Buisson found that 96% of self-funders paid more than local authorities for the same type of room in the same home, the average level of this premium being 43%. Care homes increasingly rely on this cross-subsidy to generate sufficient income (Forder and Fernandez, 2011; Jarrett, 2017).

Funding for long-term care is increasingly complex and inequitable in the UK and successive governments have failed to address it coherently. This continues to be the case.

Regulation and registration

Care homes for older people

All care homes in the UK have to be registered with the independent regulator of health and social care services. In England this is the Care Quality Commission (CQC). Corresponding agencies in the rest of the UK are: the Care and Social Services Inspectorate Wales, the Social Care and Social Work Improvement Scotland, and the Regulation and Quality Improvement Authority in Northern Ireland.

The regulatory framework in England is discussed here by way of example. Recent years have witnessed several changes of legislation, regulator, regulatory standards, and inspection regimes. The CQC was established in 2009 by the Health and Social Care Act 2008, replacing its predecessor, the Commission for Social Care Inspection. Its responsibilities cover both health and social care services, that is, both hospitals and care homes. It originally aimed to simplify the regulatory regime, with fewer requirements for providers to meet and fewer on-site inspections, especially for providers achieving high standards. The stated aim of these changes was to create a system which was more focused on outcomes, more proportionate to risk, less burdensome, and less expensive to operate.

From 2010, the CQC used a set of Essential Standards. However, these were abandoned following two high profile abuse scandals: Winterbourne View—a private hospital for people with learning disabilities where widespread abuse was exposed—and the Mid Staffordshire NHS Foundation Trust—where 1200 unnecessary deaths occurred amidst evidence of poor care for vulnerable elderly patients (Francis Report, 2013). The CQC was heavily criticized for failing to prevent or respond appropriately to these scandals. Sir Robert Francis QC (who chaired the inquiry into the Mid Staffordshire NHS Trust scandal) regarded the Essential Standards as part of the problem; describing them as ‘over bureaucratic and failing to separate clearly what is absolutely essential from what is merely desirable’ (Francis, 2013). This led to the replacement of the Essential Standards with a set of Fundamental Standards in October of 2014 (Box 26.1).

Box 26.1 Care Quality Commission Fundamental Standards

The fundamental standards are the standards below which care must never fall:

- Person-centred care
- Dignity and respect
- Consent
- Safety
- Safeguarding from abuse
- Food and drink

Care homes for older people

- Premises and equipment
- Complaints
- Good governance
- Staffing
- Fit and proper staff
- Duty of candour
- Display of [CQC] ratings

The CQC also revised its soft touch ‘hands off’ approach to inspection, and now seeks to visit *every service* at least once a year with a particular focus on those that present the highest risk. There are also stronger enforcement powers; directors of care companies have become more accountable for service failures; the director of a care company needs to be a ‘fit and proper person’; and there is more emphasis on good governance. However, it continues to be the case that there are no prescriptive standards on room size or staffing ratios.

Sanctions for poor performance include embargoes on local authority placements and, in extreme cases, regulators can close a service down. If care homes fail to achieve the standards required of them, they may be subject to enforcement powers by the regulator. Potential actions include:

- Using requirement notices or warning notices to set out what improvements the care provider must make and by when;
- Making changes to a care provider’s registration to limit what they may do, for example, by imposing conditions for a given time;
- Placing a provider in special measures, where they are closely supervised to help them improve within set timescales; and
- Issuing cautions or fines or prosecuting the provider where people are harmed or placed in danger (CQC, 2015).

In 2014/15, inspectors successfully prosecuted five care home providers and another 1000 had enforcement action taken against them (CQC, 2015). In 2016, the CQC also identified 37% of care homes as ‘failing on safety’ (CQC, 2016).

The CQC produces ratings of homes on a scale from outstanding to inadequate. In 2017, only 50% were rated good or outstanding with only a handful being in the latter category. On average, for-profit homes performed less well than not-for-profit or public sector homes; and independently owned for-profit homes performed better than for-profit group-owned homes. Smaller care homes (one to ten beds) received higher quality care ratings than medium or large care homes (CQC, 2017). Overall, people received poorer quality care in nursing homes; for example, in 2016, 4% of nursing homes were judged inadequate,

Care homes for older people

compared with 2% of residential homes, and 37% of nursing homes were rated as 'requiring improvement', compared with 24% of residential care homes. Homes that catered for people with dementia were little different from those which did not (48% vs 50% rated as 'good' or 'outstanding') (CQC, 2016).

In addition to monitoring standards of quality and safety, the CQC is also responsible for assessing the financial health of adult social care providers (DH, 2016). In 2017, the CQC described social care services as 'at full stretch', and also warned that budgetary constraints—and expectations created by the Care Act—would make it challenging for providers to balance good quality of care and financial viability (CQC, 2017). Considering these pressures, the CQC noted that most care homes perform well. The costs of operating a care home are rising because of the need for a higher resident/staff ratio to care for residents with higher levels of dependency, the National Living Wage, and the increased costs of fuel, food, and other commodities.

Consumer satisfaction

Alongside ratings by external regulatory agencies, evidence from older residents themselves and their families makes an important contribution to the evaluation of care (Ray and Sullivan, 2016). Various types of survey can be undertaken, though the simplest are very short patient-related outcome and experience measures, such as the R-outcomes, howRu, and howRwe (Benson et al., 2010).

Evidence suggests that the majority of publicly funded care home residents are 'satisfied' or 'very satisfied' with their care; but no data are available on self-funders (NHS Digital, 2015). A survey looking of the experiences of care home residents reported that most felt they had more control over their lives in the care home than they had expected; their quality of life had improved compared with when they moved in; their health needs were better met than before; they were socializing as much or more than they used to; they saw their friends and relatives as much or more than they used to; and their experience of being in a care home was 'good' (Darton, 2011).

Studies of relatives of people in care homes reveal some perennial areas of dissatisfaction: the laundry services, smell, and cleaning regimes are frequent areas of concern. Communication is also an issue, particularly when the home does not keep relatives informed and when the phone is left unanswered (Ray and Sullivan, 2016). What matters to relatives is the quality of personal care and the quality of the home's management, including supervision of staff. A key worker system is regarded as important, too. For relatives, the most important issue regarding the physical environment is the accessibility of the home to wheelchair and walking aid users. Relatives also expect to be kept informed and value the

Care homes for older people

opportunity to make comments about the home, care standards, staff, and other services (Ray and Sullivan, 2016).

A recent report (Healthwatch, 2017) based on interviews with residents, relatives, and staff at 197 care homes found that most care was fairly good. They identified several key themes:

- Quality of care varies between homes but also within the same home, with too few homes getting 'the basics' right;
- Good care homes meet all residents' health and care needs, working seamlessly with other services when residents need additional support;
- The best residential services are those that focus on enabling people to continue living as if they were still in their own homes.

Thus, the key to delivering care that responds to an individual's needs is continually to seek and act on the views of residents. This is essential to making a care home feel like an actual home.

Care home workforce

As mentioned previously, care homes constitute a substantial sector of the health and social care economy. There were around 305,000 staff employed in residential homes and 290,000 in nursing homes in England in 2017 (includes all care homes for adults, not just older people) (Skills for Care, 2017). About two-thirds are front-line staff; the rest are managers, domestic staff, administrative staff, and workers in ancillary roles, e.g. maintenance (Skills for Care, 2017).

Over half are employed on a full-time basis; just under 10% are on zero-hour contracts. In nursing homes, a higher number of staff work in a 'regulated profession', predominantly nursing (Skills for Care, 2017). Staff turnover is high, with numbers showing over a quarter of staff in 2016/17. Turnover of qualified nurses was especially high at 32%. The overall vacancy rate was 8.4%; consequently, care homes often rely on agency staff who cost two to three times as much as employees (Jarrett, 2017). Turnover and vacancy rates vary across the country; London and southeast England have particular difficulties. There is a serious shortage of care home managers: a limited cadre of skilled, experienced, and competent staff willing to take on the complex and challenging role of running a care home (Hussein and Manthorpe, 2005). The manager is often the single individual upon whom operators depend to deliver profitable services of an adequate quality.

The number of jobs in care homes has increased between 2009 and 2016, although the overall number of homes has decreased. This suggests a consolidation in the sector whereby a similar amount of care is being delivered at fewer locations, but also staffing ratios have increased in response to increased dependency levels of residents (Skills for Care, 2017). Care homes are only legally required to provide sufficient numbers

Care homes for older people

of 'suitably trained and capable staff' to meet the needs of their residents and no ratio is specified in official guidance.

The care home sector relies heavily on low-paid staff, usually women employed part-time and paid by the hour. In 2017, 83% of the care home workforce was female (Skills for Care, 2017). Care staff are often paid close to the National Living Wage (NLW). Staffing costs can be expected to rise more rapidly in the future driven by regulation, the NLW, and the strengthening economy.

Care homes are often dependent on migrant staff, particularly in areas with staff shortages, e.g. London and the South-East (Lievesley et al., 2011). In 2014, 150,000 migrant care workers were estimated to work in care homes in England (Franklin and Brancati, 2015). Compared with their UK counterparts, migrant care workers tend to be younger and more highly skilled and qualified. Migrant workers predominantly come to the UK from India, Poland, the Philippines, Romania, and Nigeria. Potential changes to immigration policy resulting from the UK leaving the European Union could have serious consequences for the care home workforce (Franklin and Brancati, 2015).

Training for care home staff is an important issue and is discussed in the section on Training later in this chapter.

People who live in care homes

The care home population

As mentioned in the first section, there are over 400,000 older people residing in UK care homes (Laing and Buisson, 2016), which represents 4% of the population aged 65 years and older (Comas-Herrera, et al., 2011). Although the proportion of older people living in a care home at any one time is relatively small, the *lifetime* risk of needing residential care is considerable—probably about one person in five will live in a care home towards the end of their life.

As might be expected, the chance of being admitted to a home increases with age: for the age group 65–74, 0.6% of the population resides in care homes, compared with 16.7% of those aged 85 and older (Laing and Buisson, 2016). The majority of care home residents are women aged 85 years or over: most have multiple health problems, have previously lived alone, are single, widowed, or divorced, and are poor or dependent solely on benefits (Bharucha et al., 2004; Milne, 2016). Factors that protect against admission are: availability of family and formal support, adequate income, home ownership, and living in a housing environment that is adapted to accommodate disability (Denning and Milne, 2011; Milne, 2016; Westwood and Daley, 2016).

Although the UK is in a period of accelerated population ageing, with the 85+ age group expanding more rapidly than ever before, fewer older people were admitted to care homes in 2015 than in 2005 (Humphries et

Care homes for older people

al., 2016). The proportion of male residents has increased in recent years: in 2011 there were around 2.8 female residents for each male resident, compared to a ratio of 3.3 female to male in 2001. Also, the care home population is getting older; in 2011 people aged 85 and older represented 59.2% of all residents, compared to 56.5% in 2001 (Office for National Statistics, 2014).

Older people are likely to move into a care home at a later stage in their life-course and illness trajectory than they did in the past. This pattern is influenced by several factors: personal preference of the older person to remain in their own home, a widely held negative perception of care homes as the place of 'last resort', policy emphasis on family- and community-based care, and, more recently, cuts to social care budgets (Demos, 2014). At the point of admission, residents often have complex comorbid conditions and unpredictable clinical trajectories (Forder and Caiels, 2011; Quince, 2013). Residents have become markedly more dependent over time (Lievesley et al., 2011). It has been estimated that 80% of care home residents have dementia and/or a hearing impairment, are in receipt of seven or more medications, and a significant proportion live with depression, mobility problems, pain, and/or incontinence (Cohen-Mansfield and Taylor, 2004; Laing and Buisson, 2016).

Census data from 2011 suggest that about 17,000 ethnic minority older people reside in care home in England and Wales (Office of National Statistics, 2011; Centre for Policy on Ageing, 2013). Factors within black and minority ethnic (BME) communities that may lower the rate of care home admission include: later diagnosis of dementia and/or other mental health problems due (in part) to high levels of stigma linked to mental illness; limited or no language to describe dementia; and reluctance to seek help from 'mental health' services (Milne and Smith, 2015). In general, BME residents are more likely to be male, have higher rates of dementia and incontinence, and are more dependent on admission than their white counterparts (Milne and Smith, 2015). It is important to acknowledge that 'race' and ethnicity' are contested terms and that the ethnic profile of the UK's 'minority groups' is increasingly diverse. There are growing numbers of more recently settled older people from Eastern Europe, Russia, Italy, Greece, and France, as well as those from more established populations, including South Asia and the West Indies.

Residents' health

Frailty

Frailty is a distinctive health state related to the ageing process in which multiple body systems gradually lose their in-built reserves (Turner and Clegg, 2014). Frailty is strongly related to age: up to half of all people aged 85 and older have frailty, compared to about 10% of those aged 65 and older. Older people with frailty are at risk of unpredictable deterioration in their health resulting from minor stressor events. In turn,

Care homes for older people

this leads to increased risk of falls, disability, long-term care, and death (Clegg et al., 2013).

Frailty was traditionally used in a loose and potentially pejorative way to refer to older people with all kinds of chronic health condition. Over the last two decades, the term has become more sharply defined in terms of physiological reserve and resilience. There are two main contrasting approaches to defining frailty, known as the phenotype and cumulative deficit models. Fried and colleagues (2001) defined frailty as a phenotype characterized by unintentional weight loss (ten pounds in past year), self-reported exhaustion, weakness (grip strength), slow walking speed, and low physical activity. The frailty phenotype, having three or more of these features, was an independent predictor of several adverse outcomes, ranging from falls to death. This led the authors to suggest that frailty was distinct from comorbidity (which acted as a risk factor for frailty) and disability (which arose as a consequence). In contrast, Rockwood and colleagues (2005) developed a model based on the burden created by accumulating deficits (*symptoms*, e.g. tremor and hearing loss, and *disorders*, e.g. arthritis or dementia), from which a Frailty Index was derived.

The two models have reasonable, but not perfect, agreement (Rockwood et al., 2007), and there are a number of differences between how they operate and their clinical utility (Cesari et al., 2014). The phenotype model is based strongly on physical characteristics, especially muscle strength and locomotor activity, so it does not take into account other types of impairment, most importantly cognitive impairment. It adopts a categorical approach to frailty—people are frail, pre-frail, or robust. Its advocates emphasize the consistency of the frailty syndrome and how its five components have a cyclical relationship, meaning that the process can start at any point, e.g. weight loss leading to sarcopenia, or muscle weakness leading to loss of activity, etc. (Xue, 2011).

In contrast, the cumulative deficits model is more flexible as it can take into account any type of pathology or impairment. It regards disability as a contributor to frailty, not as its consequence. The Frailty Index is a continuous variable and it is more sensitive to change over time than the phenotype criteria. The features of each model influence when and where they can be used. The phenotype model does not require a preceding clinical assessment, so it is appropriate to use at an early stage or to assess people who may be at risk. Also, it does not provide information as to the underlying cause of its features. The Frailty Index, in contrast, requires a full clinical assessment, ideally a comprehensive geriatric assessment (CGA). It can be cumbersome as the full checklist includes around 70 items. Once a score has been derived, though, it can be repeated over time for monitoring purposes.

Not surprisingly, there have been attempts to resolve the differences between these approaches or improve the shortcomings of each. These have included trying to unify them into a common scale or developing

Care homes for older people

new scales that may have elements of each. In a comparative review, Dent and colleagues (2016) found more than 13 scales to include. As cognitive impairment and dementia are strongly associated with frailty, it has been suggested that cognitive impairment should be regarded as integral to the frailty syndrome (Avila-Funes et al., 2009; Kulmala et al., 2014).

Shorter and more convenient methods for assessing frailty are needed, particularly for use in primary care, where CGA is not readily available (Clegg et al., 2013). Numerous briefer tools have been developed to screen for frailty in in-patient settings (see Warnier et al., 2016 for a review). Brief tools are relatively sensitive but tend to lack specificity (Clegg et al., 2015). The Clinical Frailty Scale (Rockwood et al., 2005, see Fig. 11.1 in Chapter 11) is a seven-point scale derived from the Frailty Index, and it was used in the Canadian Study of Health and Aging. The British Geriatrics Society has produced recommendations for simple means to detect frailty in community and outpatient settings (Turner and Clegg, 2014). These emphasize that any contacts between health staff and older people present an opportunity. Indications of frailty from a basic assessment include: a gait speed <0.8 metres per second; a timed-up-and-go test >10 seconds; and a score of ≥ 3 on the PRISMA 7 questionnaire (Raïche et al., 2008). In addition, the common clinical presentations of frailty (falls, delirium, sudden immobility, and non-specific symptoms like fatigue) can also be used to indicate the possible presence of frailty.

Interventions that have been studied to improve or prevent frailty include exercise, nutrition, pharmacological approaches, and CGA (Clegg et al., 2013). Several systematic reviews (e.g. de Labra et al., 2015) have found modest benefits for exercise, especially for multicomponent interventions and resistance training, though the nature of the ideal programme is still unclear. CGA, including medication review, can be beneficial as it addresses each of the conditions that may be contributing to disability. Prescribed drug side effects may include sedation, loss of appetite, postural hypotension, or effects on muscle function, any of which can contribute to the frailty syndrome. Evidence that nutritional interventions improve frailty is currently lacking.

Frailty is obviously an issue in care homes. Reported prevalences of frailty in care home residents vary wildly, from 19 to 76% in one review (Kojima, 2015), which suggests marked differences in methodologies between studies. There are a number of approaches to assessing frailty in care settings. Some of these rely on the Minimum Data Set (MDS) as mandated in North America, for example the MDS-CHESS scale (Hirdes et al., 2003), which is a composite measure addressing Changes in Health, End-stage disease, and Symptoms and Signs of medical problems. It has been found to be a strong predictor of mortality, independent of other variables such as age, sex, cognition, and do-not-resuscitate orders. Clegg and colleagues (2016) developed an electronic frailty index that can be derived from routine primary care data, though its use is probably intended mainly for people living in their own homes. Another approach is

Care homes for older people

the FRAIL-NH screening tool (Fatigue, Resistance, Ambulation, Incontinence, Loss of weight, Nutritional approach, and Help with dressing) (Kaehr et al., 2016). Each item is scored 0, 1, or 2, according to increasing deficit, apart from weight loss which is either 0 or 1, thus giving a total score out of 13. In comparison to the Frailty Index, both were significant predictors of falls and mortality, with the FRAIL-NH obviously being quicker to complete (Theou et al., 2016) and most of the required information is routinely recorded within the MDS (Luo et al., 2015). A third method is to use a measure derived from commonly used laboratory blood results combined with blood pressure measurements to construct an objective index of frailty (FI-LAB) (Rockwood et al., 2015), which was highly correlated with a clinically derived frailty measure and also a strong predictor of mortality.

It remains unclear as to what benefits might be expected by residents once they are identified as having frailty as opposed to assuming that all residents are either frail or at risk of becoming so. However, as frailty is a risk factor for other problems such as falls and delirium, it seems sensible to make them a priority for any exercise or other interventions. Frailty is not necessarily associated with lower self-rated quality of life among care home residents, either before or after adjusting for other variables, including health-related ones (Fougère et al., 2016). Siddiqi and colleagues (2016) completed a feasibility trial of an intervention (Stop Delirium!) to prevent delirium and had encouraging results even though the trial was not designed or powered to look for differences between treatment groups. Walker and colleagues (2016) reported similar results from a falls intervention feasibility trial; however, it is clear that full commitment from care home managers is required for trials to recruit to plan. Clearly in both areas, definitive trials are needed. It is also worth noting that frailty may be a barrier to the success of other types of intervention, e.g. Ellard and colleagues (2014) found that a high proportion of residents were unable to participate in a trial of exercise to combat depression, and this was a large factor in the negative result of the trial. Any intervention needs to consider carefully what residents may and may not be capable of doing.

Dementia

The prevalence of dementia in care homes is high and probably has increased in recent years. For example, Matthews and Denning (2002) reported a prevalence of 62% from data obtained in 1991–93 but Gordon and colleagues (2014) found that of a sample of 291 residents in 16 homes, 75% had a Mini Mental State Examination (MMSE) score of 22 or lower (though only 62% actually had a diagnosis of dementia). Quince (2013) considered that 80% was a reasonable estimate based on recent research. The prevalence of dementia is fairly consistent across different types of care home, though Gordon found that nursing home residents had a slightly lower mean MMSE than those in residential homes. Alongside frailty, therefore, dementia care is undoubtedly one of the principal functions of long-term care for older people: in total, there must

Care homes for older people

be nearly 250,000 residents with dementia in UK care homes. With the cost of care home residents at around £800 per week (Romeo et al., 2016)—almost all due to care home fees—this means that care home provision is worth around £10 billion per annum.

The presence of dementia is not always diagnosed (e.g. Cheng et al., 2012). There may be various reasons for not detecting and/or not diagnosing dementia. These may include comorbidity, where the dementia can be overlooked by the severity of other conditions; insidious onset of dementia over the time the person lives in the care home; or staff attitudes towards dementia (Macdonald and Woods, 2005). Nonetheless, care home residents with dementia known to mental health services are about twice as likely to have dementia recorded on their death certificates (Perera et al., 2016), which probably reflects an increased importance of recording the diagnosis. Family carers quite often appear to be unaware that their relative has dementia, especially if they have been in the care home for a longer period (Penders et al., 2015). Helping relatives to realize that dementia is a condition that causes death has been shown to contribute to better patient comfort at the end of life (van der Steen et al., 2013), so communication with families about dementia is clearly of practical significance (see also Hennings et al., 2013).

Many residents with dementia have behaviour disturbances (or behavioural and psychological symptoms of dementia; BPSD), especially activity disturbances (agitation), aggression, psychosis, and depressed mood. The median reported prevalence of such behaviour problems in a systematic review was 78% (Seitz et al., 2010). Perhaps of particular concern are self-harming behaviours, which may be active, such as scratching oneself or punching objects (de Jonghe-Rouleau et al., 2005), or passive, e.g. refusal to take food or drink (Draper et al., 2003). Overall, behaviour problems such as agitation and aggression are commoner in severe dementia and tend to persist, as does apathy, whereas affective symptoms such as depression resolve, become less marked, or are simply not recognized (Selbaek et al., 2014; Wetzels et al., 2010). The relationship between dementia severity and types of BPSD is not straightforward. The underlying mechanisms and predictive factors are incompletely understood (Serra et al., 2010; Proitsi et al., 2011) in terms of how they relate directly to neurodegeneration or to what extent they should be viewed as attempts at communication.

Subjective quality of life is not necessarily impaired by the progression of dementia in a care home. Self-ratings of quality of life are usually higher than those made by staff (Gräske et al., 2012); such ratings are affected by depression (Hoe et al., 2006, 2009); and they do not necessarily decline on admission or over time (Moyle and O'Dwyer, 2012). Similarly, evidence suggests that care home admission does not hasten health-related decline or death. In a multivariate analysis, adjusted for other variables such as dementia severity, residing in a care home did not significantly affect survival (Xie et al., 2008). Indeed, as a consequence of identifying and treating hitherto unknown medical conditions and good

Care homes for older people

nutrition, the overall health of some demented residents may improve. Furthermore, while some people with dementia are physically frail, a significant number—who tend to be admitted as a consequence of behavioural problems such as aggression and wandering—are relatively robust. For example, Magaziner and colleagues (2005) found that newly admitted nursing home residents with dementia were more physically fit and had lower rates of mortality than residents without dementia.

As regards interventions for dementia, it is usually recommended that nonpharmacological interventions for behaviour problems in dementia are considered ahead of drug treatments, as they are less likely to have serious side effects. Several reviews have examined the management of challenging behaviour, especially agitation and aggression, in dementia, with some concentrating specifically on care homes (see Livingston et al., 2014; Jutkowitz et al., 2016). Interventions based on providing individualized activities for residents are perhaps the most promising (Travers et al., 2016). The subject is discussed further in Chapter 19 of this book.

There have rightly been concerns about excessive prescribing of psychotropic drugs, especially antipsychotics, to older people with dementia in care homes. Many studies have shown high proportions of residents receiving antipsychotics, usually 25–40%. In a report for the Department of Health in England, Banerjee (2009) analysed existing data to show that approximately 180,000 people with dementia were being prescribed antipsychotics in one year, and this probably resulted in an additional 1,800 deaths and an additional 1,620 cerebrovascular adverse events.

Antipsychotics are only modestly effective in treating behavioural and psychotic symptoms in dementia. Risperidone and olanzapine are effective in reducing aggression and risperidone is effective in reducing psychotic symptoms (Ballard and Waite, 2006), but, because of the high levels of adverse events, they should only be used if there is marked risk or severe distress. Effectiveness appears to be limited in practice, too, as high levels of psychiatric symptoms persist in nursing homes despite treatment. Withdrawing patients from antipsychotics is usually well tolerated and adverse effects on behaviour are less common than might be expected (Declercq et al., 2013) although, in some cases of severe agitation, treatment may need to be recommenced. Although interventions (including educational programmes, medication review, in-reach, and multicomponent interventions) to reduce antipsychotic prescribing appear to be effective in the short term (Thompson-Coon et al., 2014), there are concerns that other types of drug, such as mood stabilizers (Maust et al., 2018) or benzodiazepines (Westbury et al., 2019), may simply be prescribed instead.

Care homes for older people

Depression

There have been numerous studies of the prevalence of depression in care homes. A systematic review by Seitz and colleagues (2011) gave an overall median prevalence for major depression of 10% and depressive symptoms of 29%, and more recent studies have reported similar figures (e.g. Stewart et al., 2014). There is an appreciable incidence of new symptoms, e.g. Boorsma and colleagues (2012) reported incidence rates for DSM-IV depression of 13.6 per 100 person years in Dutch nursing homes and 10.2 per 100 person years in residential care homes. Depression tends to persist, with over 50% of depressed residents remaining so 12 months later (Midlöv et al., 2014). Suicidal thoughts are common (Malfent et al., 2010; Mezuk et al., 2014) but completed suicide among residents is uncommon (Murphy et al., 2015). Residents with higher depression scores also have a higher death rate (Barca et al., 2010).

Several factors have been reported as associated with depression, though these vary between different studies. Functional impairment and dementia both appear to be important independent risk factors. In addition, dysphoric symptoms are associated with other behavioural symptoms, e.g. aggression or verbally disruptive behaviour, in residents with cognitive impairment (Lindbo et al., 2017). Other associations that have been described include physical health variables, e.g. pain, dysphagia, diabetes, and heart disease; psychological variables, e.g. loneliness, neuroticism, and previous history of depression; and social variables, e.g. loss and the institutional environment. Of particular interest are features that should be easily remediable: access to the outdoors (Potter et al., 2017); participation in leisure activities (Ouyang et al., 2015); and using a hearing aid (Boorsma et al., 2012) all appear to have protective effects. Access to the outside environment should be regarded as a human right (Argyle et al., 2017), so it is scandalous that residents so infrequently have access to their homes' gardens.

As there has been more attention paid to depression in care home residents, it does appear that cases are more likely to be diagnosed and to receive treatment (Gaboda et al., 2011), though there is evidence that this is patchy, and homes serving more disadvantaged areas may provide less support for depression, especially to people from minority groups and with low education (Siegel et al., 2012). Possible depression should be considered at the time of admission (Iden et al., 2014). There is concern that care home nurses and other staff may overlook depression, though their rates of detection are in fact comparable to those of medical staff (Mitchell and Kakkadasam, 2011). Watson and colleagues (2009) compared available screening methods and found that a two-item scale, the PHQ-2 (Kroenke et al., 2003), performed best against a gold standard psychiatric interview, with a sensitivity of 0.80 and a specificity of 0.71. The Cornell Scale for Depression in Dementia is frequently used to assess for depression, but Jeon and colleagues (2015) found that in practice it had low diagnostic accuracy as nursing staff often did not have the time

Care homes for older people

or relevant information to complete it accurately. The usefulness of the Geriatric Depression Scale is limited by the fact that it is self-completed and therefore not suitable for residents with significant cognitive impairment (Li et al., 2015). Koopmans and colleagues (2010) proposed a two-stage comprehensive assessment, first looking for associated factors and then looking to make a formal diagnosis of depression.

In treating depression, mixed approaches involving antidepressants and psychosocial interventions, often with a stepped care approach, seem most effective (e.g. Llewellyn-Jones et al., 1999; Leontjevas et al., 2013; Bosmans et al., 2014). Some single psychosocial interventions have been ineffective, e.g. guided self-care (Dozeman et al., 2011), and group exercise (Underwood et al., 2013). The main failing of these projects is most likely that many residents are too impaired to make use of the intervention (Ellard et al., 2014). A systematic review by Boyce and colleagues (2012) suggested that antidepressants may have modest effectiveness in treating depressed care home residents, though the quality of the included studies was often poor. There are concerns about antidepressant prescribing, for example, that residents who may benefit are not offered treatment (Dalby et al., 2008), or conversely, that antidepressants are prescribed for no documented indication (Harris et al., 2012). Rates of antidepressant prescribing for over 40% of residents have been reported (e.g. Westbury et al., 2019) even though evidence for the efficacy of antidepressant treatment in dementia is weak (Dudas et al., 2018).

In summary, depression remains a significant problem for care home residents. There is evidence that awareness and recognition of depression have improved, though the situation is still not ideal. Further progress will require improved detection and increased awareness of the importance of depression among care home staff (Dow et al., 2011). More research is needed to evaluate interventions that appear promising, and longitudinal studies of the incidence, persistence, and outcomes of depression are also needed.

Other mental health problems

Although dementia and depression are the commonest mental health problems in care home populations, other disorders may be present too (sleep disorders are discussed in Chapter 48). Anxiety symptoms are also common, though their severity varies, and anxiety may be symptomatic of other disorders, such as depression or physical illness. In a review of 18 studies, Creighton and colleagues (2016) found reported prevalence rates for anxiety disorders at 3–20%, though the higher quality studies were around 6%. However, this group's own study (Creighton et al., 2017b) reported a prevalence of 19% for anxiety disorders plus 12% for subthreshold disorders. Anxiety disorders are most strongly associated with health-related variables, notably depression, stroke, poor vision, pain, and lower quality of life (Smalbrugge et al., 2005; Creighton et al., 2017a). There is a lack of high-quality treatment studies for anxiety

Care homes for older people

disorders. One study found that a stepped care approach that was effective for preventing depression did not help to prevent anxiety (Dozeman et al., 2012). Chapter 42 discusses anxiety disorders in more detail.

Although the numbers of older people with severe long-term mental illnesses, such as schizophrenia and bipolar disorder, has risen in many developed countries (see Chapter 45), they experience worse health than others people of comparable age. For example, they have higher rates of several medical disorders (notably cardiac failure and chronic pulmonary disease) and higher rates of healthcare utilization (Hendrie et al., 2013, 2014). Middle-aged and older people with schizophrenia are much more likely to move into residential and nursing home care at an earlier age than people without previous mental illness. For example, Andrews and colleagues (2009) found that rates of nursing home admission were about four times higher. This may have to do with the loss or burnout of family carers, often ageing parents, as well as decline in the person's own health and functioning. Cognitive impairment and behaviour are important predictors of nursing home as opposed to community residence. Among older patients with schizophrenia (age range 40–97), residence in assisted living facilities was also associated with never having been married, presence of cognitive impairment, and poorer quality of wellbeing (Auslander et al., 2001). Such patients often fit poorly into conventional nursing home environments, so other models of care, e.g. separate units or supported community living, may be preferable (Bartels et al., 2003). Depla and colleagues (2003) favoured a model that deployed psychiatric staff to work with care home staff, rather than having a psychiatric unit within the home or the home itself employing its own psychiatrically trained staff.

Substance misuse remains a neglected area in relation to care homes, with almost no published research in the last decade. Clearly there is some residential provision for people with alcohol and substance misuse problems, but most of these residents are not elderly. Most of what little research there is comes from Veterans Administration (VA) homes in the US, where substance misuse disorders appear to be an independent risk factor for admission (Lemke and Schaefer, 2010). Almost half of VA residents had a lifetime history of significant heavy drinking (abuse or dependence) (Joseph et al., 1995). These residents tend to be younger, male, and more likely to be of Afro-American origin, with more psychiatric comorbidity, though more independent with activities of daily living than other residents (Brennan and Greenbaum, 2005). This distinct profile leads to challenges in providing care, but also perhaps offers some potential for rehabilitation. Elsewhere, a study of over 300 residents in northern France (Leurs et al., 2010) found that two-thirds of residents drank alcohol on a daily basis and nearly 20% were heavy drinkers. Apart from these glimpses, we have very little picture of how older people with histories of substance misuse fare in care homes. Doubtless, significant quantities of alcohol are consumed, some of it covertly, and the next

Care homes for older people

generation of care home residents will include significant numbers of people who have used recreational drugs for much of their lives.

Older people with intellectual disabilities (ID) have particular residential needs (Ward, 2012). The move of a person with ID into residential care is often a result of a social change, such as the death of a parent, rather than a change in the needs of the person him/herself. This may be associated with the double impact of a bereavement as well as loss of previous familiar surroundings. People with ID may be placed in residential care for older people at a relatively young age, which may also cause problems for them in terms of social isolation (Winkler et al., 2006) and other residents who may not understand or tolerate their needs or behaviour (Wilkinson et al., 2004). Furthermore, the staff group may be unskilled in meeting their needs. Improving the lives of older people with ID who are placed in mainstream older people's care homes requires action on several fronts. These include: ensuring that services for people with ID are better equipped to meet age-related needs; preventing people from entering older people's services that are unable to offer them an appropriate level of care and quality of life; and reviewing the appropriateness and quality of placements of all people with ID in residential and nursing homes for older people (Thompson et al., 2004).

Physical health of care home residents

Comorbidity

As already discussed, care home residents are a frail group, with high levels of physical and mental health conditions. Comorbidity is not synonymous with frailty, although the two terms overlap, since comorbidity can exist in the absence of frailty. Physical conditions, with impaired mobility seeming to be especially important, are among the most important predictors of admission to care homes (along with dementia and widowhood) (Hajek et al., 2015).

Among residents, chronic illnesses and disabilities are common, frequently with evidence of unmet need or inadequate care. Cohort studies of residents consistently describe multiple physical conditions often coexisting with mental health problems, notably depression and dementia. For example, in a survey of 16,000 residents, Bowman and colleagues (2004) found that 78% had at least one form of mental impairment, 71% were incontinent, and 76% needed help with mobility or were immobile; overall, 27% were immobile, confused, *and* incontinent. Gordon and colleagues (2014) reported a sample of over 200 residents who had a mean number of 6.2 diagnosed conditions alongside considerable cognitive and functional impairment, and were being prescribed an average of eight prescriptions each.

There have been efforts to improve the management of long-term conditions such as diabetes, helped by national guidelines such as those issued by Diabetes UK (Sinclair et al., 2011). Consequently, aspects of

Care homes for older people

diabetic monitoring and access to services like chiropody have improved, though with some inconsistencies and definite scope to involve residents more in their own care (Yarnall et al., 2012). Cancer is also common in nursing homes. For example, almost all residents have some kind of skin lesion (Deo et al., 2015) and these include skin cancers (mainly basal cell and squamous cell carcinomas) in around one-third of residents. People living with cancer in care homes often report feelings of loneliness and loss (Drageset et al., 2015), and there is evidence that cancer pain is under-recognized and under-treated in care homes (Drageset et al., 2014). There is thus plenty of scope to improve recognition of cancer, though screening for asymptomatic cancer is not warranted (Rodin, 2017), as well as providing social support, activity, and adequate pain relief.

However, there are opportunities for improving health care for older people when they move into a care home. There should be a thorough assessment of their needs, as they will often now be registered with a new GP, which provides the chance to reappraise any long-term conditions and any treatment. This should include a review of medication, aiming to simplify it where possible. It is also important to communicate realistically with residents and their families about their expectations concerning the medical care of the older person, in particular about whether resuscitation or hospital admission are appropriate or not should an emergency arise. The physical examination of frail older people is discussed in Chapter 11. The next few sections discuss some of the more important issues, but are not intended to be fully comprehensive.

Sensory impairment

The impact of hearing loss upon cognition and dementia has been the subject of much recent attention, with studies indicating that hearing loss is a risk factor for cognitive decline and incident dementia (e.g. Lin et al., 2013). In a review, Livingston and colleagues (2017) found that hearing loss from middle age onwards almost doubled the risk of developing dementia and suggested that hearing loss contributes 9% of the population attributable factor for developing dementia (i.e. the percentage reduction in new cases that would result if the risk were eliminated). The nature of the mechanism is unclear but it is likely that a combination of factors is at work, which could include shared (presumably vascular) pathology, increased cognitive load if unable to hear properly, or social disengagement as a consequence. It remains unclear if hearing-related interventions in mid-life or later can reduce the impact upon cognition. By the time dementia has been developed, the opportunity may have been lost: for example, Allen and colleagues (2003) found that fitting hearing aids improved global ratings, but did not improve other specific outcomes, e.g. cognition, behaviour, or psychiatric symptoms.

Care homes for older people

Given the advanced age of many care home residents, it is not surprising that the majority of residents have at least some degree of hearing loss. In the UK, this equates to at least 250,000 residents with hearing loss (Echalier, 2012). Additionally, many of these will also be living with frailty, dementia, and other health problems. Hearing loss leads to a diminished ability to communicate, which can lead to depression (Brink and Stones, 2007), feelings of being unable to connect with other people, and loss of control over the person's own life (Roets-Merken et al., 2017). Hearing loss is also associated with higher levels of behaviour problems (Hall and O'Connor, 2004; Yamada et al., 2014). Furthermore, noisy environments within care homes can exacerbate communication difficulties, especially at mealtimes or during group activities (Pryce and Gooberman-Hill, 2012).

Impairment of hearing may be easily overlooked as staff may lack knowledge and confidence about hearing problems (Solheim et al., 2016) or simply don't think they are worth doing anything about. Care assistants may find it difficult to distinguish between hearing loss and dementia as causes of impaired communication, though this improves if they know the individual residents well (Slaughter et al., 2014). Hearing assessments may need to be modified as most residents are unable to complete usual test procedures (Burkhalter et al., 2009), though screening should be possible nonetheless (Jupiter, 2012). It is important to check for the presence of impacted cerumen as this is commonly found and its removal often leads not only to improvements in hearing but also modest improvement of cognition (Moore et al., 2002).

Managing hearing loss in care homes can be challenging, for example, difficulties with residents using hearing aids because they fit poorly, don't work properly, batteries run out, and residents can't handle them, with many (86%) needing help (Cohen-Mansfield and Taylor, 2004). However, simply screening and providing hearing aids does not appear to be cost effective as the uptake is relatively poor (Linssen et al., 2013). What seems more effective is working with staff on aspects of care, for example, with the goal of increasing resident autonomy (Roets-Merken et al., 2016), but more work is needed to provide evidence of best practice (Denning et al., 2017). Echalier (2012) identified three areas for action: i) intervene earlier in hearing loss; ii) meet communication needs in care homes through staff training and a regulatory focus on communication; and iii) improve hearing aid use and management. A more recent realist review of hearing-related communication by Crosbie and colleagues (2019) highlighted five interlinked areas: i) leadership promoting positive regard and empathy through person-centred care; ii) communication training for staff; iii) 'knowing the person' and relationship building for responsive awareness of residents' hearing needs; iv) maintaining and monitoring hearing communication through care planning, including appropriate use of hearing aids; and v) managing noise in the care home environment. All of these, however, required a sense of permission from

Care homes for older people

the care home leaders to enable staff to be knowledgeable and feeling empowered to provide good care.

Visual impairment has perhaps attracted less research than hearing impairment (for a review, see Banks and Ward, 2017) but it is evident that visual loss is present in half or more of care home residents (Lamoureux et al., 2009; Thederan et al., 2016). The nature of the problem is often unrecorded and care staff frequently appear to be unaware even of its existence (Jensen and Tubæk, 2017). Visual loss has numerous effects on a person, including disorientation, falls, potential isolation, depression, and reduced quality of life (Banks and Ward, 2017; Ward and Banks, 2017). Uptake of potential treatment, such as spectacles or cataract extraction, appears to be poor unless there are specific initiatives (e.g. Friedman et al., 2005; Marmamula et al., 2013). Again, there is a lack of evidence as to whether potential interventions are effective and, if so, what these should be. It is probable, however, that working with staff to improve their understanding and communication will turn out to be more effective than simply providing equipment or treatments.

Dual sensory impairment affecting both vision and hearing is also common, presenting in about one-third of care home residents (Yamada et al., 2014). As might be expected, it has profound consequences, e.g. being associated with depression (Guthrie et al., 2016), more behaviour problems (Yamada et al., 2015), more rapid cognitive decline (Yamada et al., 2016a), and increased mortality (Yamada et al., 2016b), especially if the impairment has led to reduced participation in activities.

Pain

Pain is common, especially from arthritis and pressure areas. Numerous studies report that half or more of care home residents have been identified as experiencing one or more painful conditions (e.g. Barry et al., 2015; Björk et al., 2016; Takai et al., 2013). Pain is associated with low mood and reduced participation in activities (Lapane et al., 2012), and with agitation and aggressive behaviour (Ahn and Horgas, 2013). Residents with dementia less frequently indicate that they are in pain and thus are sometimes not offered analgesia as frequently as those without impaired communication (Monroe et al., 2014), though this is not always the case (Tan et al., 2016). It has often been reported that pain is undertreated, but some recent studies have shown high levels of analgesic prescribing (Tan et al., 2016; Veal et al., 2014), though this is no guarantee that treatment is being administered effectively. Improved pain management may benefit the health and quality of life of residents with dementia (Husebo et al., 2011) but there is still room for improvement, which requires a more consistent approach, with standard guidelines and wider use of pain rating scales, including those with nonverbal items (such as facial expression) that can be used for patients with language impairment (for a review, see Husebo et al., 2016).

Care homes for older people

Mobility and falls

Mobility problems are common in the care home population. Most residents have some limitation of mobility with a significant number being totally immobile. Immobility is associated with multiple other problems, such as incontinence, falls, and pressure ulcers (Lahmann et al., 2015).

The incidence of falls is high, and figures of around 10% in a year have been reported (Quigley et al., 2012), of which at least 20% have serious consequences, e.g. hip fractures, intracranial, and facial injuries. Risk factors for falls in care homes are similar to those in other settings and include impaired mobility, poor physical health, disinhibited behaviour, and medication, including antihypertensives and psychotropic drugs (Kosse et al., 2015; Kröpelin et al., 2013).

There have now been numerous trials and several systematic reviews of falls prevention programmes (Cameron et al., 2012; Choi and Hector, 2012; Lee and Kim, 2017; Vlaeyen et al., 2015). These have slightly varying interpretations but there is some consensus for multicomponent interventions that involve exercise, reducing falls in recurrent fallers. However, the best results have come from programmes that involved external input, so sustaining improvements is challenging and so far, attempts to train care staff to deliver programmes have been ineffective (Colón-Emeric et al., 2017). One criticism is that existing programmes have not involved residents sufficiently in their design and implementation (Meyer et al., 2016).

Nutrition

Concern is often expressed about poor standards of nutrition in care homes. Food may be poorly presented or unappetizing, the environment may be uncongenial, special diets (for religious observance or medical conditions) may be unavailable, and residents often have conditions, such as dysphagia or xerostomia (dry mouth), that may affect their ability to feed themselves or to swallow their food. Numerous studies have documented poor oral health among residents, with lack of teeth; high rates of decay; active symptoms, such as dental pain; and inability to clean their own teeth (e.g. Gaszynska et al., 2014; Karki et al., 2015). Overall, up to half of all care residents may have or be at risk of malnutrition (Agarwal et al., 2016). Poor nutrition adversely affects the wellbeing of residents (Muurinen et al., 2015) and poor food intake is strongly associated with various adverse outcomes, including falls, functional decline, and death (Streicher et al., 2017).

Various tools are available for assessment of nutritional status, of which the most widely used is the Mini Nutritional Assessment (MNA) (Vellas et al., 2006). Various mealtime interventions have been investigated, including changes to food service, food improvement, dining environment alteration, staff training, and feeding assistance. There is some evidence to suggest that attention to these areas can have positive effects on

Care homes for older people

resident nutrition (Abbott et al., 2013) and behaviour in residents with dementia (Whear et al., 2014). Improving the mealtime experience is generally well received by residents (Kenkmann et al., 2010) but it may be that the goals of achieving weight gain or increased body mass index may be simply too tough given the high level of frailty in the resident population.

The use of feeding tubes (percutaneous endoscopic gastrostomy (PEG) tubes) in care home residents with dementia remains controversial, though there is no evidence of benefit (Sampson et al., 2009) or increased survival (Teno et al., 2012): indeed, at least one recent study found increased mortality (Ticinesi et al., 2016).

Death and end-of-life care

Given the advanced years and the prevalence of serious health problems among care home residents, mortality rates are bound to be high. There are however relatively few studies. Shah and colleagues (2013) used a primary care database including almost 10,000 care home residents aged 65 and older and reported that 26% died within one year, compared to 3% of the same age group in the community. McCann and colleagues (2009) found a median survival in Northern Ireland of 2.3 years for people admitted to nursing homes and 4.5 years for residential homes.

Deaths often occur in care homes, with about 20% of deaths in the UK occurring in nursing and residential homes (National Council for Palliative Care, 2006). However, about 55% of deaths of people with dementia occur in care homes (Sleeman et al., 2014), a proportion that has increased in the last decade or so. This probably reflects increasing attention to palliative and end-of-life care in dementia as well as initiatives to avoid what are seen as unnecessary admissions to hospital.

Management of dying patients in care homes, especially those with dementia, varies considerably and is often inadequate. However, under the right circumstances care homes are capable of providing a comfortable and hospice-type environment (Fleming et al., 2017). Palliative and end-of-life care are discussed in more detail in Chapter 27 and Chapter 53.

Creating a positive care culture

Much greater attention is now being paid to the experience of living in a care home. Initiatives include systematic projects such as *My Home Life* (see <http://myhomelife.org.uk/>), resident and consumer surveys, and various other accounts. For people who are frail, dependent, and living in a care home, quality of life and quality of care are intertwined (Goodman et al., 2017). Positive outcomes in this context depend to a large extent on effective day-to-day care. It is important to note that 'care' includes not only those elements provided within the home, but also external services such as medical care and social support. Furthermore, good-quality care depends on a range of micro-level (satisfied staff) and macro-level

Care homes for older people

(financial stability of the provider) factors and their interaction; this make it a complex and multifaceted construct (Ray and Sullivan, 2016).

Moving into a care home precedes living in one, and the next section discusses this important transition.

Moving into a care home

Most people enter a care home because they can no longer live independently as a result of physical and/or mental illness. People are often very frail. Admission is usually unplanned following the death of a spouse, a domestic crisis, a breakdown in care arrangements at home or an episode of acute hospital treatment (Harrison et al., 2017). In fact, over half of the admissions to care homes come from hospital; many of these are of people with dementia (Laing and Buisson, 2016). Circumstances which are linked to unplanned hospital admissions include: falls; confusion and incontinence; chronic conditions managed in the community but where care has broken down; and/or a cycle of repeated hospital readmissions that disrupt formal and informal care arrangements (Westwood and Daly, 2016).

The death or breakdown of a family carer is a primary trigger for admission to both a care home and hospital. In the UK, Banerjee and colleagues (2003) found that having a co-resident carer at home had a strongly protective effect—the risk of being institutionalized was 20 times higher in people who did not have a carer living with them. This must be one of the most striking demonstrations of the importance of carers anywhere in the research literature. Other people's concerns and anxieties for the older person's wellbeing, safety, and protection can also be a driver (Bowers et al., 2009). The 'other people' include relatives, friends, and health and social care staff. There is a risk that their wish for a 'safe' option may sometimes override the wishes of the older person.

Transitions, especially from hospital, into a care home are managed in variable and inconsistent ways (Hanratty et al., 2014; Kable et al. 2015). It is well documented that unsupported transitions can have a negative impact on older person's wellbeing (Ellis et al. 2010; Goodman et al. 2017; Scheibl et al., 2019a). A positive transition is more likely if the older person is involved in the decision to move (Gilbert et al. 2015; Scheibl et al., 2019b) and for those living with dementia the reason for moving is explained and they are allocated a 'buddy' for the first 48 hours of their stay (Sury et al., 2013). A crucial part of the process is for the older person to find a sense of 'home'; this appears to be closely associated with wellbeing and quality of life (Tester et al., 2004; Bowers et al., 2009; Hall and Beatty, 2014).

But even when relocation is accepted the transition can still be challenging; it is a time of considerable physiological, functional, psychological, and social decompensation (Ellis et al., 2010; Sussman and Dupuis, 2014). Quite apart from the stress of giving up one's home, there

Care homes for older people

are other losses to contend with: of friends, pets, and community attachments. Frail older people with complex needs might make several transitions as their illness progresses, amplifying the impact of these challenges. Adverse reactions, such as feeling like an 'outsider' or social disengagement, can place a person at risk of depression (Knight and Mellor, 2007).

There is often relatively little time to plan the move or to make informed choices about which home best suits the older person. There are limited guidance and/or standards in place to support good practice regarding the management of the transitions (Harrison et al., 2017). If a move to a care home is necessary, then one of the primary needs of older people and their families is for information; some excellent guidance is available, covering many of the practical and financial issues that need to be addressed (e.g. Independent Age, 2017). Publicly available information about quality of care, including care home standards, is also published by the CQC.

Most of the evidence about moving into care from older people themselves and their families is in the form of qualitative accounts. Davies and Nolan (2003, 2004, 2006) studied the experience of transition into residential care from the perspective of relatives, based on 37 interviews with 48 people who had assisted a close relative to move in. They distinguished three phases embedded in the process of transition: 'making the best of it'; 'making the move'; and 'making it better', referring to the periods before, during, and after the move. The My Home Life programme, while seeking to improve care for people living in care homes, specifically identified managing transitions as a core theme (Owen et al., 2012). It emphasized the importance of maintaining key relationships in the process of making decisions, transition, and post-transition in promoting the older person's wellbeing. Several of these themes have been discussed in the earlier section on Relocation.

Social connectedness and quality of life

The importance of supporting older people living in care homes to participate in everyday life, in order to encourage social engagement and enhance quality of life, is now well recognized (NICE, 2013). However, *feeling* socially connected is not generated simply by encouraging older people to engage in social or recreational activities (Knight and Mellor, 2007). Getting to the older person and gaining insight into their lived experience is more likely to help them to feel included (Mikelyte and Milne, 2016). This underscores the point made earlier that care home staff must be able to engage in emotional work with residents alongside their role in meeting residents' personal and physical care needs (Lee et al, 2013). Life story work may support care home staff to engage with 'the person', and building up a picture of the older person's life with family members is also important (Kellett et al., 2009).

Care homes for older people

Obviously, an older person is more likely to feel isolated and socially disengaged if there is absence or loss of close family members and friends. The Residents and Relatives Association (2010) estimated that 13,000 care home residents had no one to visit them at all, and many more residents had family members who did not, or could not, visit for various reasons. In this context, the quality of day-to-day relationships between older residents and care workers is pivotal to quality of life.

For residents to feel truly at home, they need to be supported in various ways, e.g. expressing and retaining aspects of their identity, preserving important continuities, and being treated as an individual who is known and cared about (Bridges, 2007). Appreciation of cultural values, preferences, religious and spiritual beliefs, and personal biographies—including areas of biographical sensitivity—are crucial elements in knowing a person. Aspects of personal life, such as sexuality and intimacy, are easily side-lined in practice with older people, reinforced by persistent stereotypes and ageism (see Robinson and Molzahan, 2007; see also Chapter 50). Assuming that an older person is ‘asexual’ is to potentially deny an integral part of a person’s identity and continued desire for intimacy. Older LGBTI people have often experienced discrimination in health and social care services and may hide their sexual identity or the existence of a partner in a care home setting (Stonewall, 2011). They may need sensitive support to feel able to express their sexual identity.

Various approaches have been developed to promote social connectedness of older residents. An important example, based on relationship-centred care, is the SENSES framework developed by Nolan and colleagues (2006). This highlights the fundamental importance of relationships in care homes in supporting older residents. The six Senses in the framework (security, continuity, belonging, purpose, achievement, and significance) are described in more detail in Chapter 15. The Senses framework offers a shared language and common ground between families and care professionals, across their potential differences in assumptions, values, attitudes, and behaviours (Davies et al., 2009).

The Joseph Rowntree Foundation’s *Better Life Programme* (Bowers et al., 2009; Katz et al., 2011) identified that older people with high support needs want a quality of life that includes relationships, living somewhere pleasant and accessible, having input into decisions that affect them, and the opportunity to mix with peers and others (see Box 26.2 for the key dimensions).

Box 26.2 Dimensions of a good quality of life in a care home

- 1 People knowing and caring about you.
- 2 The importance of belonging, relationships, and links with your local or chosen communities.

Care homes for older people

- 3 Being able to contribute to family, social, community, and communal life, and being valued for what you do.
- 4 Being treated as an equal and as an adult.
- 5 Respect for your routines and commitments.
- 6 Being able to choose how to spend your time—pursuing interests, dreams, and goals—and who you spend it with.
- 7 Having and retaining your own sense of self and personal identity—including being able to express your views and feelings.
- 8 Feeling good about your surroundings, both shared and private.
- 9 Getting out and about.

Research has identified some of the barriers to achieving these goals (Owen et al., 2012), which include: negative stereotypes and ageist assumptions about the capacities of older residents; dealing with the organizational requirements that take staff away from front-line caring, e.g. excessive paperwork; permitting staff to spend time with residents thus building up a relationship separately from the delivery of care tasks; providing supervision and support; and facilitating opportunities to engage residents as 'stakeholders' in the care home, not just passive recipients of care. Other findings suggest that promoting a bottom-up culture that rewards empathy and engagement in the staff team leads to higher levels of wellbeing among both residents and staff and reduces staff turnover.

Promoting good health and wellbeing

Until recently, there has little emphasis on promoting the health of care home residents, despite evidence that even among people with advanced dementia, improvements in health and wellbeing are possible (Livingston et al., 2008). For example, multifaceted interventions to reduce depression in care home residents can not only reduce or resolve symptoms, but also can improve overall quality of life and wellbeing (Lyne et al., 2006). Interventions to promote physical health among residents also show positive results for both physical and mental health (Milne, 2009).

Other areas where good practice can improve mental health outcomes include: the careful management of transition into the care home (as noted above); knowledge about the nature and needs of the older person *before* admission; regular assessment of the mental health status of residents; and an understanding that poor health is (often) amenable to

Care homes for older people

medical and/or psychosocial intervention (Ray et al., 2009). A commitment to person-centred care in the home, with a particular focus on a biographical approach and staff spending time on developing relationships with residents, is strongly linked to the promotion of health and wellbeing (Ballard et al., 2018).

Since 2015, in England the NHS has been running an Enhanced Health in Care Homes framework as part of its Vanguard programme to develop new models of care across the health service. Six sites have participated, developing projects around interventions such as medicines management, multi-disciplinary team support (such as dementia outreach teams), and end-of-life care (NHS England, 2016). It is intended that the most successful initiatives will become widespread and commissioned across the country.

Access to health services

How well health services work with care homes and provide support to residents lies at the heart of 'good healthcare' for the care home population. Research demonstrates a long history of erratic and inequitable approaches to healthcare delivery by both primary and secondary healthcare agencies and practitioners (Goodman and Davies, 2011). Although there are examples of innovation and good practice, these tend to be time limited, discretionary, and locally determined; often they depend on an individual practitioner's interest. Care home residents have tended not to be a priority by either primary care or specialist services, with care homes effectively being regarded as 'off the radar'.

The situation has improved somewhat in recent years, due to two probable main factors: first, increased recognition of the contribution that care homes make to the spectrum of care for long-term conditions, and second, a perception that residents are often admitted 'inappropriately' to acute hospitals, with consequent high costs to the NHS. Initiatives to improve matters often consist of a genuine wish to enhance the quality of care mixed with a ruthless intent to cut costs. The Care Home Vanguard programme exemplifies both components of this mixture. Where investment is made to develop, outcomes of interest can include earlier identification of preventable illness among residents, earlier referral to specialist services, and delayed or preventable hospital admission (Goodman and Davies, 2011). So far, however, evidence that hospital admissions and healthcare costs can be reduced is generally lacking.

Consistent regular primary healthcare input to care homes is widely regarded as important by residents and care home staff. Mental health services have a specific role to play in support of care home staff and residents, though the most effective and efficient way of using specialist mental health input has yet to be adequately demonstrated (Thompson, 2011). The recently completed Optimal study (Gordon et al., 2018) used realist evaluation to investigate under what circumstances NHS health services for care homes worked effectively, and identified four context-

Care homes for older people

mechanism-outcome configurations that underlay effective working. These were: i) investment in care home-specific work that legitimizes and values work with care homes; ii) relational working that, over time, builds trust between practitioners; iii) care that 'wraps around' care homes; and iv) access to specialist care for older people with dementia. The emphasis on relational working and care home-specific expertise suggests that time is of the essence to establish trust and openness between care staff and health professionals.

Primary care occupies a crucial place in support of care homes in the UK, but alternatives are possible, e.g. in countries like the Netherlands, where specialist elderly care physicians (Verenso, 2015) are employed to work full-time in nursing homes. There are good arguments for establishing a similar specialism in the UK (Oliver et al., 2014; Gordon, 2015).

Research

Research in care homes presents a number of challenges. First of all, many of the residents are frail and lack the capacity to give consent to participate in research. Residents' families and ethics committees have in the past taken a protectionist view towards residents, even if the residents themselves would have been willing to take part. Also, as mentioned, care homes vary in size, shape, and type and, as they are often independently owned, each home has to grant access to researchers. This is complex and time consuming. Additionally, in the past at least, there has often been no culture of research and enquiry in care homes and, for some, a sense of futility about the benefits of any studies that might be carried out. Generally speaking, care home residents have been an invisible population.

However, the last decade or so has seen more attention paid to research in this area, reflected in a marked increase in the number of funded studies and published papers. This reflects a realization that care homes are providing a significant amount of care for long-term conditions, including frailty and multimorbidity, and are a major arena for end-of-life care. Furthermore, it is increasingly recognized that they are not isolated from the rest of the health and social care system, so how they operate has implications for other providers, especially hospitals. Alongside this, in England, the Mental Capacity Act 2005 specifies the conditions under which people who lack capacity can participate in research, so that there is now a reasonable pathway to ensuring the inclusion of care home residents. More recently, the National Institute for Health Research has established the ENRICH (Enabling Research in Care Homes; see <http://enrich.nihr.ac.uk/>) network, which seeks to build links between researchers and the community of care homes (Davies et al., 2014). A growing user movement among people with dementia in research, in all settings, has also contributed to research participation (Litherland, 2015).

Care homes for older people

ENRICH is probably the first national care home research network, though in other countries (notably the Netherlands and the US) there are often strong links between academic departments and nursing homes. Much US research on care homes uses data from the national Minimum Data Set (MDS), which means that information regarding large numbers of residents is readily accessible to researchers. The UK has no such dataset, which places many studies at the (costly) disadvantage that they have to start recruitment and collecting data from scratch; this underscores the case for establishing a UK-wide MDS (Goodman et al., 2017, p. 125). Care home research is also supported by the flourishing specialist *Journal of the American Medical Directors Association*, which has a rapidly increasing impact factor; it has relabelled itself as the *Journal of Post-Acute and Long-Term Care Medicine*, which accurately reflects its purpose.

In terms of what research should be conducted, we need to know about what constitutes good and effective care, how to promote positive health among residents despite the high prevalence of chronic conditions, and how to prepare and support staff to use best practice all of the time, for every resident. The positive role that can be played by increasing understanding of the lived experiences of residents and what constitutes a 'good quality of life' in a care home setting cannot be overstated. Clinical trials can be difficult to perform because of the high level of attrition in the frail population of residents, but observational studies and research involving staff and relatives are feasible, and this may be a good area for realist methodology, which seeks to enquire what works, for whom, and under what circumstances.

Training

Staff training is essential for improving quality of care in care homes, especially in supporting residents with dementia. While evidence strongly suggests that training makes a more sustainable difference when embedded across the whole care home and/or organization (including management and ancillary staff), much of the focus of training initiatives is front-line care staff (Loveday, 2011). There is a strong correlation between high-quality care and a well-trained workforce, particularly in dementia care. Research suggests that training can impact positively on staff attitudes, skills, knowledge, and performance; it can also result in increased confidence and higher levels of job satisfaction and retention (Wild et al., 2010; Skills for Care and Skills for Health, 2011).

In recent years, more attention has been accorded to formal training and qualifications for care staff. For example, the Care Certificate was launched in 2015, aimed at non-regulated care workers, including care home staff. Around two-thirds of direct care staff have achieved, or are working towards, the Care Certificate (Skills for Care, 2017). The most frequent areas of training received were: moving and handling, safeguarding adults, and health and safety. The Curriculum for Dementia Education (Dementia UK, 2014) includes core topics and more detailed

Care homes for older people

items suitable for pre-registration or non-professional staff. The Health and Social Care Act 2012 removed the requirement for specific qualification standards in care homes in England, raising concerns about how training and skills will be consistently promoted. Nonetheless, national and local investment in systemic training programmes remains necessary not only to improve care, but also to increase staff retention rates, improve staff satisfaction levels, and reduce turnover (Cook et al., 2018).

Conclusion

The care home sector is complex and controversial. It supports some of the most vulnerable and frail older people in the UK, many of whom have dementia and other mental health problems. Its profile is increasingly that of a sector divided by provider type, individual capacity to self-fund and geographical variability. Although the care home population is largely invisible in many communities and in most public discourse, it is attracting greater attention than it once did from policy makers and researchers.

There are a number of issues that characterize the sector. How it will meet growing demand for its services is a dominant concern. Capacity in UK care homes fell for 12 years up to 2009. Although it has remained fairly stable since then, the number of places will need to approximately double in the next 20 years simply to maintain the current ratio of institutional to community-based care for people with dementia. By 2081 it is likely that around 1.5 million care home places will be required in the UK (Laing and Buisson, 2016). How such an increase will be funded and how the balance of funding—private vs public and local authority vs the NHS—will be managed remains largely unresolved.

This demand reflects a steady growth in the size of the very old population and a concomitant increase in the number of people with chronic disability, comorbid ill health, dementia, challenging behaviour, limited communication skills, and incontinence. Future demand for care home places will be influenced by a range of factors, including the changing but vital role that families play in supporting older relatives at home, the changing ethnic profile of the population, the costs and quality of community-based care, the role of alternative forms of long-term care (e.g. extra care housing), and the rising number of older people with substantial assets. The sector is likely to be increasingly defined by a small number of large independent providers. The need for more nursing homes, as opposed to residential care homes, will increase or, possibly, the—often false—distinction between the two will be abandoned.

Although care homes often have a ‘bad press’—and there are prominent instances of neglect and mistreatment—overall, the standard of both environment and care has improved considerably over the last 20 years. We anticipate further change resulting from better knowledge about good practice, improved medical and psychosocial support to care homes,

Care homes for older people

greater access to training, and enlightened regulation. Perceptions about care homes should change, so that they are no longer considered the option of last refuge, but rather as valued facilities for providing kindness, care, and comfort at the end of life. We need to recognize the complex work done in care homes, and how vital their contribution is to the total picture of care for people with long-term conditions. Also needed is a greater awareness of the needs of care home residents, the potential to make an active informed choice to live in a care home, and the inclusion of care homes in community life. We hope that future work will emphasize the perspectives of residents themselves (Milne, 2011) and will invest in interventions to improve mental health and the quality of residents' lives, the quality and capacity of care home staff, and the quality of care and support residents receive.

Notes:

1 In England to be eligible for local authority funding, an older person must have capital assets of under £23,250. Care home residents with under £23,250 in savings have to contribute all of their weekly income towards the fees, except for £23.50 per week, which they can keep to spend on personal items.

Palliative and end-of-life care

Chapter: Palliative and end-of-life care

Author(s): Elizabeth Sampson and Karen Harrison Denning

DOI: 10.1093/med/9780198807292.003.0027

The epidemiology of dying with dementia

As populations age, in the UK and other developed countries there will be a steady increase in the number of deaths, and a proportion of those will die over the age of 85 years (Gomes and Higginson, 2008). Projections of future need suggest that by 2040, annual deaths in England and Wales are projected to rise by 25.4% (from 501,424 in 2014 to 628,659) (Etkind et al., 2017). Despite the fact that most deaths occur in adults over the age of 65 years, there is widespread evidence that older people have inequitable access to good end-of-life care, and for people with mental health problems such as chronic schizophrenia or with neurodegenerative diseases such as dementia, there are further barriers to adequately meeting their needs (Davies and Higginson, 2004, Sampson et al., 2006).

Globally, about 47 million people were living with dementia in 2015, and this number is projected to triple by 2050. The prevalence of dementia increases with age, affecting 6% of those aged 75–79 years and one-third

Palliative and end-of-life care

of people over the age of 95 (Knapp and Privette, 2007). Thus, increasing numbers of people will die with dementia. Estimates from the UK Medical Research Council–Cognitive Function and Ageing Studies (MRC–CFAS) project, a large multicentre study looking at the health and cognitive function of 13,000 older people, suggest that people who died between the ages of 65 and 69 years had a 6% risk of dying with dementia, rising to a 58% risk of dying with dementia in those over 95 years. In the UK, one in three people over the age of 65 will die with dementia (Brayne et al., 2006) and in 2015 dementia became the commonest cause of death in men and women over the age of 80 years (Office for National Statistics, 2017). Deaths due to dementia will increase from around 59,000 in 2014 to around 220,000 deaths per year by 2040, which will then lead to an increased need for palliative care (Etkind et al., 2017).

People with dementia may also have a range of other comorbidities and may be frail. Frailty is found in a quarter to a half of people over 85 years of age and is associated with increased vulnerability to physiological stressors (Clegg et al., 2013). Abellan van Kan and colleagues (2008) define frailty as ‘an aggregate expression of risk resulting from age- or disease-associated physiologic accumulation of subthreshold decrements affecting multiple physiologic systems resulting in adverse health outcomes’.

Frailty and dementia are multifactorial in origin and share some common aetiological pathways resulting from cumulative exposures over a number of years (Neale et al., 2001). Smoking, obesity, lack of physical activity, and depression have been linked to the development of both frailty and dementia (Woods et al., 2005, Ownby et al., 2006, Peters et al., 2008, Hamer and Chida, 2009). There is a temporal association between frailty and increased risk of developing cognitive impairment; furthermore, increased frailty will accelerate cognitive decline (Clegg et al., 2013). Both dementia and frailty have an adverse impact on a range of outcomes, including acute hospital admission (Mukadam and Sampson, 2011; Wagner et al., 2006) and falls (Myers et al., 1991). These outcomes are independent of physical comorbidity and other potential confounders such as age and gender (Avila-Funes et al., 2009).

Dementia and frailty are life-limiting conditions

Despite the impact that dementia and frailty have on older people and their families, they have not traditionally been conceptualized as ‘terminal’ or ‘life-limiting’ syndromes. For example, care home medical and nursing staff consistently overestimate prognosis in advanced dementia. In one study of nursing home carers and physicians, at nursing home admission only 1.1% of residents were perceived to have life-expectancy of under six months; however, 71% died within that period (Mitchell et al., 2004b). The median length of stay in UK nursing homes, where the majority of residents will have moderate or severe dementia, is 18 months. With a median survival time of 1.3 years, advanced dementia (as defined by a Functional Assessment Staging Scale (FAST) score of 7c

Palliative and end-of-life care

and higher) is associated with a life-expectancy similar to that of well-recognized terminal diseases such as metastatic breast cancer (Mitchell et al., 2009).

A recent UK population study gave a median survival time from diagnosis of dementia to death of 4.1 years (Xie et al., 2008); this is strongly influenced by age, with those aged 65–69 years surviving for a median 10.7 years, and those aged 90 years and above surviving for 3.8 years (Xie et al., 2008). As expected, older people defined as being frail also have a significantly increased risk of death (Clegg et al., 2013).

Identifying when frail older people with dementia are reaching the end of their life can be challenging. Numerous studies have attempted to identify prognostic indicators or indices that may guide physicians to adopting a more palliative approach to care, but these tools are more reliable at identifying people with dementia at *low* risk of dying rather than those at *higher* risk of death (van der Steen et al., 2005). Clinical judgment, discussion with families and carers, and taking the opportunity to reassess or shift the goals of management towards palliative care at times of intercurrent illness or transition may be a more practical and reliable approach (van der Steen, 2010).

For example, acute physical illness requiring emergency hospital admission, such as pneumonia and urinary tract infections, may be an indicator of imminent death in people with advanced dementia (Morrison and Siu, 2000b; Mitchell et al., 2009; Sampson et al., 2009a). This population also has markedly increased six-month mortality after hip fracture (55%) and pneumonia (53%), compared to 12% and 13% in cognitively intact patients (Morrison and Siu, 2000b). Shorter-term mortality is also very high, with 24% of those with moderate or severe dementia dying after acute unplanned medical admissions, compared to 7.5% of those who did not have dementia (Sampson et al., 2009a).

However, there is little evidence that many active medical interventions, e.g. artificial hydration and nutrition, hospital admission, prolong or improve the quality of life in people with dementia (Sampson et al., 2009b; van der Steen, 2010). Additionally, there is increasing interest in how a palliative approach may be beneficial for frail older people with advanced dementia (Livingston et al., 2017).

What is palliative care?

The World Health Organization defines palliative care as:

an approach that improves the quality of life of patients and their families facing the problems associated with life threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual (Gomez-Batiste et al., 2007).

Palliative and end-of-life care

The phrase *end-of-life care* may be used synonymously with *palliative care*, particularly in the US. Its use is favoured because palliative care is sometimes associated only with cancer, whereas end-of-life care refers to all patients with life-limiting illnesses. In European countries, end-of-life care is often used to describe the care given during the last few hours or days of life.

The European Association of Palliative Care (EAPC) published a consensus statement attempting to define the principles of practice. All definitions share a common philosophy of care, which is to take a holistic approach, valuing autonomy of patients and their families, with a focus on: dignity; a collaborative relationship between healthcare professionals, patients, and their families; good communication; and a central goal to maintain the quality of life. These are, of course, all characteristics required by professionals working in any mental health setting. It is also important to note that end-of-life care 'seeks neither to hasten death, nor to postpone it' (Radbruch et al., 2009).

For the purposes of this chapter we focus mainly on end-of-life care of older people with advanced dementia, as this is where the focus of policy, research, and clinical provision has most recently been directed.

The clinical picture of advanced dementia

There are no operationalized clinical criteria for advanced dementia, but Reisberg (1988) suggests that it can be defined as a FAST level of 7 and higher: the person with dementia (PWD) cannot dress him- or herself, is doubly incontinent, and speaks at most only a few words.

In contrast with the early and middle stages of dementia, the clinical features of advanced dementia are less well characterized and researched. People with advanced dementia suffer a range of symptoms, similar to those found in the terminal stages of cancer, e.g. pain and dyspnoea. Pressure sores, agitation, and eating problems (i.e. difficulty with swallowing or loss of appetite) are very common as the end of life approaches (see Table 27.1).

Palliative and end-of-life care

Table 27.1 Prevalence of symptoms (percentage) in nursing home residents with advanced dementia.

Study details	Mitchell et al. (2009)	Sampson et al. (2017)	Black et al. (2006)	DiGiulio et al. (2008)	Aminoff and Adunsky (2005)	Klapwijk et al. (2014)
	Proportion with symptoms 18 months prior to death (prospective study) <i>n</i> = 323	Proportion with symptoms in the last nine months of life (prospective study) <i>n</i> = 85	Proportion of residents with life expectancy of six months (prospective study) <i>n</i> = 126	Proportion of residents in the last 30 days of life (retrospective study) <i>n</i> = 141	Proportion of residents in the last week of life (prospective study) <i>n</i> = 71	Proportion of residents in last five days of life (prospective study) <i>n</i> = 24
Dyspnoea	46	47	29	39	–	30
Pain	40	55	63	26	18	35
Pressure ulcers	39	27	61	47	70	7
Agitation/ restlessness	54	45	50	20	72	19.4
Aspiration	41	20	15	–	–	–
Eating problems/ difficulty swallowing	86	57	85	–	95	38.7

Palliative and end-of-life care

A retrospective study comparing symptoms experienced in the last year of life by 170 people with dementia compared to 1,513 cancer patients showed that the symptom burden between the two groups was comparable; in particular, 64% of dementia patients experienced pain and 57% had loss of appetite. The healthcare needs of both groups were also similar (McCarthy et al., 1997). The careful management of these specific symptoms is vital in providing a holistic approach to end-of-life care for people with dementia.

Pain

Pain is common in people with advanced dementia and is often underdetected and undertreated (Scherder et al., 2009), particularly towards the end of life (Sampson et al., 2017; Klapwijk et al., 2014). Retrospective interviews with relatives and carers indicate that significantly more dementia patients are reported to experience pain in the last six months of life compared to those with cancer (75% vs 60%) (McCarthy et al., 1997), but pain control is often inadequate. In patients with fractured neck of femur, those with cognitive impairment were prescribed only a third as much analgesia as cognitively intact controls (Morrison and Siu, 2000a). There is no consistent evidence to suggest that pain experience is less intense, but people with advanced dementia will have difficulties in communicating that they are in pain and interpreting pain signals. This often manifests as behavioural change such as agitation, distress, social withdrawal, depression, or resistive behaviour (Scherder et al., 2009; Sampson et al., 2015).

The 'gold standard' for pain assessment is self-reporting. Despite widely held beliefs to the contrary, many patients with moderate to severe dementia can report pain reliably (Zwakhalen et al., 2006). In those with communication difficulties it may be necessary to use direct observation or validated observational pain scales such as the Abbey Tool (Abbey et al., 2004). The assessment of pain in advanced dementia is, however, complex and it has been suggested that there is no evidence that pain produces any unique features that may not be caused by other sources of distress (Regnard et al., 2003; Cohen-Mansfield et al., 2015); and thus tools such as the Disability Distress Assessment Tool (DiSDAT) may be more appropriate (Regnard et al., 2007).

Managing pain in a person with advanced dementia requires careful assessment for possible underlying causes. This should include clinical examination, observation of behaviours (both at rest and during movement), and discussion with family members or staff who know the person well. In some cases, response to a trial of analgesic may in itself be a diagnostic tool (Herr et al., 2006). The aetiology of pain may be acute and may, for example, be associated with urinary retention, constipation (Kovach et al., 2006), myocardial infarction, deep vein thrombosis, or acute infection. Common chronic causes of pain in people with advanced dementia include pressure sores, undetected fractures,

Palliative and end-of-life care

poor dentition, awkward positioning in chair or bed, and arthritis (Davis and Srivastava, 2003).

Treating pain in this population requires a stepped approach (Abdulla et al., 2013). Depending on the cause, nonpharmacological interventions may be helpful, particularly where there is a musculoskeletal aetiology. This may include repositioning, provision of optimal seating or specialist beds, physiotherapy, massage, heat, or cold. Simple analgesia such as paracetamol and non-steroidal inflammatory drugs can be very effective. The key to achieving a good result is regular prescribing; as-required medication is often not given as people with advanced dementia may not report they are in pain or request painkillers. If simple analgesics are ineffective then stronger analgesia such as opioids should be considered. Side effects such as delirium, constipation, and sedation may occur, but in practice these can be managed. An important recent study (Husebo et al., 2011) demonstrated how this approach to the management of pain significantly reduced agitation in residents of nursing homes with moderate to severe dementia. Regular paracetamol was effective in 63% of participants, and of the 25% who received opioids only 2% had these discontinued because of side effects. The intervention also showed beneficial effects on mood (Husebo et al., 2014) and sleep (Blytt et al., 2017).

Behavioural and psychological symptoms of dementia

Behavioural and psychological symptoms of dementia (BPSD) are common in dementia, affecting 90% of people at some time during the course of their illness. They can be extremely distressing both for people with dementia and their family and carers, and they are also a strong predictor of institutionalization to nursing or residential homes (van der Linde et al., 2016). Different BPSD tend to emerge at different stages of the illness, e.g. mood disorders and depression are noted earlier in the disease course and psychotic symptoms (hallucinations and delusions) are more common in moderately severe dementia. Wandering and agitation tend to be the most enduring BPSD. In the advanced stages of dementia, over half of patients remain agitated and distressed (Sampson et al., 2017; Mitchell et al., 2009). The management of these symptoms is complex and requires a structured approach, using a range of therapeutic approaches. Difficult behaviours, e.g. aggression and resistance to care, may be indicators of unmet needs, for example, undetected or untreated pain, delirium, or infection. Therefore, a full assessment is required, which can be challenging in advanced dementia when verbal communication is limited. Basic aspects of personal care, such as providing glasses or hearing aids, should be considered first. Environmental modifications, such as limiting noise or providing outside space or gardens where people can walk, can reduce agitation. Psychological interventions, e.g. simple 'ABC' analysis (documentation of the Antecedents of the behaviour, the Behavioural disturbance, and the Consequences of the behaviour) can reveal patterns and triggers for a particular problem, and are also very effective (Kovach et al., 2006;

Palliative and end-of-life care

Testad et al., 2010), and drugs should be used as a last resort. Antipsychotic medications both typical and atypical can cause parkinsonism, prolongation of the QT interval, and increase the risk of stroke and death (Schneider et al., 2006; Maust et al., 2015).

Eating and swallowing

People with advanced dementia often develop swallowing difficulties. Two methods of enteral tube feeding are used: a nasogastric tube (a tube that is passed through the nose and into the stomach) or via a percutaneous endoscopic gastrostomy (PEG) (directly through the abdominal wall into the stomach). Sampson and colleagues (2009b) found no randomized controlled trials of these interventions in people with advanced dementia; furthermore, the review showed inconclusive evidence that enteral tube feeding provides any benefit in terms of survival time, mortality risk, nutritional parameters, and improvement or reduced incidence of pressure ulcers. There have been no studies on the effect of these interventions on quality of life. Enteral tube feeding may increase pulmonary secretions, incontinence, mortality, and morbidity. PEG is an invasive surgical procedure with significant postoperative risks, including aspiration pneumonia, oesophageal perforation, migration of the tube, haemorrhage, and wound infection.

The decision to use enteral tube feeding is emotive and influenced by complex ethical issues, clinical need, local practice, physician and carer preference, and whether there is an advance directive or care plan in place. Clinicians may feel pressurized by institutional (Lopez et al., 2010), societal, or local laws to intervene. For example, in the US, only the state of Illinois requires a physician to seek a court order to withhold or withdraw tube feeding. Ethical considerations include whether life in advanced dementia should be artificially prolonged and what is considered to constitute 'euthanasia', i.e. the difficult issue that by withholding food and fluids death will be hastened. It has been argued that the absence of evidence demonstrating a benefit of tube feeding does not mean that it is inappropriate in all patients with advanced dementia and that each individual deserves a holistic assessment by a specialist in swallowing; all appropriate interventions should be considered, including the option of a gastrostomy (Regnard et al., 2010). Some ethicists suggest that artificial nutrition and hydration are medical treatments that can legitimately be withheld if their risks, *judged according to the patient's values*, outweigh their benefits (Gillick, 2000); however, this implies that values are known or documented and this is often not the case.

Whether 'to feed or not to feed' is perhaps not such a stark binary decision as it may seem. Modifying or thickening foods, providing finger foods, and offering alternative choices that the person likes (identified from personalized care documentation such as *This Is Me*) may improve nutrition and increase weight (Hanson et al., 2011). 'Comfort feeding' (sometimes referred to as 'risk feeding' is becoming more widely used (Palecek et al., 2010); tastes and sips of food combined with mouth

Palliative and end-of-life care

care are used to promote comfort and pleasure, focusing on the quality of the interaction with the care giver as much as the provision of nutrition.

Infections and pneumonia

Pneumonia and other infections, especially of the urinary tract, are common in advanced dementia. Over 18 months, 53% of nursing home residents with advanced dementia will have a febrile episode, and 41% will have pneumonia (Mitchell et al., 2009) and people with dementia are more than twice as likely to die from pneumonia compared to those without (Foley et al., 2015). People with advanced dementia are often immobile, bed bound, at increased risk of aspiration, and may have impaired immunological function. The use of antibiotics to treat fevers and recurrent infections is one of the most controversial issues in this field. Fabiszewski and colleagues (1990) demonstrated no difference in mortality between people receiving antibiotics and those receiving only 'palliative' care. In a cohort of Dutch nursing home residents, van der Steen and colleagues (2002) found that those treated with antibiotics survived for longer (27% died compared to 90% of those who did not have antibiotics); however, this may have been related to the fact that antibiotics were withheld from residents whom physicians believed had more severe dementia. Some research has suggested that withholding antibiotics increases the level of discomfort (van der Steen et al., 2009), but it has also been argued that antibiotics might delay death, leaving the patient exposed to the risk of further pain and suffering and prolonging the dying phase. In this situation, adequate symptomatic control using analgesia may be more appropriate.

Care settings

Many recent national and international palliative care policies have focused on how best to provide people with the opportunity to die in a place of their choice (Department of Health, 2008). International population surveys have demonstrated how over two-thirds of people say that they would prefer to die at home (Gomes et al., 2012). However, in western populations over the last hundred years there has been a large shift away from deaths at home to deaths in hospitals and care facilities. For example, in the UK, between 1974 and 2003 the proportion of home deaths fell from 31% to 18% overall. This occurred at an even higher rate for people aged 65 and over, women, and people dying from non-cancer related causes (Gomes and Higginson, 2008). Concurrently, the proportion of older people dying in long-term care facilities such as residential and nursing homes has increased across Europe and the US, where 40% of deaths occur in long-term care facilities. In the UK there has been a trend towards decreased deaths in hospitals and increasing numbers of deaths in care homes for people with dementia (Sleeman et al., 2014).

Palliative and end-of-life care

Care homes

When frail older people with dementia are moved to a care home, they frequently experience multiple losses: physical, mental, social, and spiritual. Although death may not necessarily be imminent, residents of care homes are highly likely to die there, making these settings where palliative care is most needed (Cartwright, 2002; Oliver et al., 2004; Froggatt et al., 2006). Several barriers may obstruct the provision of good-quality palliative care in these settings. These include high rates of staff turnover, lack of access to primary care medical support and specialist palliative care resources when required, and fear of censure by regulatory authorities if deaths occur in the care home (Denning et al., 2012). In the UK, medical support to care homes is variable and concerns have been raised when acute illness occurs at night and on-call doctors may not have the information necessary to make the decision that a resident requires palliative care and not active intervention. This can lead to the distressing situation where a resident is admitted to the acute hospital and dies there. A related issue is that of anticipatory prescribing. For example, care homes may not hold drugs, particularly opiates, which are commonly held by palliative care teams and hospices. The funding of long-term care and palliative care varies widely between different countries. In the US, there is a focus on 'hospice appropriateness', whereby Health Management Organizations will fund palliative care for people with dementia, once it has been agreed that they have a likely survival time of fewer than six months. In the Netherlands, care homes are served by specialist nursing home physicians, and therefore much palliative care is given 'in house' (Koopmans et al., 2010).

Hospices

It is often stated that people with dementia are 'denied' access to hospices; fewer than 1% of hospice patients in Europe have a neurological diagnosis (Davies and Higginson, 2004), and in the US, fewer than 7% of hospice patients have a primary diagnosis of dementia (Jennings, 2003). The reasons for this are complex and related to many of the issues described earlier, e.g. that dementia is not perceived to be a terminal illness, concerns that hospice staff will not be able to manage BPSD (McCarty and Volicer, 2009; Sanders and Swails, 2009). People with dementia are also less likely to be referred to palliative care services, and in many health systems access to hospices is dependent on recommendations from these services. It has been argued that hospices provide 'specialist' palliative care and that they should rightly focus on cases of complex need—most of the symptoms experienced by people with dementia at the end of life, such as pain and difficulties with swallowing, do not require specialist intervention but good generalist care.

Over recent years there has been a shift in hospice care and their willingness to embrace dementia. Progress was galvanized by the launch of the Hospice UK report on hospice-enabled dementia care (Hospice UK,

Palliative and end-of-life care

2015). While this may not result in more people with dementia being admitted to and dying in hospice, many are now providing or developing community and hospice outreach services (Denning et al., 2017b).

Person-centred care and spirituality at the end of life

What it is to be a person is central to our understanding of person-centred care. Person-centred care is now a widely acknowledged basis for dementia care delivery and is a term that is synonymous with treating people as individuals, respecting their rights as a person, and (from a professional carer perspective) in building therapeutic relationships (McCormack and McCance, 2010).

Tom Kitwood, a noted leader in the movement for person-centred care in dementia, extended the concept of person-centred care (see Box 27.1) to consider personhood and the status of being a person, and developed a definition of personhood as a '... standing or status that is bestowed upon one human being by others, in the context of relationship and social being' (Kitwood, 1997). This established the concept of person-centred care within relationships with others.

Box 27.1 Key features of person-centred care

- Looks at care from the perspective of the individual.
- Acknowledges each person as a unique individual with a rich history and own memories, preferences, wishes, and needs.
- Respects the dignity, autonomy, and independence of the person with dementia.
- Focuses on the positive rather than the negative.
- Focuses on strengths and abilities rather than weaknesses and disabilities.
- Promotes wellbeing.
- Ensures care is planned around the individual, not around the care system.
- Acknowledges there is usually a reason for a behaviour, and views behaviours that challenge others as an expression of feelings and/or a means of communication.
- Accepts the reality of the person with dementia and does not insist on bringing the person into another reality that can cause distress.

Reproduced with permission from Denning, K. H., et al. Advance care planning for people with dementia: a review. *Int Psychogeriatr*, 23(10):

People with dementia, particularly those in the advanced stages, are reportedly often denied care that is ‘person-centred’, and Post (1990) suggests they may be classified as already ‘dead’; he states that, due to the lack of empowering capacities, people with advanced dementia may be seen as ‘nonpersons’. The ethical and philosophical debate on the concepts of self and personhood draws together the central issues of both dignity and spirituality.

Spiritual care is an important aspect of patient care and there is growing interest in spirituality and spiritual care. These have become increasingly essential components in person-centred care and quality of life of people with dementia, especially towards the end of life, when capacity may be lost. A review of spiritual care (Holloway et al., 2010) commissioned to support the implementation of the End of Life Care Strategy (Department of Health, 2008) found spirituality to be of particular concern within the nursing literature, though most material was more concerned with its assessment, rather than on specific interventions. Ensuring spiritual care is met in people with dementia is the responsibility of all members of the health and social care team (Department of Health, 2008). Fulfilling spiritual needs has a positive impact on people’s psychological and physical wellbeing (Agli et al., 2015). However, spirituality is a complex phenomenon and is not well understood by practitioners (MacKinlay and Trevitt, 2007). Thus, spiritual needs are often ignored, particularly in relation to people with dementia (Skomakerstuen Odbehr et al., 2015).

Namaste

Sensory stimulation is a form of spiritual care that requires no verbal communication. It can help foster people’s sense of connection with themselves and families/friends/caregivers (Simard and Volicer, 2010; Nicholls et al., 2013). Gentle massage of the hands, shoulder, neck, and face has been found to cause people with dementia who are normally withdrawn to reach out and touch the caregiver’s hands, face, or body, in a gesture of reciprocation (Nicholls et al., 2013). Namaste Care (Simard, 2013) is an example of a systematic, multisensory care programme that is aimed specifically at meeting the spiritual needs of people with advanced dementia who are no longer able to participate in social or group activities (‘Namaste’ means to honour the spirit within). It integrates meaningful activity with multisensory stimulation, nursing care, person-centred care, and reminiscence (Simard, 2013). It has been shown to enhance the wellbeing of people with dementia, decrease agitated behaviours, improve communication and nutritional intake, and help people and their family/loved ones to reconnect with each other (Simard and Volicer, 2010; Stacpoole et al., 2017).

Advance care planning

Palliative and end-of-life care

The fear of not being seen as a 'whole person' or cared for in a person-centred way has contributed to the anxieties that people have about their future health. For example, when asked what health worries they were most concerned about when they got older, more people worried about developing dementia (58%) than were concerned about getting cancer (47%) or having a heart attack (47%) (Fernández and Forder, 2010). The experiences of people with dementia are starting to have a positive influence on our understanding of person-centred care from the perspective of the PWD. Based on her personal experience as a PWD, Bryden (2005) maintains that people with dementia should take the opportunities to explore with other people more existential issues about life and death, while they still retain the capacity to plan their future care.

Advance care planning (ACP) is understood in a variety of different ways. The term is often used without definition or explanation and different emphases are placed upon the different elements of the care planning (Henry and Seymour, 2007). ACP usually involves a process of discussing and recording priorities and wishes for future care and treatment between individuals and their health and/or social care providers. It attempts to anticipate the future deterioration of a person's condition so that when a person is no longer able to communicate, for whatever reason, wishes and preferences that have been recorded earlier can be met (Froggatt et al., 2008).

In contrast to those with cancer and other advanced chronic disease, people with dementia may have profound cognitive impairment and lack the capacity required to make decisions about their care and treatment. People with dementia are significantly less likely to have an ACP compared to those with cancer, although uptake of the process in cancer remains variable (Mitchell et al., 2004a). Ideally, developing an ACP should be attempted in the earlier stages of dementia when a person is still competent to make decisions. An MMSE score of 18–20 appears to be a consistent threshold score required to make an ACP (Fazel et al., 2000; Gregory et al., 2007). Below this threshold, individuals appear more likely to opt for life-sustaining treatments (Fazel et al., 2000) but as dementia progresses there is increased caregiver involvement in decision-making (Hirschman et al., 2006). In current UK clinical practice, it remains rare for a person with advanced dementia to have an ACP, while little is known about how ACP may benefit people with dementia and their carers (Denning et al., 2011).

Advance care planning and decisions about life-sustaining treatment

Professionals and family carers often anticipate an adverse reaction to pursuing ACP with the PWD, but this is not necessarily the case. Finucane and colleagues (1993) found that such concerns in family carers were unfounded, and that the PWD showed no distress either before or after ACP discussions. Carer attitudes may influence the likelihood of people with dementia being exposed to aggressive treatments at end of life. Mezey and colleagues (1996) found that carers with a greater sense of

Palliative and end-of-life care

burden were more likely to consent to life-sustaining treatment. Fazel and colleagues (2000) found that people with dementia were more likely to make decisions that were impulsive or opt for life-sustaining interventions than controls, but Finucane and colleagues (1993) found that people with dementia were more likely to refuse life-sustaining therapy as they became more cognitively impaired.

Family carers and decision-making

Decision-making for people with dementia at the end of life may be fraught with problems, with prompts for discussions about ACP perhaps triggered by a medical event, transitions and changes to the living situation, or a hospital admission for the PWD. In the absence of any defined ACP, decision-making often falls to family carers, with increasing caregiver 'burden' being a significant predictor of caregiver-dominated decision-making (Hirschman et al., 2004). However, family carers are often unprepared to make effective decisions about end-of-life care for the PWD (Forbes et al., 2000; Denning et al., 2012).

A study of dyad interviews (a PWD and their family carer) found that, although the partners claimed to have a shared approach to decision-making, this had in fact been largely untested until the diagnosis of dementia was made (Denning et al., (2016, 2017b). Despite this lack of preparedness, carers are often called upon to support clinical decision-making at a time when the PWD no longer has the capacity to do so. Family carers found the increasing burden of assuming the day-to-day decision-making on behalf of the PWD wearisome, which meant that they did not have the emotional energy to consider medium- or long-term planning (Denning et al., 2017c). Furthermore, both PWD and carers showed marked uncertainty about end-of-life treatment choices, often reflecting that they did not have enough information about potential future health states to make such decisions. However, this meant that carers could accurately predict the PWD's preferences in the here-and-now, but, at best, were only moderately able to predict treatment choices in future hypothetical health states (Denning et al., 2016).

Professional attitudes

A priority of UK government policy is to improve the diagnosis rates of dementia (Banerjee and Owen, 2009). However, of equal importance at this time must be supporting people with dementia to consider their end-of-life care preferences and choices while they still have the cognition, capacity, and language to do so. Professionals often find this a difficult area to address. Studies show that there is inadequate preparation of both people with dementia and their carers for future care issues and related decisions, with some not engaging in ACP discussions at all (Cavalieri, 2002). Despite agreement on many aspects of end-of-life decision-making, physicians, nurses, and relatives hold different views arising from their religious beliefs, their assumptions about the perspectives of the patient, and their contrasting care responsibilities

Palliative and end-of-life care

(Rurup et al., 2006). Where ACPs do exist, relatives often attach great importance to them and believe they *must* be followed, whereas with the widespread use of the Mental Capacity Act 2005, professionals know that only certain types of ACP documents have any legal standing (Rurup et al., 2006).

Advance care planning process and tools

ACP tools are emerging, with little evidence as yet for any improvement in associated outcomes for people with dementia (Denning et al., 2011). As part of a wider study in Australia, Caplan and colleagues (2006) used an ACP (Molloy et al., 2000) as part of a programme to reduce acute hospital interventions. The combination of education and ACP led to a reduction in emergency calls, fewer hospital admissions, and a decrease in mortality compared with homes in the control group.

In the UK, the Mental Capacity Act 2005 provides a legal framework for the ACP process. The Act gives competent adults in England and Wales the legal right to refuse treatment (i.e. artificial feeding and resuscitation) through the writing of an 'advance decision'. People can also make an 'advance statement' that reflects their general beliefs and personal values about the sort of care they would like to receive in the future.

Lasting Powers of Attorney (LPA) were also introduced through the UK Mental Capacity Act 2005 and enable the appointment of an attorney to make proxy decisions when the PWD no longer has the capacity to do so. A 'Personal Welfare' LPA allows the attorney to give or refuse consent to medical treatment, if such preferences have been expressed in the document.

Due to the advancing cognitive difficulties of the PWD, nurses and allied healthcare professionals must ensure they communicate with a main carer(s) in addition to the PWD in order that appropriate care and support is given. This can give rise to ethical and legal challenges, e.g. receipt of third-party information, disclosure of confidential health information, consideration of the PWD's capacity for decision-making, and potential disagreements among family members on the best interests of the PWD. This demands that dementia care professionals should be aware of the legal and ethical issues involved in ACP, as well as developing the skills required to embark on such difficult conversations.

Interventions in end-of-life care for older people

The role of nursing care and allied health professionals

Dementia affects the whole family, and people close to the PWD find themselves providing increasing amounts of care and support as the disease progresses. Hence, care delivered is required to be mindful of the whole family unit and the relationships therein. Various health and social care professionals have a role in supporting palliative and end-of-life care

Palliative and end-of-life care

for PWDs. For example, occupational therapists may provide assessment of the home (or usual place of care) environment for equipment and adaptation needs; social care workers may provide assessment and provision of personal care and domestic support needs; district nurses may help in accessing vital equipment and meeting physical healthcare needs; physiotherapists may provide care and support, and advice on mobility and falls prevention, and chest care in cases of pneumonia. Many health and social care professionals are keen to provide better quality end-of-life care to people with dementia. In our own studies, using a rapid participatory appraisal methodology, we found that all professionals involved in palliative and end-of-life care in dementia were acutely aware of the limitations both in their own knowledge and skills and in the health and social care system within which they worked (Denning et al., 2012; Sampson et al., 2012). Many of the barriers to good-quality end-of-life care in dementia highlighted in this work were associated with lack of interagency communication, not having a clear dementia care pathway, and a sense of helplessness.

There are two very clear elements to good quality dementia care: the medical model/approach and the social model/approach. Both are inextricably linked and both of distinct value to the care delivered to PWD and their families. Early on in the illness it will be necessary to discuss the purpose of diagnostic investigations, what they entail, and how results will be given. This is an important time to establish a relationship with people with dementia and their family, understanding the main problems from their perspective, and liaising with other health and social care providers.

What is appropriate treatment at the end of life?

Despite the high mortality in advanced dementia, particularly for those who are admitted to the acute hospital, people with dementia receive as many painful investigations and procedures (e.g. arterial blood gas sampling) as, and are more likely to be physically restrained compared with, patients without dementia (Morrison and Siu, 2000a). This suggests that clinicians fail to adopt a palliative or supportive approach to patient care, possibly because people with advanced dementia are not perceived to be suffering from a 'terminal illness'. This may be due to poor understanding of the pathophysiology of dementia among healthcare professionals (Thuné-Boyle et al., 2010). Other vital components of good end-of-life and person-centred care are also neglected with little acknowledgement of spiritual needs, failure to withdraw inappropriate medications, and non-referral to hospital palliative care teams (Sampson et al., 2006). People dying with dementia in nursing homes often receive burdensome interventions. In an American study, Mitchell and colleagues (2009) found that 29% received enteral tube nutrition and 12.4% were hospitalized.

Palliative and end-of-life care

The evidence base on palliative care in dementia is somewhat limited, particularly when compared to research on palliative care for people dying from cancer. Systematic reviews have identified how care mainly focuses on specific interventions such as fever management policies, pain control, or the withdrawal of care, i.e. *not* prescribing antibiotics, rather than a more active palliative model (Sampson et al., 2005; Goodman et al., 2009; Murphy et al., 2016). Good person-centred care requires a more rounded approach, and a number of multicomponent complex interventions and pathways have been developed that may improve the quality and outcomes of care for older people with dementia in the acute hospital and in the community.

Care management

There is a growing interest in a 'care management' approach for families affected by dementia; this entails detailed assessment of need and a coordination of care and support from health, social, and voluntary care professionals. Such an approach is considered essential in meeting the palliative and end-of-life care needs of people with dementia and their family carers (Judd et al., 2011). A care management approach is identified as a positive determinant of how well a carer is supported in his or her caring role (Hibberd, 2011), and is an approach that is best applied throughout the illness, from the diagnosis of dementia, living with dementia, to death and beyond in supporting families in their loss (Denning et al., 2017b).

Admiral Nursing is one approach in providing care management throughout the course of the illness (Denning et al., 2017b). Following diagnosis, appropriate follow-up is essential to discuss the prognosis and issues of legal and financial planning, give advice on the next steps, commence the discussion of ACP, and continue liaison with local services. Later in the illness, nursing and allied healthcare input will depend largely on symptoms and their management. Information and guidance provided within the context of continuing professional support, as in the case of Admiral Nursing (specialist dementia care nurses), is effective in supporting family carers and reducing anxiety levels (Wills and Woods, 1998). A distinct advantage of the Admiral Nurse service is the long-term nature of the work with families of people with dementia and the support offered throughout the trajectory of the illness; this support is of particular value during transitions from community to care home (Denning et al., 2017a).

Care pathways and policies

The English National Dementia Strategy (Banerjee and Owen, 2009) contained little regarding end-of-life care, and the English End of Life Care Strategy (Department of Health, 2008) made little specific reference to dementia. This illustrates how people with dementia fall through gaps in the health and social care system. The National Institute for Health and Care Excellence (NICE) guidelines for dementia (NICE, 2018) include

Palliative and end-of-life care

some recommendations, notably about offering ACP soon after diagnosis and the application of other NICE guidance in relation to palliative and end-of-life care for adults (NICE, 2015).

End-of-life care pathways and decision-making tools

End-of-life care guidance for people with dementia is lacking and this has been made more problematic in England (and in some other countries) with the removal of one of the main end-of-life care guidelines that offered some structure: the Liverpool Care Pathway (LCP) (Ellershaw, 2007). The LCP was an approach to care for the dying, intended to ensure that uniformly good care was given to everyone thought to be dying within hours or within two or three days, whether they were in hospitals, nursing homes, or in their own homes. However, concerns were raised about how the pathway was implemented in practice, e.g. that food and fluids may be withdrawn too early from people with dementia (Treloar, 2008). After a highly politicized debate use of the LCP was phased out from the British health and social care system in 2014.

Davies and colleagues (2016) used an iterative co-design approach using qualitative interviews and focus groups with family carers and focus groups with health and care professionals to develop a toolkit of heuristics (rules of thumb) to support decision-making in practice. Four heuristic decision-making algorithms were developed; 1) eating/swallowing difficulties, 2) agitation/restlessness, 3) ending life-sustaining treatment, and 4) providing 'routine care' at the end of life. Each topic became a heuristic consisting of rules arranged into flowcharts. Such decision-making tools have the potential to be used alongside existing end-of-life care recommendations, adding more readily available practical assistance.

Complex interventions and care programmes: Interventions in hospital settings

Ahronheim and colleagues (2000) conducted a randomized controlled trial of an intervention in which people with dementia received assessment and care plan recommendations from a palliative care team with the goal of enhancing patient comfort in an acute hospital. The intervention did not decrease rates of readmission to hospital, average length of stay, or mortality, but there was a significant increase in written palliative care plans and patients received fewer intravenous drugs. The authors highlighted the 'unique barriers' to providing good end-of-life care, including prognostic uncertainty, and suggest that care planning may be more effective when done outside the busy acute hospital environment.

Lloyd-Williams and colleagues used multi-disciplinary prescribing guidelines on wards for older people with dementia. There was a significant decrease in the prescribing of antibiotics in the last two weeks

Palliative and end-of-life care

of life and patients were much more likely to be prescribed analgesia, including opiates (Lloyd-Williams and Payne, 2002).

Interventions in nursing homes and specialist care units

Training and educational programmes on end-of-life care and ACP for nursing home staff appear to be effective in improving knowledge and increasing satisfaction with end-of-life care in bereaved family members (Arcand et al., 2009; Garden et al., 2016; Moore et al., 2017).

A specific approach in the US has been that of the Dementia Special Care Unit (DSCU). Volicer and colleagues (1994) compared this approach to nursing home settings and found that the DSCU, which provided a palliative care approach focusing on 'maintenance of patient's comfort rather than maximal survival', led to less discomfort, fewer antibiotic prescriptions, less use of intravenous drugs, and decreased transfers to the acute hospital. Mortality in the DSCU was higher but costs were significantly lower.

The UK Gold Standards Framework (GSF) is a multidimensional programme that supports and trains staff to identify residents requiring palliative or supportive care towards the end of life (<http://www.goldstandardsframework.org.uk/>). It uses a structured approach to recognize when the last year of life may have begun, to assess residents' needs, symptoms, and preferences, and to plan care around these, particularly in supporting people to live and die where they choose. Although not developed specifically for residents with dementia, the GSF developed for care homes attempts to enhance communication between GPs and other specialists, particularly out-of-hours care. Introduction of the GSF has been shown to increase the proportion of residents who have an ACP and to reduce the numbers admitted to acute hospitals (Badger et al., 2009).

Interventions in the community

The Palliative Excellence in Alzheimer Care Effort (PEACE) Programme is an American programme set up to improve end-of-life care for people with dementia. It takes a long-term disease management model, integrating 'palliative care into ongoing comprehensive primary care of persons with dementia over the disease course, from initial diagnosis to death' (Shega, 2003). The patient-centred principles of the programme include ACP, education on the disease process, improved care coordination, and family support. This is implemented by clinical nurse specialists who coordinate care between families, physicians, and other health and social care professionals. Those involved in the programme were more likely to die in hospice or a place of their choosing, less likely to die in the acute hospital, and their carers were more satisfied with the quality of care received.

Palliative and end-of-life care

In the UK, the 'Hope for Home' service has supported people with severe dementia and their families, providing a multi-disciplinary and holistic model coordinated by a specialist in old age psychiatry. Preliminary results have shown that total cost savings of home care compared to nursing home care for 14 people was £696,930 and that 57% of participants died in their own home (Treloar et al., 2009)—a significantly higher proportion than would be expected in the UK general population (22%) (Gomes and Higginson, 2008).

Carers and relatives: Burden, grief, bereavement, and support

As the number of people with dementia increases, so also will the number of family carers, with current estimations in the UK of 670,000 (Lakey et al., 2012). Given that the period during which people with dementia require ongoing care is generally longer compared to other illnesses, this means that carers of people with dementia have a potentially long and tortuous journey ahead of them. Many carers are spouses and therefore likely to be old and to have physical or mental health needs of their own, to the extent that these may hamper their ability to provide care to the PWD (Denning, 2011).

However, the relationship that the carer had with the individual prior to his or her illness still remains and 'carer' is an additional but not a replacement identity for previous relationships and roles, e.g. husband or son. The changing nature of the relationship often requires physical and emotional adjustments throughout its course and it can bring a number of pre-death losses that cause caregivers to grieve (Liken and Collins, 1993). Liken and Collins stated that even when family carers are able to work through their pre-death grief, they cannot fully re-establish their lives until after the death of their relative.

It is often assumed that when a PWD is admitted into a long-term care environment this largely resolves the carer burden and stress. This is often not the case and may leave the carer with feelings of guilt at 'giving up'. They may feel they have gone against the expressed wishes of their loved one and they may have a sense of failure that they were unable to continue with care at home (Givens et al., 2011a,b). This can manifest itself in the carer at times being overly critical of the care provided, so it is important to consider that the previous levels of burden and separation stress (Kiely et al., 2008) may not be resolved and are in danger of going undetected and unsupported. Providing support to carers, recognizing the circumstances in which they find themselves, and allowing them the opportunity to talk about their situation can enable some to provide at-home care for longer periods prior to institutionalization (Etters et al., 2008).

Loss, grief, and bereavement

Caring for a PWD is considered more burdensome and 'unrelenting' when compared with other long-term conditions (Sachs et al., 2004), with

Palliative and end-of-life care

increased vulnerability to complex or abnormal grief reactions (Schulz et al., 2008). Some carers find that they have grieved so much during the course of the illness that they have no strong feelings left when the person dies, yet others feel a further acute sense of loss when the person dies.

A sense of loss is one of the most powerful feelings that carers of PWD experience. This sense of loss and associated anticipatory grief can be felt while the PWD is still alive, and depending on the relationship with the PWD, the carer may experience grief for many forms of loss (see Box 27.2). How family carers experience and manage their grief reactions to the pre-death losses can influence not only caregiving outcomes but also subsequent adjustment once the PWD has died. It is therefore crucial that their grief is addressed (Almberg et al., 2000; Collins et al., 1993).

Box 27.2 Losses that may be experienced by a carer of a person with dementia

- The person they once knew.
- The relationship enjoyed prior to dementia.
- The future they may have planned together.
- The loss of companionship, support, or the special nature of the relationship.
- Loss of freedom to work or to pursue other activities.
- Loss of finances.
- Loss of lifestyle.
- Loss of childhood when a young person or carer.
- Bereaved female spouses are at higher risk of depression following death of their husbands/partners.
- Separation bereavement when the person with dementia is admitted into care.
- Regret and guilt.
- Loss or lack of social support networks.

In a systematic review, Chan and colleagues (2013) described grief in dementia carers as a complex reaction to losses occurring before and after death, and argued that anticipatory grief is greatest in moderate-to-severe stage dementia and spouse carers, especially when the PWD is

institutionalized. Evidence about the prevalence of grief is less robust, with studies reporting anticipatory grief between 47% and 71% and complicated grief after death in around 20% of dementia carers. Carer depression increases with anticipatory grief. Being a spouse carer and being depressed are the strongest predictors of complicated grief after death (Chan et al., 2013).

It is important that bereaved carers of people with dementia receive follow-up care in recognition of their loss and bereavement. Many carers feel a second, and huge, sense of loss and they may also feel that their life no longer has the meaning that it has had for many years. Often the care services that were present in meeting the PWD's needs instantly withdraw, leaving a void in the carer's life. Carers are often discharged from services that were related to the PWD so their expressions of grief are often not observed or addressed adequately. Care, such as Admiral Nursing, that is delivered with a focus on the whole family affected by dementia will take into account carer issues and provide much needed support after the death of the PWD (Lloyd-Williams et al., 2017; Moore and Denning, 2017).

Conclusion

Older people dying with dementia often have complex physical and mental health needs. These require a multi-disciplinary approach that pays attention not just to physical symptoms but also to their spiritual and social needs, supporting their family carers and the staff that work with them, in a range of settings from community to the acute hospital. A number of promising care initiatives and pathways have been set up, most of which take such a holistic approach, in keeping with the core values of palliative care and the philosophy of those working in mental healthcare of older people. The recent research and policy interest in this field underlines its importance and provides hope that the care of many frail older people dying with dementia can be improved.

The experience of dementia

Chapter: The experience of dementia

Author(s):

Keith Oliver, Hilary Doxford, Louise Lafortune, Carol Brayne, June Hennell, and Tom Denning

DOI: 10.1093/med/9780198807292.003.0028

Introduction: Tom Denning

The clinical and academic worlds have been relatively slow to tune into the voices of people living with dementia and those of their families and others who care for them. The assumption has been that it would be pointless to do so. However, this assumption has been shattered by numerous contributions. These have included books, blogs, films, and documentaries, as well as the emergence of organized groups, such as the European Working Group of People with Dementia.

The heroes of this movement are brave and articulate people who face many obstacles in being heard. One common problem is a grumbling scepticism about their diagnosis, along the lines of: 'If they can speak or write like this, then they can't have dementia.' This issue is met head on, for example, by Kate Swaffer (2016; 2017). There are, of course, many

The experience of dementia

types of dementia, with different presentations, but it is clear from people's first-hand descriptions that they have subtle cognitive difficulties, for example, involving memory, word finding, visuospatial skills, and so forth. The push to diagnose dementia earlier means that the diagnosis may be given to people whose functional impairment is relatively mild and therefore not immediately visible. Importantly, not everyone with dementia is elderly. Therefore, accusing people of not having dementia seems offensive. We wouldn't do this to someone who says they have cancer or heart disease, would we? People who emerge as dementia activists are likely to be exceptional people, but this is not uncommon in other areas of life. For example, members of parliament often come from backgrounds that are far from representative of the constituencies that have elected them.

Diagnosis is clearly a turning point in people's lives—one that is often regarded with great dread as akin to a death sentence. However, it is clear that the reality is more subtle. From the clinical point of view, it would be helpful if giving a diagnosis of dementia led to tangible health benefits, such as increased survival or fewer hospital admissions. Objective evidence for this, though, is lacking (Dubois et al., 2016b; Pimouget et al., 2016; Aldus et al., 2020). Nonetheless, from the individual's point of view, obtaining a diagnosis is at least sometimes valued as an explanation of their experiences and an opportunity to access information and support.

This chapter aims to make a small contribution to these areas by following the course of dementia from diagnosis to the end of life, and beyond. Two parts of the chapter are written by people living with dementia (Keith Oliver and Hilary Doxford), about their experiences respectively of diagnosis and life afterwards. The third section (Louise Lafortune and Carol Brayne) considers the contribution of diagnosis and the evidence for and against identifying cases of dementia at the earliest possible stage. Now that it is possible to diagnose Alzheimer's disease prior to any symptoms, it makes it important for us to consider what the risks and benefits of this may be. The concluding account is provided by June Hennell, who cared for her late husband. In this chapter, we aim to present a balanced and authentic account of certain aspects of the journey through dementia.

Getting a diagnosis: Keith Oliver

The day began normally. The sun was shining. The BBC Breakfast weather girl predicted warm sunshine which pleased me as a trip in the sun is always better than in the rain. Dinner duty back at school awaited me, and it is *much* less hassle if the children are able to run around outside. Today, because it was so dry and warm, they would have the added bonus of playing on the field.

The experience of dementia

My wife Rosemary and I arrived in good time. I hadn't been to this hospital before so I was more nervous about being late, and not finding the right reception area, rather than to receive the results of my MRI scan. Why would I need an MRI scan if I had problems with my balance and ears? I only briefly dwelt upon this question. I was relieved to be met by a friendly receptionist in a quiet, rather than crowded, foreboding waiting area. A promising start. What time is it? ... 10:15 ... my deputy would be standing in for me and conducting the assembly today. I did chat to her before leaving school last night and we agreed the story and the hymn—a story about being positive, and the hymn we chose was 'One More Step Around the World I Go'—that should go with a bounce as always, the children love that one.

Exactly on time the neurologist's nurse calls me in to have my weight and blood pressure checked. All very routine, I'm assured. Back into the waiting room. Break time back at school now—again, thank goodness for the sunshine.

Thoughts of school were interrupted by 'Mr Oliver, will you please come this way?' I was led, accompanied by Rosemary, across the waiting area to a typical doctor's consultation room. Square. Modern. Paperwork strewn across a table. Computer screen idling on the corner of a desk. NHS files much like the Department for Education equivalents in my office. And there, centre stage, was the neurologist, who, until this moment, was merely a name on an appointment letter. In the next few moments this was to change, but not only that: you could also say that my *life* was to change.

The consultant then asked us to take a seat and asked a series of questions about my health, why I had gone to my GP a month or so previously, to which I explained about the falls, the tiredness, the inability to concentrate, the petit mal type phases recently experienced. He listened intently to what seemed like a long explanation, but wasn't really. Then he embarked on a series of what I thought of as silly questions, what month is it, what season, who is the prime minister, count back from 70 in sevens—all very easy. Then onto him reading three words and asking me to repeat them—I hadn't a clue, where are we at this moment—can't remember the name of the hospital but it's in Margate, isn't that good enough? Then the three words/objects again—still they didn't register. This prompted him to pause and turn his attention (and ours, too) to his computer screen.

'Well, Mr Oliver, I think that the results of your scan and what you have said to me today is consistent with early stages of Alzheimer's disease.'

He went on to say that the GP had referred me for the scan to rule out a brain tumour. He assured me there was no tumour. Along with Alzheimer's, this was the first time this possibility had been mentioned.

The experience of dementia

I was speechless. My wife was speechless. He sensed our shock, and went on to explain that this was at the moment only a suggested diagnosis and lots more tests and scans would be required in order for it to be confirmed. He then drew two helpful pictures, showing as he described it, a healthy 54-year-old brain; and then he drew mine based on the scan—he did try and explain the scan to us, but it was too difficult to draw sense from it. The comparisons illustrated by the drawings were helpful then, and subsequently, as we came to terms with the diagnosis and tried to explain it to our friends and family. By now I was regaining some sense of the moment. I began to realize that we'd need to have a serious dialogue. The first question revolved around the subsequent tests and scans. Then we moved to talk about carrying on working, which was what I wanted to do.

Next, we raised the question of our forthcoming, long-booked, annual trip to Australia. We were alarmed by his response to this which was ... not to go. Despite our remonstrating that 'everything is planned and paid for', his advice remained the same. Subsequently, I reflected upon this. I was determined, with Rosemary's support, to go ahead with the trip, albeit with a slightly amended itinerary, so I wrote to the neurologist to say I felt with us visiting friends and having been many times before the benefits far outweighed any potential risks. Thankfully, he was kind enough to send a written reply stating that if I felt well enough, then I should go. It left me though with the thought (which I've never forgotten) that had I taken his advice, as many people would have done in that situation, we would have missed a wonderful trip. And it has subsequently been followed by four more trips to South Australia, our beloved place in the sun.

The sun was still shining as we emerged from the confines of the hospital. I suggested to Rosemary, 'Let's have a walk on the beach nearby'—a favourite spot of ours, to clear our heads and take stock—and 'I'll ring school to get someone to cover my lunch duty.' That's what we did, and I turned to Rosemary the moment we felt the sand under our feet, and I said, 'One door closes and one door will open'. I didn't know which door it would be, but I was to be proved right.

Beforehand

I had been in teaching for 35 years and was the head of a primary school. I had all the skills and experience that you'd expect. I could meet deadlines, multi-task, and use a computer with a fair degree of expertise. I would keep my office door open so as to be accessible, and I could cope with the resulting distractions that would waft through into my office.

Health issues had been creeping up on me for some while, but in the last three months I had noticed more significant changes that I could no longer simply ignore. I had some unexpected falls. I felt wobbly, as if I was on a boat, all the time. I had fatigue and felt generally slightly unwell. I went to see my GP, who thought I might have an ear infection so he

The experience of dementia

prescribed antibiotics. When these had no effect on my balance or health, he arranged an MRI scan and soon after that followed the appointment with the neurologist.

During the process of diagnosis

Having left the tender care of the neurologist, I landed up soon afterwards in Canterbury's Memory Clinic. My route through the continued assessment was complex because, despite my difficulties, the last thing I really wanted was a confirmed diagnosis. I tackled each assessment as being crucial and I tried to retain a positive attitude allied to a real determination to score as highly as possible. I quickly developed coping strategies to protect myself from my difficulties—something I still do. Over a period of three months, I had a number of cognitive assessments. I gave 100% effort to all of these and I would come away exhausted. I was extremely well supported and informed by the psychiatrist, the clinical psychologist, and her assistant. Every assessment was scored, analysed, and reported back to me at each stage. Gradually, a comprehensive picture emerged. In some areas I was functioning at best at about the 40th centile, but at worst was performing in the bottom fifth centile. This was really alarming, as especially with my background in education, I understood very well what this meant. Only nine months earlier, despite some worries at the back of my mind, I'd been well on course for an MA in educational leadership. By now, even following Coronation Street was a challenge.

At work, I was having some difficulties. I found I could not retain information so well. Not so much that I had problems with my memory—it was more that I found it hard to take things in or to bring information to my fingertips. I could only concentrate on one thing at a time. I began to have difficulties answering the phone. I confided my situation to my deputies and to the school secretary, as I thought they really needed to be aware. I managed to carry on to the end of the school year. The staff were beginning to be concerned that there might be a problem with my health. Over the summer, I reflected on my position, which was beginning to seem untenable. So, I returned in September for the first two days of term, and then took sick leave. When eventually I received a definite diagnosis, this brought my teaching career to an end on 1 April 2011.

Subsequently

People know how dementia is portrayed in the media, and by large sections of the public, and thus they are often frightened and can be depressed. Giving people encouragement to live in the moment and to take each day as it comes is essential. Coping strategies to recover and retain one's own personhood, skills, and enthusiasms are essential. Positive living requires the person living with dementia and those close to them to accept that not every day will be as clear as we would wish for.

The experience of dementia

What we need are services that provide the opportunity for people to be interdependent, so that they can relate to others on a range of levels. Some people like the dementia cafe type model. Others prefer more active collaborations, such as the writing group we established through the Forget Me Nots, which is an active service user group in East Kent. Some people want to live life without reference to dementia; others want to fight it, others to live with it, and others alongside it.

Through person-centred care, I want to see a range of therapies and activities made available to people which are local, interesting, and accessible. Please keep people living with dementia on the radar—what is rejected now might be extremely helpful and appealing later. A care plan is central to the notion of Dementia Pathways. It must be written jointly with the person and a clinician and reviewed at a relevant period, perhaps every six months. A care plan worthy of the name should monitor the person's wellness in the light of the Pathways they are following, not solely their medication. The emphasis needs to be both realistic and positive. I remember being offered antidepressants on two occasions because the doctor—the neurologist—felt I would need them. However, I never cashed the prescription, and I know other people who have done the same. For some it might help, but medication shouldn't be regarded as the first solution.

Resources, such as post-diagnosis groups, are very inconsistent across the country. A range of disciplines such as clinical psychologists, psychiatrists, and occupational therapists need to be available. Some people are comfortable with the support of the GP, but others feel that the GP lacks knowledge and understanding of dementia. The worst feeling is that sense of being on one's own, with little or no effective support from outside the immediate family or social circle.

We must ensure that agencies work together and that the person with dementia is at the centre of this collaboration, not each vested interest or agenda. We need much better signposting and mutual support for professionals and the public. We *must* avoid the notion that the clinician's sole role is to diagnose and then hand over to the voluntary sector: some of the best post-diagnosis support that both I and others have received has been from clinical psychologists via these groups and through their support of the Forget Me Nots.

Often it is helpful to use metaphors to describe what it is like to live with dementia. One of the most accurate is that of the weather—the foggy days that are challenging and difficult, the cloudy ones when some things are clearer than others, and the sunny days we crave. In your reading of this account, I appreciate your consideration and consequently making it a sunny day for me.

After the Diagnosis: Hilary Doxford

The experience of dementia

I was diagnosed with early onset Alzheimer's disease around December 2012. Since then, I have discovered I am one of the 25% of people given an Alzheimer's diagnosis that has the symptoms but does not have amyloid plaques in their brain. I have not been re-diagnosed or un-diagnosed. I am still in the early stages and some would probably say I have mild cognitive impairment (MCI), rather than the dementia diagnosis I have been given.

Five years on, my cognitive function is still above average but my short-(and now medium-) term memory is extremely poor. It was my failures on the memory tests and scans showing brain shrinkage that were the basis of my diagnosis.

I have been reading back over my notes and presentations made since I was diagnosed to help me decide how to present my thoughts and experiences. Initially I was thinking of having two sections, 'before 2017' and '2017'. But I have decided I can see four clear phases of my life since I was diagnosed:

1. Post diagnosis: The first five months
2. May 2013 to December 2016
3. January to September 2017
4. October to December 2017

I have decided on these as health wise, functionally, and emotionally, I can identify tangible changes within each period.

Post diagnosis: The first five months

Health

Unlike many people, I cannot recall the date I received the diagnosis, it was sometime in late 2012.

Although not wanting to hear it, I was relieved to receive the diagnosis as I finally had an explanation for my concerns of the last seven years. Now I could deal with something tangible and move on, instead of living a life of stress and worrying about the changes I was experiencing. I firmly believe that as an individual you can make a difference to the trajectory of a disease and, even if that is not true, you certainly can take control of what happens with your life whilst you still have your faculties.

My first question on receiving the diagnosis was, 'How long have I got before I will need support and care?' The answer was 18 months to two years. That bleak statement had a profound impact on my life over the next five months. Sleep became very interrupted. My brain would not switch off until the middle of the night as I tried to work out what to do with my remaining time and adjust to the impact I was going to have on my husband Peter's life.

The experience of dementia

I was offered one of the standard drugs, which I took for a while but did not feel well, experiencing several side effects, the worst of which was falling over. The third fall was a particularly bad experience, when on a cold February day, we went to Weymouth to check our boat was OK. The ropes were slack so whilst Peter went on board, I started re-tying the ropes. I do not know how it happened, but one minute I was on the pontoon, the next I was in the freezing water, not knowing where I was or what was happening. I just knew that the rope in my hand was important and not to let it go. Fortunately, Peter and a friend managed to get me out. Peter decided that day we were selling the boat as I was unsafe. It is the biggest regret, as we loved that boat and loved being at sea: it was our escape from the stresses of life. That added to my guilt. I stopped that drug and tried an alternative. The first day I took the alternative, I thought I was dying: if breathing was not an automatic action, I would have stopped. I decided no more drugs; I would rather have a better quality of life even if it was for a shorter time.

My second question on being diagnosed was, 'What research can I get involved in?' The answer, fortunately, was 'I don't know'. I say fortunately, as being given no information I did my own research into research. Having worked as General Manager for the UK Renal Registry I knew a fair bit about clinical audit and research, and so I applied to become a research network volunteer for the Alzheimer's Society. The result of that has transformed my life, enabling me to 'live well with dementia' and I am convinced that this has helped to slow my decline. As I became more involved, I moved away from feeling desperate and fearful to a place where I experienced possibly the most contentment in my life so far.

Functioning

On being diagnosed, I am grateful that I did not hand in my notice at work as I am convinced that continuing to work has helped keep my brain active. I did tell my boss and immediate colleagues as they were having to deal with my oversights and memory lapses.

A close family member was ill at this time and so Peter and I decided not to tell anyone else about the diagnosis as we did not want to add to their worries. After all, nothing had really changed from yesterday other than I had probably lost some more brain cells and I now had a name for my troubles.

Emotions

On a practical level, it was 'business as usual', but I developed an overwhelming feeling of guilt at the burden I was going to be. Having been very independent (and selfish) I did not want to have to rely on anyone.

The other thing I was dwelling on far too much was the late middle/end stage of the disease. As I had only been married for four years, I was dreading the day I would not recognize Peter, would not understand that

The experience of dementia

people were trying to help me, and would not be able to tell people when I was in pain. I decided I was never going to get to that stage and started looking into Dignitas. Once I understood what needed to be done, I did nothing more for the time being. I was angry at the UK's stance on assisted dying as it meant that I would have to go to Switzerland sooner than perhaps necessary to ensure I could get myself there independently. I did not discuss any of this with anyone, especially Peter, as I knew I would upset him very much.

May 2013 to December 2016

For the next three and a half years, I continued to work and the rest of my time was taken up with voluntary work and also participating in research studies and trials.

Health

I started to take high doses of vitamin B following a research paper I read. This had a noticeable (to me) effect on my brain function. Within a week or so, I felt as though my brain had improved to where it was two or three years earlier. Whether this was a placebo or actual effect did not matter to me: it made a tremendous difference, especially at work. My boss said I had stopped giving him blank stares when he was asking me about projects. And amongst other benefits, I was again able to remember the names of new staff members, as it had become embarrassing in meetings when I was unable to introduce them.

I had a 12-month follow up appointment after the diagnosis. I was excited as I believed I was managing quite well and that my decline was slow. I wanted this confirmed. I saw a different neurologist this time and he confirmed, as I hoped, that things were stable although he would not change the diagnosis.

Twelve months after that appointment I heard nothing. I was expecting another appointment so I called the memory clinic to be informed I had been passed back to my GP and they would not see me until I was re-referred. I was annoyed that I found out this way, but went to see my GP as I needed my driving licence to be renewed. I told him that I really wanted to know my rate of decline to give me some idea of what I should be planning for, and when. He said he would be happy to refer me again but, as I thought about it, I know the pressures the memory clinics are under and felt I was being selfish as the tests were not essential.

Functioning

During this period, it was easy to hide any difficulties I experienced. My IQ was still well above average and memory problems were addressed with better note taking and using reminders.

Over this period, I noticed that I had to focus more on completing a task in its entirety. I could not pick up a partially completed task without

The experience of dementia

having to work through it again from the beginning. My typing accuracy was declining—I could not believe what I typed sometimes. Words would appear on the page that were not even in my conscious mind. Easily dealt with, it just needed more focus on proof reading. The downside though was that it took me up to 50% longer to do stuff. I did not want work to be aware of the difficulties so I would work longer hours to deal with it.

I would have meetings as required with my boss to discuss any changes we needed to make as a result of my declining abilities. He was very supportive and recognized that, after ten years of working for the organization, I had a 'knowledge capital' that was still of use. He said to me, 'You focus on what you can do and I will take care of the rest'. We did change my line management responsibilities. People who were not performing would sometimes exploit my memory issues to their advantage. Several times I was told I had said something I just knew I would not say, but I could not put my hand on my heart and tell them they were making it up. As a result, I felt much less confident. After this, we restructured and I now managed a small but incredibly supportive team who became Dementia Friends and understood my difficulties. Long sentences, complex paragraphs, and busy PowerPoint slides were hard to deal with, but I would break things down and get by.

Away from home, I do not like background noise. It distorts things and I find it hard to concentrate. However, conversely, I also find silence extremely stressful. I have to have the radio or TV on in the background at home and I seem to be able to shut it out and focus on the task in hand.

During this period, learning became a real problem. Stuff would go into my brain OK but I could not retrieve it when I needed it. If I was given a prompt or trigger, out it would come. Peter would frequently say, 'Can't you try a little harder to remember?', and I would respond with, 'I know whether or not I know the answer.' But I did start to wait a little longer before responding, and he was right, sometimes when I thought I did not know the answer it did, in fact, come.

I have learned a new memory trick. I noticed that if I imagined what I wanted to remember on a blank piece of paper then I do better at recalling it. I assume I am using my 'photographic' memory. I am not aware that I used this in the past. It still helps now; I even managed to recall a full address on a memory test. Maybe this is why I can still recognize people I have met only once, but have no idea of who they are, their name, or where I met them. I just know I have met them. There are always the funny incidents. I attended a two-day meeting and, going down for breakfast, I went and sat with a man I believed had been in the meeting the previous day. Taking out my notes I proceeded to enlighten him with my thoughts for 20 minutes or so. It gradually dawned on me he hadn't a clue what I was talking about, but he was very polite, making appropriate noises or nods as I rambled on. Eventually I said, 'You are not who I think you are,' which he confirmed, and I made a hurried exit.

The experience of dementia

Another thing I noticed was that I used to recall my dreams vividly. Now I was either not dreaming at all or, if I had dreams, I could not recall them when I awoke. But, strangely, I discovered that if I got stung by nettles when walking the dog, more often than not, I would recall a dream the next morning. I started deliberately walking through nettles to see if it would help my recall, and it seems to do just that.

Satnav has been a saviour. I can no longer visualize a route I have been driving for eight years; instead, it appears as a jigsaw with missing pieces. When I was younger, I only had to drive a route once to know it for the future.

Emotions

At the end of 2013, Peter succumbed! Having heard dogs were good for people with dementia, he allowed me to have Tilly, who needed a home after a colleague moved abroad. He now loves her as much as I do and she makes such a difference when I feel low.

Peter is very sociable, and we would have visitors every weekend. I started to isolate myself and put a stop to having visitors and going out. This was primarily because I felt that I had nothing to talk about. I could not remember what happened yesterday, let alone last week. As a result, I started finding socializing very stressful, so I avoided it. One afternoon, driving home from work, I passed a massive barn fire with all the emergency services present and cows being herded to safety. 'Must tell Peter about this', I thought. When I got home 15 minutes later, it had gone from my mind, despite the usual 'anything exciting happen today?' question. However, it was so dramatic that it made the evening news, and then of course I remembered, 'Oh, I passed that on the way home'.

Another example of my shocking memory: we were fortunate to be invited to the Queen's 90th Thanksgiving Service, so I took a day's holiday to go but did not tell my colleagues where I was going. When I went into work the next day, they asked what I had been up to and I had forgotten I had attended the service. I could remember I had had a good day, but not why.

Over this period, I noticed I was becoming irritable and impatient, often with no valid reason. For example, I would get angry if a driver overtook me—how stupid; he was perfectly within his rights.

Decision-making was also harder, I would fret that I had made incorrect decisions. I would go over the facts as I could recall them time and again, trying to work out if I had missed anything essential. As a result, I started to avoid taking responsibility or making a decision.

I also started to eat more and gained three stone in weight.

During this period, I got involved in so many activities. These included media work, becoming a champion for Join Dementia Research (about which I am passionate), and also a member of the World Dementia

The experience of dementia

Council and the Government's 2020 Dementia Programme Board. This involvement has forced me to keep my brain working. It has also given me so much hope but also frustration, in that I was seeing first-hand just how much was going on in the UK and around the world to improve the lives of those affected, but this was not being shared with those who really need to know. I saw examples of excellent practice and novel ideas that worked but many of these seemed to stop at a publication in a journal and presentation at a conference. In my view, policy makers, the research funders, and the researchers themselves place insufficient focus on dissemination and implementation.

Among other things, I also visited the dementia village at Weesp in the Netherlands. That visit convinced me that I could live with dementia even into the later stages, and so I now feel that I will not be travelling to Switzerland. Others need to see and know what is achievable. There is no working group of people with dementia in England, so I and some friends decided we needed to set up a group covering England, Wales, and Northern Ireland. That group is now known as the 3 Nations Dementia Working Group. At the time of writing, we are still a small group, but we have big ambitions to help and inform those affected by dementia.

January to September 2017

So, to 2017, where for the first time, I would say that my niggles are starting to become problems and issues. I have had to work much harder mentally to appear 'normal'.

Health

Another twelve months on and back to the GP for my driving licence review. I felt that there had been changes in my cognitive function this time and really wanted to do the tests again to see if my feelings were justified. This time I was told that unless I took treatment, the memory clinic would not see me. I laughed, as I wondered what treatment they could be talking about. It seems crazy to me, that I have to take drugs that I know will make me feel really ill in order to be referred. I just let it go, as again, despite changes, I can still manage and my GP was not concerned about my abilities. Also being involved in a clinical trial and other research studies, I was getting a lot of information on my condition, including the scan that showed that there was no amyloid deposited in my brain.

Functioning

I never appreciated that just thinking required an effort and could be so tiring. I have started to need to use quiet spaces to stop me wanting to scream out loud at times. In the past, I asked my brain for something and it would be delivered with no effort on my part. I now realize what a gift of a brain I had been given and regret I did not use it better. I was a member of Mensa, and it is only now I realize how hard some people must have been working to do what they did. As a manager, I know I was not

The experience of dementia

the best and I wish I had had the insight back then that I now have. I must have made people miserable over the years by making unreasonable demands and by not appreciating that what was easy for me may not be so easy for others. I went from being a person who could instantaneously multiply two four-digit numbers to a person who cannot multiply a two-digit number by a single digit. It is demoralizing.

Things became increasingly difficult, to the extent that I decided I had to stop working in July 2017. I could still perform administrative tasks but more complex problem solving and dealing with management issues was too hard. In addition, my memory issues were getting worse, for example, I could no longer remember the names of colleagues who had recently joined.

I can no longer follow a plot or storyline in a book or on TV. However, I love documentaries and quiz shows, where I do not need to remember what's gone before. I may not remember anything afterwards, but it does not matter as I do not need to. This has advantages, as if I forget to watch something I wanted to see, I do not remember that I've forgotten!

For the last few years, I have been happy to travel alone in the UK, only wanting Peter with me when we go abroad. This is changing. I now find going to a new place quite stressful and occasionally frightening. I feel like I am adventuring into the unknown and do not like it. I am still doing it, but I feel that it will not be long before Peter will need to come with me to new places.

I like to do puzzles, both of words and numbers. This year, cryptic puzzles have become all but impossible. When driving to work, I used to work through the alphabet trying to name places beginning with each letter. A few years ago, I could manage 50 place names for most letters, this year, I am lucky if I can manage 10. So, I feel things are getting worse, although most of these difficulties are still easy to hide.

You had better not come to us for a meal more than two or three times, as my repertoire seems to now consist of three dishes. I cannot decide what to cook, and so I stick to the tried and tested of recent times. I have also noticed that I wear the same clothes over and over, my 'comfort' outfit. I cannot decide what suits me and what matches, so again I stick with the tried and tested.

Emotions

Emotionally, this year has seen changes. I do not know if it is the dementia or something else.

I thought stopping work would be really hard to deal with, but although I miss the structure it gave me, I have a great sense of relief and I had not appreciated how much I had been stressing over it. At least my voluntary work more than fills my days. However, one fear that I had about stopping

The experience of dementia

work has come true. I feel my brain is slowing down and the cognitive difficulties are increasing.

Work worries have now moved to financial worries. Because of my relatively young age, I have a six-year gap with no income to manage before I am eligible for my pension. I am hoping to be able to work in an admin role or maybe in a care home.

I am really struggling to deal with examples of cruelty, both to people and animals. It upsets me greatly and ironically, I can remember it all too well. Animal charities sending literature with distressing photos play on my mind, and the TV adverts showing the appalling conditions people have to live with will not go away. It makes me feel helpless and hopeless. I cannot find a positive way of managing these emotions. I am finding it difficult and sad.

Words have always moved me and now I have to be careful with what I listen to when people are around, as again I have trouble controlling my emotions. I find it difficult to manage when things go wrong, even when they are out of my control. I have always been a bit of a control freak, but now I find it even harder to cope when things do not go according to plan. I rely more on Peter: in the past I would never pass a problem to him but now I find myself doing so more and more.

I really struggle to answer questions and make decisions that come out of the blue. I was at the fish counter and the assistant asked me whether I wanted it in a 'cook in' bag or a normal bag. I had decided what fish I wanted, job done I thought, so the follow up question totally threw me to the extent that I almost walked away in tears. Looking back, whichever answer I gave did not matter, but in the moment I could not rationalize.

I struggle to start up conversations on the spur of the moment. Previously, although I did not like socializing, I could start up a conversation when I was out walking the dog. If the other person has a dog I now rely on my 'stock' pieces: 'he's a lovely colour,' 'what a lovely face'. If they have not got a dog, I will not engage in conversation as I have nothing to say.

I have become very nostalgic. I have always had an interest and a love of history and archaeology, but this is different and new. I want to watch programmes and events from the 1940s to 1970s, despite being born in 1959. I find it comforting and easy.

I am now feeling that the world is moving on without me. I cannot keep up with all that is happening and I struggle to understand interactions, cause, and effect. In particular, technology is worrying me. I have always worked in or close to IT since the days of DOS programming in the late 1970s. Now, I do not 'get' social media. I cannot understand many Twitter messages and I do not have the time or desire to read unimportant (to me) trivia.

The experience of dementia

However, then I worry that if I do not read them, I will miss something important. I worry that my bank account is going to be cleared out online or my identity stolen and so I do not feel in control anymore. I am starting to feel that I could take the easy way out and give up, handing everything over to Peter. But then I fear my decline will speed up.

October to December 2017

At the beginning of October having been out of work for two months, I felt I needed a 'reboot' and decided I was going to join some local groups, get fit, and lose the three stone in weight I had put on. I found a ballet and dance group for the over 50s and was about to sign up, when I slipped in our local woods whilst walking Tilly and broke my leg very badly (the second worst break that the surgeon had seen in his career). Ten weeks on and the bones have healed very well but I still cannot walk or even sit at a desk for very long.

It has been a reality check as to what it means to be disabled, albeit I hope temporarily.

I was in hospital for a week on a dementia ward. The staff were wonderful but stretched. The patients had no cognitive stimulation, no TV, radio, or other activity. I could see people declining over the week. The dementia-friendly clocks in the bays were great as they showed the day and date, but it was just a pity they showed the wrong day and date.

I had only one what I would call 'dementia moment'. I had been told the operation would take three to four hours. The anaesthetist came to see me and asked me if I wanted to have an epidural and remain conscious whilst they fixed my leg. I was not expecting the question and could not answer it. I felt he wanted me to have the epidural, whereas I had no desire to be awake. I got upset and was incapable of making the decision or assessing the pros and cons. Fortunately, the surgeon made the decision for me and I was knocked out.

When I came home, I found things noticeably harder. Possibly this was partly due to the pain, but I also felt that my cognitive function had declined. As we drove home, we were held up at a roundabout and I tried to count the cars in the queue ahead of us and could not do it. I kept thinking I was missing cars or counting them twice. Getting dressed, when putting on a strappy top, my arms would go through the wrong bit. Never a problem before. It is still early days, so maybe things will improve.

I am very frustrated at how long it takes me to do anything. The weird thing is every morning, when I wake up, I feel that I have only just injured myself. I have an overpowering feeling of déjà vu rather than a continuation of the recovery. I have never broken my leg before, but every morning I feel as though I am reliving a previous injury. When I think about it, I am frustrated that the fall has so far wasted three months of

The experience of dementia

my life. But it does not feel like three months, my brain compresses anything dimensional into a 'moment', rather than real time.

All this has made me realize how hard it is to live with a disability and to stay positive. It is making me wonder how well I will cope if my decline continues. For now, it is easy to say I live well with dementia but I am becoming more aware of the difficulties that lie ahead.

Closing thoughts

I know how lucky I am.

I am constantly impressed by what people with dementia can achieve. I have a wonderful circle of friends and we support each other as we can comprehend each other's difficulties. Like everyone, we have good and bad days. Our bad days can be very depressing.

It was not until my brain stopped functioning as it once did that I appreciated the gift of a brain I had been given. Thinking was never tiring, but now I find it very draining.

There are those who question whether or not I have dementia. I have questioned it myself over the last few years. Then I stop and think about the difficulties I have now compared to before and how much harder it is to perform everyday activities. The changes are significant to me, although apparently not so to others. I know there is something wrong with my brain.

Two things in particular give me a wonderful life: my amazing husband and my adoring and adored little dog. They give me purpose and something to live for. I continue to live for today and count my blessings. I take time to enjoy the world and all that is good. Peter is my greatest blessing and my greatest worry. I know he will sacrifice his health and happiness to look after me and that worries me. He is a saint and my greatest sadness is what lies ahead for him.

Today, I do not need Peter as a carer, but I know if he were not always there quietly supporting me and loving me, things would be very different. I would be living in fear, but for now the fears I had are long gone.

The Serenity Prayer is now my mantra:

God, grant me the serenity to accept the things I cannot change

The courage to change the things I can, and

The wisdom to know the difference (*Reinhold Niebuhr*).

The experience of dementia

Postscript

It is now April 2020, over two years since I last wrote. Quite a bit has changed for me.

My leg as predicted took nearly two years to repair, and 30 months on I am finally able to run again. I am still not working but need to find some form of employment. I have continued with voluntary work.

As for my dementia diagnosis, this is now being challenged by myself and others. Last summer, I was at a meeting at the Department of Health where a clinician I had not met before told me I did not have dementia. Initially, I thought, 'how can he say that based on hearing me speak during a meeting?' But then I considered that there are times when I wonder myself, and it is now eight years since I was diagnosed and I am managing just fine. This led me to ask my GP last August if I could be re-assessed. He was happy to refer me. I eventually saw a neurologist in January who requested a brain scan, which I had in February. Then coronavirus arrived in the UK and I am now waiting for the results. So, as I write, I am in a period of limbo, although I now doubt the dementia diagnosis, especially after reading a paper on Functional Cognitive Disorder (FCD) (McWhirter et al., 2020).

My symptoms and behaviours fit better with the description given of FCD, rather than dementia. My symptoms have not really progressed and in some areas, I feel I am improving or I have found ways to better manage them. I believe my cognitive abilities are stable. My memory problems persist, but there are glimpses of improvement in some areas. Sadly, we had to put Tilly to sleep 20 months ago. These days, my only really strong and detailed memories are of happy times with her and it still feels like only yesterday she was here. But then everything feels like it happened yesterday. I find I do well on remembering future activities such as meetings (ironically, missing meetings was one of my earliest problems). Strangely, once they have occurred, I have the same problem of retrieving and recalling them, even though I knew for weeks ahead what they were and when they were going to happen.

With the doubt over my diagnosis, for now I have stopped doing any voluntary work involving the general public but continue to support research and policy work where I feel I can justifiably do so. Some of my friends with a dementia diagnosis have also been told they do not have dementia because of how they speak in public. Several of them have found this very upsetting, as in clinical consultations, they are still being told they have dementia. The most upsetting aspect is the false hope it gives to their partners and family, which I can understand; if it turns out I do, after all, have dementia, I will be very upset for Peter.

The dementia diagnosis changed my life. If it was incorrect, so be it. I have been lucky in that my changed life, if a little more challenging, has still been good and given me many inspiring new friends and

The experience of dementia

opportunities. It has had a significant financial impact, which I think at my age I will not be able to recover, which is a worry. But I understand how hard it is to accurately diagnose and I sought an explanation of my problems.

So today, I live in hope that I have FCD, that it will remain relatively stable, and that I will be able to find employment. I intend to put to good use what I have learned about dementia over the past eight years.

The contribution of an early or timely diagnosis: Louise Lafortune and Carol Brayne

To consider the importance of diagnosis we should start by listening to the voices of those who have direct lived experience of dementia, either through having a recent diagnosis themselves or by virtue of caring for someone with dementia. People living with dementia who have written and spoken about their experience have often drawn attention to delays in diagnosis and also advocated the benefits of early diagnosis. Although this sounds unobjectionable, it is worth thinking about some of the implications of this call to action.

It is likely that people writing about their own dementia may not be typical of the wider population with the condition. For example, they are likely to be better educated and to have had a younger onset of dementia than the majority. They may also have less-typical subtypes of dementia. On occasion, unfairly, doubt is even raised as to whether they really have dementia (for a discussion of this issue, see Swaffer, 2017). Therefore, while the accounts of dementia activists are extremely important and to be welcomed, we have to accommodate these alongside a bigger picture of hundreds of thousands of people with dementia who are less public in their views.

This section discusses some of the issues raised by diagnosing dementia, and considers the relative merits of screening, early diagnosis, and timely diagnosis.

The meaning of a diagnosis

There is a large literature on this area, most of which reflects that, until recently, dementia disorders have been diagnosed relatively late. Even cancer and heart disease tend to be diagnosed at the point of an event or through formalized screening. Under these circumstances, diagnoses are delivered by health systems and through particular investigations of reasonably well-established validity and prognostic value.

For conditions that are less straightforward, and involve clinical manifestations that are distributed in the population in a continuous manner, diagnosis is much more of a challenge. Conditions such as autism, dyslexia, and dementia fall under this area. However, the fact that dementia is subtyped into a series of ‘diseases’ suggests, wrongly, that

The experience of dementia

the situation is more clear cut, and that the existence of the condition is a simple matter of yes or no.

In dementia we have the additional challenge that its frequency varies greatly with age. The dementia syndrome is very common indeed in extreme old age, with decline the norm towards the end of life in these ages. In contrast, dementia in middle and early late life is relatively rare. An individual with dementia at these ages is manifesting cognitive change at an age when this is unusual, rather than common, as it is in the ninth or tenth decade. Thus, the meaning and value of a diagnosis will vary according to age.

Diagnoses are made for many reasons—to establish the appropriately effective treatments, to provide prognoses, to label an individual so that that person or those around them can receive appropriate and available support, and as an explanation for changes that can be bewildering, distressing, and frightening without a label.

The tendency in modern dementia research is to push for biological definitions of disorders at earlier stages, even in the absence of clinical symptoms. In these circumstances, we need to think carefully about what we really want in relation to the diagnosis of dementia. Especially, we need to consider carefully, what is meant by, and what are the implications of the terms ‘screening’, ‘early diagnosis’, and ‘timely diagnosis’.

Individuals will need to consider what might be meant by an ‘early’ diagnosis, when there is little clear evidence of what the future implications of this may be. Societies should be concerned about the value of having substantial groups of people carrying labels of risk for dementia. This already occurs in the case of hypertension, where treatment is offered to asymptomatic people in order to reduce the risk of stroke and heart disease, but with the consequence that vast numbers of individuals are treated. Although the risks of major events are reduced for the population, the health care system incurs costs for all the treatment offered and the individuals are labelled as having a condition and placed at risk of side effects when they individually do not benefit.

The nature of dementia

‘Dementia’ describes a progressive clinical syndrome that encompasses difficulty in memory, language, and behaviour. When the resulting cognitive impairment is sufficiently great, such that there is interference with daily function, the patient is diagnosed with dementia of a particular type (e.g. Alzheimer’s disease (AD), vascular, frontotemporal, or Lewy body dementia). The incidence of most types of dementia increases with age, but each has its own natural history driven by a complex array of exposure to risk and protective factors throughout the life course. There is a growing consensus that the pathological process in the brain of

The experience of dementia

people with dementia starts between ten and 20 years before the occurrence of the first dementia symptoms.

In turn, the clinical features that, when seen together, make up the diagnostic criteria are all continuous such that no fixed event defines the onset of dementia. Furthermore, one of the essential criteria for diagnosing dementia concerns impairment of day-to-day functioning, and this is variable across a range of social and cultural settings. There is thus no 'one test fits all' for dementia within life. It is possible to confirm a diagnosis such as Alzheimer's disease at post-mortem (McKhann, 2011; Beach, 2012), but even this is not straightforward since post-mortems are not often undertaken in routine practice. We also know from population studies that people over 80 years of age (that is, most of those with dementia) have a mixture of pathologies in their brains, and that these changes are also common in those who die without dementia (Brayne et al., 2009). To date, the diagnostic criteria for dementia remain controversial and are still changing (American Psychiatric Association, 2013). Although research criteria increasingly introduce biological criteria (e.g. Dubois et al., 2010), in routine practice the diagnosis still remains clinical and relies upon societal norms for cognition and function.

Greater understanding of the pathology and course of AD has led to it being reconceptualized as a disease continuum (Chen et al., 2016), though this idea is by no means new (Brayne and Calloway, 1988). There is a long phase with no symptoms, followed by a symptomatic phase of progressive cognitive decline, before the onset of functional impairment and overt dementia. As no treatments are available that significantly alter the natural history of the dementia syndrome, there has been an increased focus on dementia risk reduction and a shift towards diagnosing at an earlier stage, before patients have crossed the threshold into dementia (Dubois, 2016a; Jack et al., 2018).

The rationale for diagnosing at the earliest possible stage is that detection of people before cognitive symptoms start (i.e. at the prodromal or pre-symptomatic phase) or in the initial stages of cognitive impairment may lead to better outcomes, such as enabling better planning of appropriate current and future care and support, potentially delaying progression of cognitive decline, and improving general health outcomes for both patients and carers (Lin, 2013; Dhedhi et al., 2014).

Although these may appear perfectly reasonable arguments, this line of thought is controversial for dementia. The most important problem is that, for dementia, along with many other conditions, the more upstream (earlier) you go in the disease process, the weaker the evidence that detection by whatever means is actually beneficial for individuals or populations. So, the question for practice and policy—and society for that matter—is *where* in the disease pathway can we say that our understanding and the supporting evidence is good enough to ensure that we do more good than harm by shifting detection upstream?

The experience of dementia

In the following sections of this account, we discuss what ‘early diagnosis’ actually means, present the current state of evidence for and against diagnosis ‘as early as possible’, and conclude with our view of where efforts should focus to optimize the journey through dementia.

Early versus timely diagnosis

Getting the diagnosis of dementia ‘right’ is high on health policy agendas for many countries. The last five to ten years has seen a steady cultural shift and proliferation of reports calling for ‘early’ diagnosis of dementia (Department of Health, 2012). These policies and the entry of the term ‘early’ diagnosis in public discourse has exposed a debate in the scientific and clinical press of what it actually means.

The prevailing view from many patients, their representatives, and professionals is that a diagnosis should be made as soon as possible in every individual case. This is understandably driven by personal and professional experiences of delays in access to diagnosis and appropriate support. Providing a *timely* diagnosis for an individual person, at an appropriate time, in their particular setting, is undeniably current good clinical practice, even if it is not universally available (Brayne, 2012).

‘Timely’ here implies an approach appropriate for the circumstances of individual patients, of benefit to the patient. It does not tie the diagnosis to any particular disease stage or chronological scale in the way that ‘early’ does (Brayne, 2012; Brunet et al., 2012; Nuffield, 2009). Yet the two terms are often used interchangeably, disregarding their different meanings, and with the emphasis often placed firmly on *early* diagnosis. This is unfortunate, since timeliness is not experienced in terms of simple chronological notions of time and, in the diagnosis of dementia, timeliness involves balancing a range of judgments (Dhedhi et al., 2014).

Until recently, before the current international emphasis on detecting dementia, recognizing and diagnosis of dementia relied on a ‘passive’ case-finding approach. Patients are evaluated for dementia because they or someone else bring a concern about memory, cognition, or behaviour to their GP, or because their GP raises the issue based on their clinical judgment (Mate et al., 2017). If this works well, the diagnosis would be made at the right time for the person with dementia at a stage where they, and/or those around them, will stand to benefit from it. Ideally, we would know from research at what point this is best for people at different stages of their lives, and with different risks of dementia.

However, more recently there have been moves towards much more active case detection—often driven by national policy. This has included estimations of the ‘expected’ number of people with dementia in localities, based on crude age distribution figures, without using the uncertainty limits that rigorous statistical analysis would require. At one stage, it appeared that dementia screening was being advocated, though the authorities have backed down from this in the light of reasoned

The experience of dementia

criticism (e.g. Fox et al., 2013). The evidence for enhanced case detection and screening remains an area without robust evidence. No government or arm's-length agency has yet alleged that the evidence base is strong enough to recommend the costs and implications of nationwide screening programmes.

Evidence for and against diagnosing at the earliest possible stage

In the absence of any symptoms or concerns, early detection of dementia or detection at preclinical stages increasingly focuses on measures of biomarkers from body tissues (Dubois 2016a). This work aims to create large national or international groups of research-ready cohorts who have biomarker profiles indicating higher risk of progression to clinically diagnosed Alzheimer's disease within the individual's lifetime (e.g. the European Prevention of Alzheimer's Disease programme, or EPAD; see Ritchie et al., 2016).

Biomarkers (see Chapter 6 and Chapter 7) include peptides and proteins that are analysed in bodily fluids such as blood, urine, or cerebrospinal fluid (CSF), as well as brain imaging methods (Blennow and Zetterberg, 2018; Weiner et al., 2015). Biomarkers can be used in screening (prognostic markers; see Schaffer et al., 2015), as diagnostic tests for early disease detection (including detection of MCI; see Lewczuk et al., 2015), for predicting disease progression from MCI (Dickerson et al., 2013), and for treatment validation when used to monitor response to therapy (Blennow, 2010; Pillai and Cummings, 2013). The shift towards earlier diagnosis has occurred in parallel to the push for growing use of molecular biomarkers, not only as a diagnostic tool for dementia, but also for detection at the prodromal stage or in people with MCI. So far, not surprisingly, most of this work relates to Alzheimer's disease. Newer strategies include testing for profiles of genes, which together have been shown to confer increased risk (polygenic risk scores, e.g. Escott-Price et al., 2015) or a more individually tailored precision medicine approach using combinations of markers (Hampel et al., 2016).

However, we need to ask ourselves how well such tests perform and to what extent current evidence supports their use. The Cochrane Collaboration has developed a programme of systematic reviews of Diagnostic Test Accuracy for Alzheimer's disease to test the strength of evidence of various tests for early dementia. So far, these reviews have concluded that most tests have not been evaluated in sufficiently robust settings that relate to populations and clinical utility to be rolled out into routine practice. Despite this, the UK's most recent NICE guidance on dementia (NICE, 2018) recommends various forms of imaging and CSF testing to establish subtypes of dementia.

So far, rigorous research to test the hypothesis that treatment and management is altered by earlier or more intensive investigation for the benefit of the patient is lacking. It may help a clinician to feel more confident about their diagnosis, but the extent to which additional

The experience of dementia

investigations actually benefit patients has not been demonstrated. Examination of a group of people seen in a true population study and assessed for a study diagnosis of dementia when compared with their medical records is one way of attempting to examine the value of a diagnosis, and what might influence the timing of that diagnosis. In the Cognitive Function and Ageing studies this was possible with an analysis of those people in a population-based sample who did *not* have a diagnosis in their medical records despite having cognitive impairment that could warrant a diagnosis as assessed by the study (Aldus et al., 2020). The mean time from first having discernible signs of dementia to obtaining a diagnosis was three years. People without a diagnosis tended to be older, to live alone, and to have predominantly non-memory symptoms. Importantly, though (in common with other studies), we found no demonstrable benefit of having a diagnosis in terms of any health outcomes.

The evidence base thus remains controversial for the use of tests for dementia within clinical settings. A further degree of uncertainty exists in the context of MCI, which itself is highly unstable as a diagnosis, especially in the group of worried individuals who present with subjective memory complaints. MCI is a state with a higher risk of subsequent dementia, but it is an inaccurate predictor, and probably the majority of people with MCI will not go on to develop dementia in the next few years. A significant proportion of people, especially those who are anxious about their memory, may indeed move back out of MCI into ‘normality’ over time (Matthews et al., 2008; Pandya et al., 2017).

Initiatives such as EPAD aim to research MCI and to offer medications at the ‘early’ stage of ‘disease’. However, especially among older people, a significant proportion with Alzheimer-type pathology will die before they ever would have developed dementia—if, indeed they would have ever done so. Honest communication with the participating public about the nature of the ‘risks’ of having MCI or evidence of biomarkers is therefore imperative. We will need to weigh the as-yet unknown risks of long-term brain-active medication (some substances could lead to brain changes that may be adverse), alongside the likelihood of the person developing dementia in their lifetime. Into this equation will come other variables, such as the person’s age, the possible role of risk and protective factors, and any evidence of neuropathology that they may have.

Future prospects

There is a real need to integrate the tensions described in this chapter. On the one hand, there are the very powerful voices of individuals—who may be very atypical in terms of their dementia, but who have important messages nevertheless—combined with pressure from biologically orientated researchers who wish to treat pre-symptomatic diseases. On the other hand, we have data from more ‘usual’ populations—these are

The experience of dementia

people with the common forms of dementia, and often in the oldest age groups, with considerable comorbidity and thus much closer to death.

For this latter group, the area of early detection and screening may not be as valuable as some who advocate for these would think. Research is needed to test fully the different implications and implementations that might be necessary as the biomedical research efforts yield their results. The nature of the 'biomedical bubble' has recently been challenged (Jones and Wilsdon, 2018) and the Alzheimer's Society led roadmap (Pickett et al., 2018) provides a very clear mapping of the gaps that there are in the research needed for dementia as a whole in society—now and into the future. This will go well beyond the narrow disciplines currently dominant in the dementia research fields.

The end of the journey and life after dementia: June Hennell MBE

My husband, Brian, was diagnosed with frontotemporal dementia in 2008, about three years after the first symptoms developed. We wrote about our experiences living with his condition in the previous edition of this book (Hennell and Hennell, 2013). In late 2012, he was found to have prostate cancer and he died in July 2013. This chapter reflects on my experiences from this time and subsequently.

'You're the best thing'

Here's a snap-shot from December 2011. Stroking my neck, cradling me in one arm with a glass of Buck's Fizz in the other, 'You're the best thing that ever happened to me', said the man next to me in bed that morning. What inspired such an outburst? It was simply the effectiveness of the dementia medication.

A course of seven weeks of daily radical radiotherapy was due to start only six days from now. 'Where shall we go next New Year?' he said, immediately after we had been discussing this serious issue.

My usual reply, as a carer, would have been, 'Let's consult our "still to see list"'. However, this seemed like a facile thing to say when taken in context with us living with frontotemporal dementia and fighting an aggressive prostate cancer. Our struggles were greater because previously excellent dementia medication was being rendered much less effective by the hormone therapy that was being prescribed to block the testosterone that was feeding the tumour.

His next question was about our dog. 'How old is Jack?' 'Seven,' I replied. 'Gosh, I'll be eighty when he dies. I can't bear the thought of living without him.' Faced with such extreme optimism, I couldn't bear the thought of where this conversation was leading. If only it was possible for Brian to live until the age of eighty, I mused.

This caused me to reflect on how difficult it is living with comorbidity alongside dementia. Just imagine being told you have an aggressive

The experience of dementia

cancer and then forgetting this vital information. When you are told that you are going to the hospital for a CT scan, you have to ask why. You then hear again the reason why but it doesn't remain in your library of chosen memories. When you go to the surgery for your hormone therapy injection, the nurse asks how you are. 'Absolutely fine,' you reply, because you are fine at that moment and you can't remember that a few hours ago you felt confused and distressed.

Life with two diagnoses

These issues are perhaps best illustrated by some extracts from my diary at the time.

'Did old Tommy die?' Brian asked, scratching his head. 'Yes,' I say, 'at least twenty years ago'. 'What did he die of?' 'He was ninety-seven,' I reply, 'so it was probably old age'. A puzzled look appeared upon his face and a settled contentment glowed in his eyes. 'That's good then because I thought that was another thing I'd forgotten ... not seeing him ... but if he is no longer around to see, I don't have a problem, do I?'

'Happy Christmas everyone,' said Brian when, on New Year's Eve, our family gathered to spend the evening together. Everyone felt that it could be our last such occasion. For Brian we were just starting Christmas, the festivities of the previous seven days completely unregistered.

Next day ... 'No, I won't wear my seat-belt and, if you insist on nagging me, I'll get out and walk. I don't care; I don't want to drive any more anyway'. The following day he got into the car, and fastened his belt before driving off. He had obviously forgotten the tirade and very draining experience for everyone else the day before.

'Did I feed Jack?' he asked, only five minutes after doing just that.

'I may as well move out now since I can't do anything right,' came the outburst after I had suggested Brian removed his muddy shoes before walking through the house. 'All you do is nag, nag, nag.' Where had all the good feelings gone?

Checking his dossette box (medication dispenser), I found that two days of important evening tablets had been missed. I realized that Brian can no longer remember to take them whereas he was almost infallible before starting hormone therapy. So, this is yet another thing that I am going to have to remind him about and he'll resent it ... and call it nagging.

'Oh! I'm absolutely fine, thank you,' was Brian's reply to the senior radiographer undertaking a radiotherapy review. Her raised eyebrow to me offered me the opportunity to comment. I was able

The experience of dementia

to mention the increased deterioration in his dementia and the almost total absence of short-term memory.

Brian's inability to find our son's home five minutes away shocked me yesterday. Brian's inability to retain a telephone message long enough to write it down on the ever-ready notepad was a big disappointment.

These jottings are just from a couple of days of our living with comorbidity. I am left wondering how differently things may have turned out if cancer had not entered our lives.

Difficult choices

After 35 consecutive days of radical radiotherapy, we learned that hormone therapy will be needed for at least another two years to keep the tumour controlled. Our hearts sank for we knew the likely impact on Brian's behaviour of reducing the dose of his dementia medication.

We had to make choices and in April 2012 our decision was to stop the hormone therapy in favour of returning the Q to Brian's quality of life with dementia medication. We would let the cancer look after itself.

Brian's quality of life *did* return and throughout 2012 life went on. Our diaries were full of interesting social and dementia-related events, including the following examples:

- The Association for Dementia Studies at the University of Worcester had become very important in our lives. We were members of the LINK group, people with dementia and their carers who were happy to share their stories with students and to bring their experiences to influence course contents and research projects. Brian and I were invited to participate in many training events and we were filmed as part of the *Stand By Me* dementia training resource, which has now been converted to an excellent online tool. We gained a great deal of satisfaction from being involved. Feedback from the students and tutors was very kind, respectful, positive, and humbling.
- The Royal College of Nursing invited us to be part of the team designing *The Triangle of Care for Dementia* and it was with pride that we saw the finished material containing many of our contributions and a recommendation to read our booklets. I attended the government launch in January 2014 on my own.
- We were invited to contribute a chapter entitled 'Living Well with Dementia' for the *Oxford Textbook of Old Age Psychiatry*. Seeing the finished book and learning that it is translated into different languages and sold worldwide made us feel very humble.
- Healthcare authorities in Victoria, Australia asked permission to capture some of our ideas and reproduce them for their own use. We felt privileged.

The experience of dementia

- We participated in staff training, research studies, conferences, and summits for The National Council for Palliative Care and NHS Gloucestershire.

Brian's walkabout

On 4 March 2013, I woke suddenly at 4 am to the barking of Jack, our black Labrador. At the front door, two Community Support Officers awaited me. I was informed that Brian was safe in an ambulance at the end of our drive. This was our first nightmare incident living with dementia. Brian had let himself out of the home, wearing no clothes or shoes and walked to the end of the drive and beyond, passing around sixty houses. By good fortune, he met a milkman on his morning round who was able to listen to Brian's questions, asking where he was, and subsequently called 999. Luckily, Brian was able to tell paramedics his name and mine, so we could be traced and reunited. However, Brian was sure that he was in Australia and had been watching the Ashes. He was quite simply lost and unable to identify his way home to the house in which he had lived for the last five years. Such is short-term memory loss, which prevents new memories being made. He was a serious risk of hypothermia on that cold March morning. How lucky we were.

Brian's comment later was simply: 'I don't know what happened but it is all right now, no harm done.' One learns to live with such understatements.

This incident made it necessary for us to change our routines and our home became like Fort Knox. I had to find ingenious excuses when Brian asked why the keys to the door had disappeared. But I had to keep him safe.

Changing times

As Easter 2013 approached, Brian's physical strength deteriorated, so we cancelled our planned break-away. We spent the time quietly at home. Brian's developing weakness meant that he could no longer take Jack for a walk and, as I couldn't leave Brian alone, I couldn't walk Jack either. Thus, with sadness and the help of our understanding daughter-in-law, Lorna, Jack was rehomed courtesy of the RSPCA, Stroud. All turned out well. Jack joined a lovely household and, many months later, when he asked where Jack was, I was able to tell Brian about what had happened. He was so grateful and, with hindsight, I give thanks for my timely action.

Brian's SAGE test

SAGE (Safer Driving with Age; <https://roadsafety-gloucestershire.org.uk/safer-journeys/driver/keep-learning/sage-safer-driving-with-age/>) is a programme run by our local Road Safety Team to provide support, guidance, and coaching to older drivers to enable them to continue driving for as long as it is safe to do so. It is not a test as such, but it

The experience of dementia

probably feels like it! Early in May 2013 it had been arranged for Brian to take the SAGE assessment. By this time, he was starting to experience back pain and I felt that he was probably too weak to take this test. However, he wouldn't hear of cancellation, saying that he would simply take extra painkillers.

He was right! The examiner returned with a broad smile, pronouncing that the last hour had been a pleasure and that Brian was indeed safe behind the wheel. What a puzzle dementia is—and how many persons without dementia would be proud of passing such a test in their mid-seventies?

Hello Gloucester Royal Hospital

Brian enjoyed his 75th birthday on 8 June 2013, but just two weeks later he was taken to our hospital because of a severe internal bleed. He was admitted to an acute care ward, where the staff were very kind and accepting of me as Brian's carer.

We were able to contribute towards dementia care on the ward. For example, we took in a *This Is Me* booklet that we had completed for Brian. We knew that the staff read it because of the questions they asked. A blue butterfly motif was placed on the wall behind his bed to signify that he had a diagnosis of dementia. I was permitted to carry out Brian's personal care for as long as practical. Doctors consulted me at every turn. In fact, often I heard news before Brian did, and the medics clearly trusted me to tell him things at the right time.

One morning I was a little later arriving and Brian's bed was empty. The patient next door directed me to a bathroom and there I found Brian having a deep bubble bath, a lovely shave, and kind, caring attention from two healthcare assistants. It must have been a challenge for them getting him into the bath with the use of a hoist, but succeed they did and he felt wonderful afterwards. How kind they were and we told them so.

I was very grateful for the help for carers provided by the Patient Advice and Liaison Service (PALS), with free parking and reduced costs in the restaurant. I also appreciated being able to make myself hot drinks on the ward.

We enter the world of palliative care

When we learned with great sadness that Brian's cancer had spread into his spine, we were offered a visit from the hospital's Palliative Care Team. The nurse came specifically to see us the very next day. She was really knowledgeable and informative. She explained in detail what challenges might arise and helped me to make choices. I say 'me' because Brian was having difficulty staying awake, but she didn't stop the conversation simply because he opted out of it.

The experience of dementia

Common sense prevailed and together we assessed that a hospice would enable Brian to spend his last days pain-free with 24-hour care. How grateful I was for this wonderful advice and for her professional and experienced approach. To most carers the subject of palliative care is new and, without help, can look like a minefield.

I had always suspected that preconceptions about end-of-life choices were pointless. Surely the all-round situation would need to be considered *at the time*, including the ability of the carer and/or family to cope? I now know this to be true. I am also aware that the availability of palliative care is quite variable from one place to another, making it into what we call a postcode lottery. This is unfair: everyone deserves the same quality of care at the end of life that we give to babies at the start of life.

And in palliative care, as in other parts of the dementia journey, it is very important for carers to receive informed support. Why doesn't it always happen?

Our hospice experience

I wish there were more hospices.

I felt wrapped in a comfort blanket; that feeling gave me confidence that everything would be dealt with appropriately whether I was there or not. Had I taken Brian home from hospital, I would have been too exhausted coping with his double incontinence to have quality time with him. Instead, we had three weeks of love, pain-free companionship, and expert care.

Nothing could have predicted it but, when staff recognized that there had been a change in his vital signs, I was called and came to return to Brian's side. I spent his last twelve hours with him. He died at 9.10 am on Monday 22 July 2013, having smiled and told me he loved me. I told him that I loved him too, dementia and all. Had he been at home, the changes in his vital signs could have gone unnoticed and he may have died alone.

Dementia Brain Bank research

We had both offered to donate our brains to the National Dementia Brain Bank in Bristol and their smooth system clicked into place following Brian's death. It was simple and unobtrusive during our time of grief. I was to receive results of their examination two months later, and I was pleased that this information may go some way to adding to the data bank for the future improvement of medication or prevention of this cruel condition. In due course my brain will be examined and used for comparative purposes.

My hopes for the future

My hope is that dementia will no longer be used as an excuse for denying people with the condition and their carers the right to make informed choices assisted by a palliative care team. I also wish that the horrors of

The experience of dementia

comorbidity become better recognized. We all know that living well with dementia means making compromises, being flexible, and always looking for positive opportunities to increase quality of life.

However, when comorbidity becomes an issue, all such choices disappear. For the person with dementia, the arrival of a second condition can be devastating. It can lead to all sorts of new problems in managing either condition, or both. One example from our experience was that the dementia drugs became less effective when a second treatment was started. We have to encourage culture change among specialists working in silos, often in different clinics, hospitals, or NHS Trusts. The patient must be treated holistically across boundaries, with each clinician discussing the potential areas for conflict in their proposed treatments.

Going forward

I was grateful to many people for the help Brian and I had received, but I didn't realize how long my uphill struggle for survival would become following his death. I had lost *myself* in my caring role. When that role ended, not only had I lost the very meaning of existence, but I didn't know how to care for myself. These instincts had been buried beneath many layers of day-to-day coping.

It was on 15 August 2013, almost four weeks after Brian had died, that I hit rock bottom.

In retrospect, I realised that no-one should die during July or August. Trying to get support from recognised bereavement organisations simply didn't work. They were on holiday, or they had closed their offices in my area, or they didn't have email and only a phone connection on designated mornings. These times invariably clashed with my own commitments, such as having to attend another funeral, a hospital appointment, or whatever! I simply couldn't telephone them to 'register my needs'. I'd like bereavement services to take note: when a strong person seeks help, it is because they need it—and right now. Being told that there is a three-to-six month waiting list for bereavement counselling is particularly unhelpful.

So, I struggled on. It was only when the academic year recommenced and I was invited back to join colleagues at the Association for Dementia Studies at the University of Worcester that I cheered up. Attending my first events with them in September became a challenge, but I did it.

Friends and family said 'You know where we are. If we don't hear from you, we'll know that "no news is good news" '. In reality, it is very hard to pick up the phone and try to describe what you feel/need/want ... because you simply don't know. Nothing makes sense and the more you talk about it, the worse it becomes. Trying to make meaningful new daily rituals is very hard. I just wanted the phone to ring with someone saying, 'Hi, how are you? Fancy a coffee?', but it didn't happen often. People don't know what to say in bereavement, so they tend to say nothing, including

The experience of dementia

avoiding one in the street. I had rarely thought about this before but I shall in the future.

Help came in many unexpected forms:

- Art lessons at Artlift, courtesy of a referral by my GP's surgery.
- Dancing on Prescription provided by the local district council, also by referral.
- Grand-children's hugs and sometimes innocent remarks about their 'Pops' all helped, especially five-year-old Ethan's commitment to looking for Pops' star in the night sky and Caitlin's pleasure at lighting a candle for Pops at every church and cathedral she visited.
- At the Positive Caring Course organized by the county council, I had met other carers with whom I bonded closely. We committed to meeting monthly at a local pub and our mutual support became a powerful influence for us all.

It is true that the first year is the worst, coping with anniversaries. But sitting through concerts where special memories came flooding back could also be heart-rending, not because of bad memories, but in learning to cope with good ones. For that was my problem: I couldn't recall bad times, only the privilege of a relationship, which I wanted back, that spanned 48 years.

My diary was full, but not overfull, with interesting invitations and gradually I resumed visits to London with organizations wanting to support me, but also to learn from my lived experience of dementia diagnosis to death or palliative and end-of-life care.

I was invited to join research boards, management committees, and advisory boards, and some of these I accepted. Ultimately, it was the grandchildren who saved my bacon and helped me to realize that their future was worth my survival. Now it is a thrill to take part in students' training sessions and conferences. They never seem to tire of hearing our story—'Better than textbooks,' they say.

On reflection

There are many things that I have learned from my experience as Brian's wife and as his carer. I reflect on these in the next few sections, and look at the direct legacy of Brian's life and his dementia, explore (explode?) some of the myths that exist around dementia, and finally offer some thoughts for dementia carers who have recently been bereaved.

Brian's legacy

The Hennell Award

It was a thrill for me in May 2014 to launch the Hennell Award for Innovation and Excellence in Dementia Care. Two of my eldest grandchildren, Katryna and James, came with me to the Association for

The experience of dementia

Dementia Studies (ADS) at the University of Worcester for the launch and spoke inspiringly of their understanding of dementia and their respect for their Pops. I have committed to sponsor this award for five years. It is open to anyone registered with ADS who puts their learning into action in their workplace, creating innovation and excellence. Self-nomination is allowed but so is nomination by a manager or tutor. I want to reward motivated persons who, as Brian used to say, 'dare to be remarkable'. Full details are on the ADS University of Worcester website (see the end of the chapter for Internet link).

Stonehouse Memory Link

In October 2013, together with two local town councillors and a community builder, I launched Stonehouse Memory Link, which is a dementia awareness project for our locality. Our aim was twofold:

1. To learn from the experiences of those with memory loss how we could improve things for them in Stonehouse.
2. To provide a help line for those worried about their own memories or that of someone close.

We ran a poster campaign from which we learned that our town was fortunate in its provision of care. In October 2014 we launched a postcard campaign sponsored by the Barnwood Trust. By providing a postcard that people could complete and post to my address, we made help more accessible. We gained the support of GPs which was invaluable.

NASA

NASA reported that some astronauts had experienced depression and anxiety disorder while in low earth orbit. Scientists were looking at data from circadian and ultradian rhythms after processing with predicted algorithms. Clearly long-term activation of fight/flight responses can cause accelerated ageing of the brain. Data from spacecraft equipment can illustrate this using predictive algorithms and I am in close contact with a space expert who is interested in this research. Who knows how this may progress our understanding and help in the future dealing with dementia?

The University of Worcester

In September 2014, I was privileged to help in the launch of a Foundation Degree in Dementia Studies for the Association for Dementia Studies. Working with the students in pursuit of excellence in their results continues to be thrilling and satisfying.

Dementia myths

During my time as a carer, a mentor for other carers, a guest lecturer in dementia, and an expert by experience, I have heard many myths spoken about dementia. Here are some of those myths and my reactions to them. These are personal opinions. Please remember, when you have met one

The experience of dementia

person with dementia you have indeed met just *one* person with dementia. And when you have met one carer you have indeed met just *one* carer—for we are all unique in our acceptance, flexibility, positivity, and ability to make those compromises which are required to live well with dementia.

Myth 1: It is easy to get a diagnosis

You only have to *book an appointment with your GP and describe to them what you feel*. It is anything but easy for the person suffering symptoms of memory loss to explain realistically how frustrated and confused they feel. It is even worse for a family member who feels disloyal to be 'complaining' about the person's behaviour.

Akin to the situation with domestic violence, spouses may secretly fear that it may be their fault, that they have changed and caused the behaviour, or that they should be more understanding. Divorce versus diagnosis: ask yourself, how many relationships end because of personality changes and irascibility? Yet these can be symptoms of dementia.

Solutions to this include:

- *Write it down.* Writing brief notes of the date, time, what happened where, and what the outcome was, may help in many ways. It saves confusion with the GP. It ensures accuracy of recall without the emotional upset of being disloyal.
- As this will require some time, I recommend that you book a double appointment with the GP. Expect that they will need to arrange several tests to rule out other possible conditions. For instance, a urinary infection or vitamin B12 deficiency may be enough to create symptoms similar to dementia.

Myth 2: Getting a diagnosis of dementia is bad news

In fact, receiving a dementia diagnosis can be *good* news. It can be a relief that there is a cause other than marital problems for the unhappiness, frustration, and tension being felt. It can identify other conditions needing attention and open the door to obtaining medication and support.

Having a diagnosis can also help various practical issues, for example, that downsizing (property, plans, activities) may be a good idea. If the person is still driving, they should inform the Driver and Vehicle Licensing Agency (DVLA) of the situation. And it is a good time to think about establishing a Lasting Power of Attorney for Health and Finance while there is still sufficient mental capacity to keep the process simple.

The experience of dementia

Myth 3: Diagnosis is a waste of time because there is no cure

It is true that there is no cure on the horizon, but there is help available which, if you remain in denial, you can't access. If you get a dementia diagnosis, you may be eligible for research trials, you may be prescribed medication, and you will certainly have access to information and organisations that can help.

If you get a diagnosis you may also gain in confidence, for there are many people living satisfactorily with dementia. Making compromises and adopting a 'can-do' attitude can mean that life, while never being the same again, need not lack meaning or the feel-good factor.

The financial implications of living in denial can mean job jeopardy, mortgage worries, and concerns about dependants and living accommodation. Getting things out in the open enables you to address each issue at the best time, involving benefits and advocacy if necessary.

Myth 4: Medication may work only for a while, so why bother?

This may not be true. All the time results of research, often provided by ordinary people reporting successes, are recommending different approaches. For instance, at first, memantine was licensed only for clinical trials. Now, in some circumstances, it can be beneficial to reduce reliance on some other drugs and add memantine too. Worldwide research is having success. We can also hope that there continues to be crossover in the effectiveness of drugs that were originally developed for other conditions.

Myth 5: People fear dementia and don't understand—it is best not to tell friends

In reality, the opposite can be true. Ordinary people can show understanding if they know how to react and how their actions can offer support. It really means honesty all round, enlisting help to make changes, and making compromises on social outings to play to the strengths of the person with dementia. For some people, there is the opportunity to be more informed for the future, in case dementia affects their own family. Of course, some people react better than others, so it is true that you *do* learn who your friends are, but this can be a blessing and not a hindrance. And there are opportunities to make new friends by activities such as attending memory cafes, carers classes, Singing for the Brain and other dementia-related events. Your dementia adviser or community nurse can signpost these for you.

If you have never been a person who joins in, dementia won't necessarily assist you to change your attitude to participation in the community. Loneliness, in that case, can be the ultimate outcome. However, sometimes people are inspired to seek help and making that first step towards sharing information may change your life.

The experience of dementia

Myth 6: Health care staff don't understand

Often you may feel that you tell one person that you are a carer, but the message doesn't get passed on. They asked my husband things that he didn't understand but they didn't ask me. At times, nobody seemed to care.

I discovered that this really isn't true. There has been a lot of effort in recent years to raise levels of awareness and knowledge among health staff, across all professions and levels of seniority. For example, in 2013 more than 100,000 NHS staff received dementia training that emphasizes communication skills. Dementia education is a priority for Health Education England. There is a huge job to do up-skilling staff, but at least the commitment exists. A useful resource is the Royal College of Nursing's *Triangle of Care for Dementia*, published in 2014. This gives guidance, based on contributions from actual carers, of how healthcare professionals should work in partnership with carers and those with dementia.

Good communication is absolutely vital to any training for dementia care. Everyone needs to be taught the basics of memory loss. Someone with a poor short-term memory is quite vulnerable to emotions in the here and now. Sometimes, a recent bad experience can leave the person with a feeling of being down without knowing why. Information told to someone with dementia can be lost in seconds. Healthcare professionals sometimes overlook this, but they can often save themselves time and trouble by ensuring that they tell things to the patient and the carer together.

Professionals also receive training in the use of the Mental Capacity Act, which emphasizes that patients have rights and, as long as they have capacity, they should be consulted. To carers this sometimes makes little sense, but we have to accept that the Act is there to protect patients and encourage them to be involved in decision-making. Having a Lasting Power of Attorney for Health and Welfare can give you powers if the mental capacity of the person you care for diminishes.

So, many people *do* care and many staff *do* understand. I believe that healthcare professionals choose this career wanting to do their best for their patients. In my experience most of them succeed most of the time.

Myth 7: Hospitalization for someone with dementia is a nightmare

Hospitalization can be very difficult for the carer as well as the person with dementia, and generally we assume that disorientation is bound to occur. However, this is not always the case.

Various things can be done to reduce the risk of becoming confused. The blue butterfly scheme, where a blue butterfly sticker is placed at the head of the patient's bed, alerts staff that dementia exists. This permits a more considered approach to difficulties that could arise, opening the door to

The experience of dementia

person-centred care. Staff shortages and time restraints can limit this, but intervention can be meaningful—I have witnessed it. Another useful thing is to take a completed *This Is Me* document and hand it to the nurse on admission. This will give the clinical team useful information about the issues that exist and provide possible solutions to them. It is essential.

I found that my husband slept like a baby in hospital, just like at home. When he was awake, he lived very much in the moment. If bored, because nothing was happening, he went back to sleep. If thirsty, he poured himself a drink and if he needed anything else, he tried to attract someone's attention. Because I spent all day there every day, he showed few signs of disorientation. He would not eat breakfast until I arrived, which became his way of coping and making a reality of this new existence.

We shouldn't expect the worst. It is *not* always a nightmare because there can be a level of adjustment that works. I communicated right from the start so that specialists and senior staff knew that I needed to be kept informed and involved in debates about anything important. I thanked junior staff when they performed routine personal care for my husband and they appreciated this.

New routines, travelling, and sheer tiredness can make things difficult for carers when the person for whom they care is hospitalized, but this can be partially offset by taking some time out and asking family or friends to take a turn. As carers, we find it difficult to stand back and look at the implications for ourselves of what we are doing, but we must try. We find it hard to ask for help at any time and, when we have left our loved one in the care of others, the isolation can be devastating. Conversely, we could turn hospitalization into the opportunity to place our confidence and trust in other people—and have a break ourselves.

Myth 8: Socializing is impossible with dementia

It is completely false that there is nowhere to go where people understand. Give people a chance to understand and be prepared to adapt yourself. There are numerous sources of meeting people, many of which are supported by the Alzheimer's Society, such as memory cafes, Singing for the Brain, and dementia advisers. Other places include local offices of the Carers Trust UK; local council events and other community functions; day centres; and community nurses and health centres. There are social interest companies, such as Dementia Adventure, who organize trips to appreciate nature in a supported environment. Organized short walks are held in many areas. Walk short distances before returning. Increasing regular short walks can bring all-round health benefits and improve the feel-good factor. Local parks can be a good place to meet others in an unchallenging environment. Cinemas may have special screenings for older people or especially for people with dementia. Even if they don't, you could choose to watch programmes with shorter films.

The experience of dementia

Save money and thrill your family and friends by making your own personalized greetings cards. They will be valued and a good talking point if you add some extra memories of time spent together, courtesy of old photographs, magazine entries, tickets, and programmes. You could start a reminiscence series of coffee mornings with your friends and invite neighbours. You could identify similar interests to pursue. It is also worth mentioning the 'Keep Safe' scheme, where traders offer to make a phone call for anyone in distress who has signed up. There you know that showing your card in a shop with a Keep Safe logo on the door means that help is at hand.

There is so much help and support out there to make it easier for those with dementia and their carers to socialize.

Myth 9: Nobody listens—I am invisible

Reread the previous section about the options for social life! As well as this, many organizations are eager to learn from carers. Offer your input and it will most certainly widen your horizons. You can contact your local authority and take a carers class. There you will meet others in your situation; camaraderie, when things get tough, is *invaluable*.

If you are confident at writing, record your learning points for others. Write to magazines. Campaign for things to get better. Speak on local radio or to newspapers. You have a voice and you have influence if you want to use it. Buddy up with others if it helps.

Myth 10: The person I care for won't know me at the end of his life

You may fear that, in the last stages of dementia, the person you care for won't know who you are, and that dying will be a relief, the end of torment for your loved one, and a living loss for you. This is untrue.

Dementia itself causes *very few* deaths. Most people die of another condition, with dementia being quoted as a secondary condition. Where death occurs because of a major second condition, such as cancer, this can be before the dementia has taken away recognition of loved ones. As I have mentioned before, the arrival of a second condition can make dealing with the dementia much more complicated. It sometimes seems that the different specialists involved in the case don't talk to each other. Sometimes they don't work in the same hospital. At times, their treatments seem to work in different directions. This can be challenging. Often it is left to the carer to liaise between different clinics. It can be very helpful to get to know the medical secretaries so they can help sort things out.

Advance Care Plans can be really useful. Planning end-of-life care and detailing what really matters to both the person with dementia and the carer is very important, but only if it is reviewed regularly. When the end is near, it is important not to adhere rigidly to written expressions of

The experience of dementia

choice, but instead to take into account various factors, including: the general situation; the cognitive ability of the patient; incontinence issues; pain management; blood sugar levels; and the ability of the main carer to cope. It must be remembered that a carer may already be near exhaustion and future sleepless nights and trying days may impact upon their *future* quality of life as well as the current.

As I have mentioned, palliative care teams can be worth their weight in gold. Staffed with experienced people who really understand the options, emotions, and confusion at such a time, they can steer a family through even the darkest hours. There is no substitute for open and honest two-way discussion, but reality must feature heavily in the decisions that are eventually made.

Chasing rainbows: Some words for bereaved carers

Living with dementia can be a challenge, but living without it can be worse. These challenges can bring deep closeness, and when the challenge has gone, there is suddenly an unmanageable gulf. You might think that some kind of preparation, almost like a bereavement apprenticeship, following diagnosis would help. However, the chasm of bereavement grief may surpass any attempts to prepare for it.

Therefore, to those carers still making a dementia journey I say, 'Try to value each day.' For when those days of being a carer cease, the horrors, like the pains of childbirth, quickly fade, leaving you at risk of unwelcome invasion by feelings of emptiness. That invasion by these pangs of loss defeats logic or planning, and it has nothing to do with guilt.

During the time of caring for a person with dementia, it may seem that life in the future without those challenges will be a great relief. Instead, afterwards, when they are gone, it seems to be that memories of the smiles, the hugs, the true joy in achievement living *with* dementia take precedence. The rainbow to wipe away the clouds of sadness will surely rise, creating a future of blue skies. It is that optimism that keeps us going.

DOI: 10.1093/med/9780198807292.003.0029

Introduction

Mild cognitive impairment (MCI) is a descriptive term that refers to the presence of cognitive impairment out of keeping with normal ageing but of insufficient severity to constitute dementia. The concept of MCI has evolved since its introduction, and at present it is considered to be heterogeneous both in terms of clinical presentation and aetiology. This chapter aims to outline the current thinking about MCI, including its underlying pathophysiology, diagnostic criteria, and a proposed clinician's approach to the diagnosis.

The concept of MCI

By logical extension, the definition of dementia in terms of cognitive impairment of sufficient severity to compromise activities of daily living and functional independence created the need to define a lesser state of cognitive impairment that did *not* result in such functional compromise.

Mild cognitive impairment

However, MCI was not operationalized as a diagnostic entity until 1999 when work on the Mayo Clinic Study of Ageing, a longitudinal community-based population study, highlighted a subset of participants with memory impairments of a severity that fell between that associated with normal ageing and dementia. This prompted the first diagnostic criteria for MCI (Table 29.1; Petersen et al., 1999) in terms of: i) a subjective report of memory decline; ii) objective evidence of memory impairment; iii) relatively preserved general cognition and function; and iv) the absence of dementia.

Mild cognitive impairment

Largely preserved independence in functional abilities	x	x	x	x	x	x	x	x
Not demented	x	x	x	x	x	x	x	x
Additional requirements			AD biomarker negative	AD biomarker negative	AD biomarker positive: low CSF A β ₄₂ and high CSF tau/p-tau; amyloid PET	AD biomarkers uninformative /not tested	AD biomarker positive: see Table 29.2.	

¹ Listed cognitive domains that may be impaired include: memory; executive function; attention; language; and visuospatial skills.

² Listed cognitive domains which may be impaired under the DSM-5 criteria include: complex attention; executive function; learning and memory; language; perceptual motor; and social cognition.

Mild cognitive impairment

³ Objective impairment in *episodic* memory specifically is required for prodromal typical AD using the IWG criteria, characterized by a free recall deficit that does not normalize on cueing. This may or may not be associated with impairment in other cognitive domains. In the absence of episodic memory impairment, prodromal atypical AD may be diagnosed if the presentation fits specific clinical phenotypes that include cognitive impairment in other domains. Mild cognitive impairment

The initial focus in the 1999 criteria on episodic memory as the core affected cognitive domain of MCI reflected the primacy of Alzheimer's disease (AD) as a cause of dementia and the occurrence of memory impairment as the hallmark presenting symptom of AD. Over time, in acknowledgement of the possibility that MCI could reflect problems beyond memory alone, the concept of MCI was broadened to include other cognitive domains such as executive function, visuospatial processing, and language (Table 29.1; Winblad et al., 2004; Petersen, 2004). In these revised 2004 criteria, cognitive impairment was classified based on whether a memory component existed (amnesic vs non-amnesic MCI) and whether impairment was seen across more than one cognitive domain (single vs multiple domain MCI). This 2x2 classification resulted in four subtypes of MCI, namely single domain amnesic MCI, multiple domain amnesic MCI, single domain non-amnesic MCI, and multiple domain non-amnesic MCI.

This expansion of the clinical extent of the MCI concept has occurred in step with an increasing appreciation of the heterogeneous nature of its underlying causes. Petersen and colleagues themselves posited that each subtype of MCI in the revised 2004 criteria had the theoretical potential to progress to a variety of dementias, with single domain amnesic MCI being most heavily implicated in progression to AD dementia (Petersen et al., 2001). Currently, the prevailing view is that the umbrella MCI term represents a transitional state between healthy ageing and dementia, with the latter caused by differing disorders. This biological diversity is evident in the use of biomarker-based tests to identify the underlying disease state in MCI patients, notably in the National Institute on Ageing-Alzheimer's Association (NIA-AA) workgroup guidelines (Table 29.1; Albert et al., 2011), which make specific reference to 'MCI due to AD' as the symptomatic, pre-dementia stage of AD. While the workgroup reiterates Petersen and colleagues' original emphasis that MCI is a clinically diagnosed syndrome, the NIA-AA extends the diagnostic process with guidelines for establishing AD as the primary underlying aetiology (Box 29.1 and Table 29.2).

Mild cognitive impairment

Table 29.2 NIA-AA research criteria for diagnosis of MCI due to AD, incorporating biomarkers.

Biomarker test outcome			=	Biomarker probability of AD aetiology	⇒	Diagnostic category
Aβ (amyloid PET or CSF)	+	Neuronal injury (tau, sMRI, or FDG-PET)				
Conflicting/indeterminant/untested		Conflicting/indeterminant/untested				MCI: core clinical criteria
Positive		Untested				MCI due to AD: intermediate likelihood
Untested		Positive				MCI due to AD: high likelihood
Positive		Positive				
Negative		Negative				MCI: unlikely due to AD

Aβ = beta-amyloid; PET = photon emission tomography; CSF = cerebrospinal fluid; FDG-PET = fluoro-deoxyglucose photon emission tomography

Mild cognitive impairment

Developed in parallel to the NIA-AA criteria, the Second International Work Group (IWG-2) criteria for AD (Dubois et al., 2010, updated in 2014) places less emphasis on MCI as a syndrome in itself, and more on AD as a distinct pathological entity characterized by a progression from a preclinical phase, prior to symptom onset, through to the occurrence of MCI and then on to AD dementia. According to this formulation, 'MCI due to AD' is considered to be 'prodromal AD', preceding the onset of dementia, and its diagnosis requires biomarker evidence of AD pathology in addition to the MCI syndrome.

In the absence of guidelines linking the clinical syndrome to distinct disease processes (notably AD), the clinical features associated with MCI are used also to define other syndromes that differ from MCI in nomenclature but are similar in terms of presentation. The *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition: DSM-5* (American Psychiatric Association, 2013) introduced a new classification of 'mild neurocognitive disorder' (mild NCD) that closely mirrors existing MCI criteria (Table 29.1: American Psychiatric Association, 2013). Paralleling the difference in severity of cognitive impairment that separates MCI from dementia, this new DSM-5 classification differentiates mild NCD from major NCD, with the latter diagnosis divided further in terms of underlying aetiology. Subjective cognitive decline (SCD) is another emerging concept (see Box 29.2).

Box 29.1 NIA-AA clinical characteristics supporting likelihood of MCI (diagnosed as per core clinical criteria) being due to AD

- 1 Memory impairment present
- 2 Progressive decline in cognition over months to years (very rapid decline may suggest prion disease, neoplasm, or metabolic disorders)
- 3 Lack of Parkinsonism and visual hallucinations (suggestive of Lewy body disease)
- 4 Lack of vascular risk factors and extensive cerebrovascular disease on brain imaging (suggestive of vascular cognitive impairment)
- 5 Lack of prominent behavioural or language disorders (suggestive of frontotemporal lobar degeneration)

Mild cognitive impairment

Box 29.2 Subjective cognitive decline

As the concept of MCI has evolved, so too has the distinct phenomenon of subjective cognitive decline (SCD); namely, a self-perceived decline in cognitive performance in daily life, which does not reach the level of objective impairment required for MCI diagnosis (Jessen et al., 2014). The decline should be persistent and unrelated to an acute event. Cognitive testing is useful in helping to exclude an objective deficit that would suggest established MCI.

As with MCI, the possible underlying causes of SCD are many and varied. Longitudinal studies support SCD as a risk factor for MCI and AD (van Oijen et al., 2007; Reisberg et al., 2010). It is not currently possible to differentiate SCD in preclinical AD from SCD due to other causes, but the SCD initiative (SCD-I) working group, convened in 2012 to develop a conceptual framework and research criteria, identify features that increase the likelihood of preclinical AD, including: subjective decline in memory rather than other cognitive domains; onset within the last five years; age at onset over 60 years; worries associated with SCD; feeling of poorer performance than peers in age group (Jessen et al., 2014). Other potential aetiologies of SCD include non-AD neurodegenerative diseases, psychiatric conditions including depression and anxiety, attentional bias in normal aging, and medication- or substance-induced decline.

Comparison of studies investigating the rates of progression of SCD to dementia has thus far been limited by the heterogeneity of SCD definitions employed. Nevertheless, a systematic review revealed that 24% of individuals progressed from SCD to MCI over a mean follow up period of 4.1 years (11 studies) and 11% progressed from SCD to all-cause dementia over a mean follow up period of 4.8 years (28 studies) (Mendonca et al., 2015). The same review established that SCD individuals were twice as likely to develop dementia as healthy controls (pooled relative risk 2.07 over 28 studies with 3821 SCD individuals and 15009 controls): for comparison, in their meta-analysis, Mitchell and Shiri-Feshki (2009) found individuals with MCI have a relative risk of 13.8 for progression to dementia. The heterogeneity of SCD as a condition, the inherent instability of the diagnosis (with a tendency for some patients to revert to normal cognition, as in MCI), and the fact that the overwhelming majority of SCD individuals do not develop MCI and dementia, mandate that caution should be exercised when considering the prognosis of the individual with SCD.

Diagnostic criteria

Mild cognitive impairment

Epidemiology

The conceptual evolution of MCI has led to a number of challenges when considering its epidemiology. In particular, the fact that the definitions for MCI were developed in the context of a specialist cognitive clinic setting, with attendant detailed history taking and examination of patients, complicates its translation to large-scale epidemiological studies, where detailed clinical assessments are not routinely undertaken. This is reflected in the difficulties in estimating prevalence of MCI in the general population, as evidenced by the inability to perform a meta-analysis of ten studies of the prevalence of MCI as a result of between-study heterogeneity in choice and implementation of diagnostic criteria (Alexander et al., 2015). Studies have been forced to use a variety of adaptations of the MCI criteria to fit with already existing datasets. Those using the more recent diagnostic criteria, and with adequate sample sizes and clear methodology, have shown prevalence among older people to be between 5% and 20%, with incidence of 21–71 per 1000 people per year (Sachdev et al., 2015; Petersen et al., 2014; Roberts and Knopman, 2013; Ward et al., 2012). These figures bear comparison with those from the Mayo Clinic Study of Ageing, which prompted the introduction of the MCI concept. In this population-based study involving around 3000 participants aged 70–89 who were non-demented and cognitively normal or who had MCI at entry, the prevalence of MCI in the non-demented population was estimated at 15%, with amnesic MCI being twice as common as non-amnesic MCI (Roberts et al., 2008).

Many studies estimate much higher prevalence and incidence statistics than those reported in epidemiological studies using recent diagnostic criteria and uniform methodology (Brodaty et al., 2013; Wong et al., 2013; Ward et al., 2012). There are numerous factors that contribute to this between-study variance. Studies recruiting from community settings generally yield lower rates of prevalence and incidence than studies recruiting from specialist memory clinics; in the latter setting, the referral bias associated with the process of clinical referral results in a patient population enriched in terms of pathology by comparison with the non-referred general population. Retrospective studies are further limited by the fact that cognitive assessments employed at the time of data collection might not have been designed with detection of MCI in mind. Additionally, age-specific prevalence rates are not always quoted, and as the age ranges sampled vary between studies, it follows that prevalence will also vary. Finally, the use of qualitative, rather than quantitative, criteria to identify MCI leads to between-individual differences in the application of the diagnostic criteria between centres and researchers, and in the case of retrospective studies, cruder diagnostic algorithms may be employed where clinical judgment is more difficult to apply. Even when the diagnosis is based on some quantitative evaluation of the severity of cognitive impairment, the absence of a consensus guideline for cut-off scores in cognitive testing, or of the type of cognitive test(s) to be applied, results in the adoption of different cut-off scores (e.g. cognitive

Mild cognitive impairment

performance 1, 1.5, or 2 standard deviations below that of the control mean score), introducing further variability.

Prognosis

Four potential outcomes have been documented in prospective follow up of MCI patients: progression to AD, progression to non-AD dementia, stable disease without progression, and reversion to normal cognition over time (Matthews et al., 2008). The rate of progression from MCI to AD or other dementia varies across studies and is largely dependent upon source of referral. In memory clinics, clinical trials, and specialist centres, the rate of progression to AD dementia ranges from 10–15% per year, whereas for epidemiological studies in which participants are approached prospectively and followed up, the rates are lower at between 6–10% per year. Table 29.3 shows how a meta-analysis of 41 studies yielded differential rates of progression (Mitchell and Shiri Feshki, 2009). This difference in outcome mirrors the differential prevalence of MCI in specialist and population-based settings, and is likely to be due to similar factors, including the a priori probability of having an early dementia (which will be higher in specialist settings).

Mild cognitive impairment

Table 29.3 Progression of Mayo-defined MCI cases to dementia in a meta-analysis of 41 studies.

MCI disease progression	Cumulative progression (%)		Annual progression rate (%/year)	
	Specialist setting	Population-based setting	Specialist setting	Population-based setting
All-cause dementia	39	22	10	5
AD	34	29	8	7
Vascular dementia	6	5	2	2

Source data from Mitchell, A.J., Shiri-Feshki, M. (2009). Rate of progression of mild cognitive impairment to dementia—meta-analysis of 41 robust inception cohort studies. *Acta Psychiatr Scand*, 119(4):252–65.

Mild cognitive impairment

Mitchell and Shiri-Feski (2009) noted in their meta-analysis that the cumulative proportion of cases that progressed to all-cause dementia rarely exceeded 50%, even in medium-term studies with follow up exceeding five years, suggesting that in a significant proportion of MCI cases may not have underlying neurodegenerative disease.

Reversion to normal cognition is a well-documented alternative outcome in MCI studies. Population-based studies have consistently demonstrated that between 6% and 55% of those diagnosed with MCI appear to return to normal cognition a year later (Sachdev et al., 2013; Koepsell and Monsell, 2012; Ganguli et al., 2011). Single domain MCI classifications, particularly non-amnestic single domain MCI, appear to be the most susceptible to returning to normal cognition (Jak et al., 2009; Bickel et al., 2006). Other factors increasing the probability of reversion include: less severe objective cognitive impairment; lack of apolipoprotein $\epsilon 4$ allele; lack of informant corroboration of impairment; comorbid depression; and good blood pressure control (Sachdev et al., 2013; Koepsell and Monsell, 2012). The phenomenon of reversion is perhaps unsurprising, given the many temporally variable factors that may influence cognitive performance in older people, e.g. psychiatric comorbidity, physical illness, and medication usage. This is particularly relevant in community settings, where one deals with a more unselected population than that seen in a specialist memory clinic, and where the opportunity for extensive assessment and stringent application of MCI diagnostic criteria may be less forthcoming (Farias et al., 2009; Gauthier et al., 2006). However, there is evidence that in those who have previously had MCI and reverted to normal, the lifetime risk of subsequently developing MCI and dementia remains increased (Roberts et al., 2014).

The outcome of non-AD MCI has been less well investigated. Within the Canadian Study for Health and Ageing, Wentzel and colleagues (2001) followed those with presumed vascular cognitive impairment without dementia (vascular CIND) and found that of 149 participants, 46% developed dementia after five years. Patients with MCI after stroke are also at increased risk of subsequently developing dementia, with rates of 25% at two years reported (Altieri et al., 2004). However, improvements are also seen in some subjects (Ballard et al., 2003).

Ferman and colleagues (2013) studied 337 patients with MCI and found 49 progressed to probable dementia with Lewy bodies (DLB) over 2-12 years' follow-up, while 162 progressed to probable AD, 116 remained as stable MCI, and ten progressed to other dementias. For those with an initial diagnosis of non-amnestic MCI, the annual progression rate to DLB was 20%, compared with 1.6% to AD. Conversely, an initial diagnosis of amnestic MCI yielded an annual progression rate of 1.5% to DLB, compared with 17% to AD. The occurrence of REM sleep behaviour disorder (RBD) was found to be strong predictor of progression to DLB, with a history of probable RBD noted in 80% of DLB progressors. Similarly, Jung and colleagues (2017) followed 14 patients with MCI and

Mild cognitive impairment

RBD over three to nine years, with three patients progressing to DLB and a further two exhibiting DLB features.

The syndrome of MCI of frontotemporal type has been described in a small case series by de Mendonca and colleagues (2004), who found that a combination of clinical features (apathy, disinhibition, irritability), cognitive impairments (in attention, initiation, and conceptual thinking), and neuroimaging (frontal atrophy) was predictive of progression to a frontotemporal dementia (FTD) diagnosis within two years. The syndrome of mild behavioural impairment (MBI) has been shown to be a better predictor of progression to FTD (Box 29.3).

Box 29.3 Mild behavioural impairment

In recognition of the fact that some patients with dementia, particularly frontotemporal dementia (FTD), exhibit a prodrome of neuropsychiatric symptoms without cognitive impairment, Taragano and colleagues (2003) proposed criteria for a separate syndrome of mild behavioural impairment (MBI), consisting of: i) persistent behavioural changes and mild psychiatric symptoms, especially disinhibition; ii) no serious cognitive complaints; iii) normal activities of daily living; and iv) absence of dementia. They found that a diagnosis of MBI without cognitive symptoms predicted progression to FTD (in their 2009 study of 60 patients, 68% progressed to FTD, 3% to AD, and 2% to DLB), while a diagnosis of either MBI with cognitive symptoms or MCI with neuropsychiatric symptoms favoured progression to AD (of 59 cases of MBI with cognitive symptoms and 85 cases of MCI with neuropsychiatric symptoms, the rates of progression to AD/FTD/DLB were 42%/20%/4% and 43%/17%/2%, respectively) (Taragano et al., 2003). The International Society to Advance Alzheimer's Research and Treatment (ISTAART) have subsequently proposed revised MBI diagnostic criteria that allow for, but do not require, the presence of concurrent MCI (Ismail et al., 2016).

Causes

Causes of MCI include many underlying neurodegenerative pathologies, as well as potentially reversible metabolic, psychiatric, and drug-related causes (Table 29.4). Risk factors for the development of MCI include: advanced age; apolipoprotein $\epsilon 4$ allele; low level of education; vascular risk factors (smoking, type 2 diabetes mellitus, dyslipidaemia, obesity, and hypertension); cardiovascular disease (coronary artery disease, atrial fibrillation, congestive cardiac failure); cerebrovascular disease; depression; and anxiety (Roberts and Knopman, 2013).

Mild cognitive impairment

Table 29.4 Potential causes of MCI.	
Neurodegenerative causes	Other causes
• Alzheimer's disease • Parkinson's disease • Lewy body disease • Frontotemporal lobar degeneration • Huntington's disease	• Vascular cognitive impairment, including post-stroke cognitive impairment and small vessel disease • Metabolic (e.g. recurrent hypoglycaemia; hypothyroidism; liver or renal failure) • Nutritional (e.g. B12 deficiency; pellagra) • Alcohol-related • Drug-related (e.g. anticholinergics; opiates; benzodiazepines) • Psychiatric (e.g. depression; anxiety; schizophrenia) • Traumatic brain injury • Infective (e.g. HIV) • Inflammatory (e.g. multiple sclerosis; systemic lupus erythematosus; vasculitis) • Autoimmune (e.g. limbic encephalitis, paraneoplastic syndromes)

Neuropathology

As the clinical syndrome of MCI is likely to encompass a variety of different underlying aetiologies, the pathophysiology of MCI is generally approached using this same aetiological framework. As might be expected, AD pathology is most frequently observed in MCI, particularly amnesic MCI (Jicha et al., 2006; Petersen et al., 2006), with cerebrovascular disease as the next most frequent pathology (Markesbery, 2010; Bennet et al., 2005; O'Brien et al., 2003). Other molecular pathologies associated with neurodegenerative diseases, including synucleinopathy, are seen less frequently. In some cases of MCI, no observed pathology or non-specific pathology is identified (Saito and Murayama 2007).

Mild cognitive impairment

However, attempts to establish causal links between the presence of pathological change and the symptoms of MCI are complicated by two issues. First, there exists a high degree of overlap in the amount of histopathological change seen in the brains of cognitively normal older adults, MCI patients, and dementia patients. For example, the sequential spread of β -amyloid and tau neuropathology in AD is well described by the Braak staging system (Braak and Braak, 1991), but neuropathological changes predate the onset of dementia and are observed frequently in individuals without dementia. Both β -amyloid and tau pathology are observed in the brains of cognitively normal adults (Stephan et al., 2012; Braak et al., 2011). In MCI patients, the amyloid burden varies in amplitude and cortical distribution but largely appears to lie at an intermediate level between that seen in healthy ageing and AD (Markesbery et al., 2006; Petersen et al., 2006; Jicha et al., 2006). In contrast to β -amyloid pathology, the presence of which does not correlate strongly with symptomatology, there is a close association between tau pathology, neuronal loss, and cognitive impairment in MCI. Even in very mild AD, stereological studies have shown 60% loss of layer II entorhinal cortex neurons, indicating that there is already significant neurodegeneration by the time that individuals present with symptoms (Gomez-Isla et al., 1996).

The second issue is that multiple pathological processes frequently coexist in the brains of MCI patients. Jicha and colleagues' (2006) longitudinal community-based study of 34 MCI patients who progressed to dementia and underwent post-mortem analysis revealed primary AD pathology with concomitant cerebrovascular pathology in 35% of patients, and concomitant Lewy body pathology in 26% of patients. Furthermore, a non-AD primary pathological abnormality was observed in 29% of the participants who had progressed clinically to AD dementia. The presence of mixed AD and cerebrovascular pathology is especially common (Bennett et al., 2005), but determining the relative contribution of each to the development of MCI is challenging.

Biomarkers

Given the importance of identifying AD in its earliest stages, the use of biomarkers in the diagnosis of MCI has been extensively investigated. At present, these biomarkers can be divided into two categories, detectable either by neuroimaging (MRI or PET) or by cerebrospinal fluid (CSF) assays:

- Markers of amyloid deposition:
 - Reduced CSF levels of $A\beta_{42}$
 - Positive amyloid PET imaging
- Markers of downstream neuronal injury:
 - Elevated CSF levels of tau or phosphorylated-tau (p-tau)

Mild cognitive impairment

- Hippocampal/medial temporal lobe atrophy on structural MRI
- Hypometabolism in the temporo-parietal cortex on FDG-PET

In terms of the temporal progression of biomarker change in MCI and AD dementia, Jack, Sperling and colleagues (Jack et al., 2013; Sperling et al., 2011; Jack et al., 2010) proposed a widely referenced hypothetical model (Fig. 29.1), in which amyloid deposition is the first pathological change, occurring prior to cognitive impairment, followed by neurodegeneration and then symptom onset. According to this model, biomarker evidence of both amyloid deposition and neuronal injury is established by the time MCI is diagnosed.

Fig. 29.1

Sperling and colleagues' proposed stages of pre-clinical AD. Some individuals may not progress beyond any one stage.

Copyright © 2011 Published by Elsevier B.V. <https://doi.org/10.1016/j.jalz.2011.03.003>.

CSF biomarkers

In the context of clinically diagnosed MCI, CSF amyloid/tau biomarkers have been suggested to have prognostic value in indicating likelihood of progression of MCI to AD (Blennow et al, 2010; Hansson et al., 2006). A meta-analysis of 12 studies by Olsson and colleagues (2016) confirms significantly increased CSF tau and p-tau and significantly depleted CSF A β_{42} in MCI patients who progress to AD compared with patients with stable MCI. The sensitivity and specificity of CSF biomarkers for predicting progression of MCI to AD was further examined Ritchie and colleagues (2017) in a Cochrane systematic review of 15 studies encompassing 1172 MCI cases, of which 430 progressed to AD and 130 to non-AD dementia over the follow up period of up to four years. CSF tau sensitivities were quoted between 51-90%, with specificities of 48-88% (seven studies); CSF p-tau sensitivities were 40-100% and specificities

Mild cognitive impairment

were 22–86% (six studies); and the ratio of CSF p-tau/ A β ₄₂ yielded sensitivities of 80–96% and specificities of 33–95% (five studies). These rather cautionary results suggest that CSF biomarker testing in its current form is of greater value in identifying those with low risk of progression to AD than identifying those at high risk of progression. While this initially seems problematic considering the inclusion of biomarkers in the NIA-AA and IWG-2 research criteria above, there is potential for further work to be done to overcome existing limitations of CSF biomarker testing to improve accuracy and prognostic value (Box 29.4).

Box 29.4 Limitations of CSF biomarkers in MCI due to AD

Although CSF biomarkers are increasingly used in specialist clinics within the diagnostic workup of MCI, extensive validation work needs to be done before they are recommended for use in routine clinical practice. At present, there remains a paucity of research comparing individual biomarkers or combinations of biomarkers with one another in multivariate studies and there have been few studies directly comparing biomarkers in life with post-mortem data. It is therefore currently difficult to understand the relative importance of different biomarkers when used together or to interpret results when biomarker data conflict with one another, e.g. when CSF amyloid is low but CSF p-tau is normal. Furthermore, normative values for each CSF marker vary according to age: CSF tau and p-tau both increase with age over the lifespan of cognitively normal adults, while the association between CSF A β ₄₂ is complex, modified by both gender and APO ϵ 4 status (Li et al., 2017). Finally, interlaboratory variations in CSF biomarker results can arise as a consequence of various factors (including differences in CSF acquisition/storage protocols and assay kits). As the field of CSF biomarker research matures, harmonization of standardized operating protocols and implementation of an international quality control programme will address many of the current limitations.

Neuroimaging changes in MCI due to AD

Amyloid PET

Amyloid PET imaging, using either ¹¹C or ¹⁸F ligands, is listed by both IWG-2 and NIA-AA research guidelines as a means for determining the presence of underlying AD in patients with MCI due to AD. Comparison studies of CSF and PET biomarkers have shown a very high concordance between low CSF amyloid and abnormal amyloid PET deposition (Palmqvist et al., 2015). While the ¹¹C-based Pittsburgh Compound B was the first amyloid PET ligand to be introduced, the short half-life of ¹¹C has

Mild cognitive impairment

seen its usage overtaken by longer half-life ^{18}F ligands. In terms of the sensitivity and specificity for AD, a Cochrane systematic review of nine studies encompassing 274 MCI patients indicated that amyloid PET was sensitive, but not particularly specific, for MCI due to AD (S. Zhang et al., 2014). In this review, 112 out of 274 MCI patients (34%) converted from MCI to dementia during follow-up, with positive amyloid-PET yielding sensitivities ranging from 83–100% and specificities of 46–88% for predicting conversion. As with other markers of amyloid deposition, amyloid PET positivity is seen in cognitively normal adults and increases with age, accounting for its low specificity: one prospective cohort study of 177 healthy controls observed positivity in 18% of 60–69 year olds, 37% in 70–79 year olds, and 65% in those aged over 80 years (Rowe et al., 2010).

Tau PET

Historically, in vivo imaging of tau has been more challenging than amyloid imaging because of its intracellular aggregation. The development of tau-specific PET tracers, e.g. THK5117, THK5351, AV-1451, and PBB3, has changed this. Early studies of tau PET imaging show tau deposition in the medial temporal lobes of MCI patients, consistent with Braak staging of neurofibrillary tangles, and extension of tau PET changes into the neocortex correlates with progression of cognitive impairment (Cho et al., 2016; Johnson et al., 2016). As such there is considerable interest in the future use of tau PET as a biomarker for use in future clinical trials as an outcome measure.

Structural imaging: CT

CT scanning is used primarily to exclude alternative cerebral pathologies when MCI due to AD is suspected, such as malignancy, bleeds, and normal pressure hydrocephalus. While global and regional brain atrophy are detectable on CT, volume loss is more easily detected on MRI in view of its higher spatial resolution (O'Brien, 2007).

Structural imaging: MRI

Whole brain atrophy and atrophy of medial temporal lobe structures, such as the hippocampus and entorhinal cortex, are commonly seen in MCI due to AD (Frisoni et al., 2010) and can be predictive of progression from MCI to dementia, with 73% sensitivity and 81% specificity reported in one meta-analysis (Yuan et al., 2009). The importance of MRI evidence of neurodegeneration is reflected in its inclusion as a diagnostic marker in both the IWG-2 and the NIA-AA guidelines. However, two cautionary observations need to be considered. First, atrophy may not be detected in the earliest stages of any neurodegenerative disease and may therefore not be present in earlier stages of MCI. Second, hippocampal atrophy is not specific to AD, and can occur in normal aging as well as in non-AD disorders such as syndromic variants of frontotemporal dementia (Chan et al. 2001, van de Pol et al., 2006), though less so in Lewy body dementia

Mild cognitive impairment

and subcortical vascular dementia (Burton et al., 2009). Improvements in the diagnostic specificity of hippocampal atrophy for prodromal AD may be achieved with longitudinal studies of atrophy rates (Leung et al., 2013), combinations of different structural MRI measurements (Falahati et al., 2017; Eskildsen et al., 2013) or use of high-resolution MRI to measure hippocampal subfields (Khan et al., 2015).

FDG-PET and SPECT

Single photon emission computed tomography (SPECT) and fluorodeoxyglucose photon emission tomography (FDG-PET) studies in MCI patients respectively show hypoperfusion and hypometabolism affecting medial parietal areas (including the precuneus, posterior cingulate, and retrosplenial areas), consistent with their early neuropathological involvement in AD (Chetelat et al. 2005; Pakrasi and O'Brien, 2005). In terms of predictive ability, a Cochrane meta-analysis found FDG-PET to be 76% sensitive with a median specificity of 82% for predicting progression from MCI to dementia (Smailagic et al., 2015), while a separate meta-analysis found SPECT to be 84% sensitive and 70% specific (Yuan et al., 2009).

As a hypothesized marker of downstream neuronal damage in the temporal model of AD (Jack et al., 2013), hypometabolism on FDG-PET appears to have good specificity for differentiating AD from other neurodegenerative diagnoses. Silverman and colleagues (2001) conducted a longitudinal study of MCI patients with FDG-PET scans. Among the 138 patients who developed dementia with confirmed neuropathological diagnosis, FDG-PET correctly predicted the presence or absence of AD in 88% of cases, with 94% sensitivity and 73% specificity. In a study of 548 individuals (consisting of 110 healthy controls and 114 MCI, 199 AD, 98 FTD, and 27 DLB patients), Mosconi and colleagues (2008) found disease-specific FDG-PET patterns allowed correct identification of 95% of AD, 92% of DLB, and 94% of FTD patients. The study also identified differential patterns of hypometabolism within the MCI group, with an AD-like PET pattern seen in 79% of MCI patients.

Additional imaging modalities

Structural imaging (CT or MRI), amyloid PET, SPECT, and FDG-PET are all used to varying degrees in the diagnostic workup of MCI with usage dependent on several factors including clinician preference, cost, and availability of scan options. In addition to the aforementioned imaging options, there exists a number of additional imaging modalities that are being extensively investigated in research studies of MCI, most notably the US-led Alzheimer's Disease Neuroimaging Initiative (ADNI, <http://adni.loni.usc.edu>), but currently lack validation as potential clinical diagnostic tools. Some of the more extensively studied modalities are summarized in brief next.

Mild cognitive impairment

MR Spectroscopy

Magnetic resonance spectroscopy allows non-invasive, in vivo measurement of the concentration of different brain metabolites that may be affected by neurodegenerative processes. Several spectroscopic alterations have been described in MCI, including changes in the myoinositol/creatinine ratio (Kantarci, 2013) and reduced N-acetylaspartate (NAA) within the hippocampus (Ackl et al., 2005). Given that myoinositol and NAA respectively reflect glial activity and neuronal integrity, these MRS data may provide some mechanistic insights into alterations of brain function in early AD. γ -aminobutyric acid (GABA), glutamate, and glutamine are also significantly reduced in amnesic MCI patients when compared with age-matched controls. However, this reduction does not correlate with amyloid PET positivity, suggesting that these metabolic changes are unrelated to amyloid deposition and perhaps reflect other aspects of AD pathophysiology (Riese et al., 2015).

Functional MRI

Functional MRI (fMRI) involves the detection of changes in blood oxygen level-dependent (BOLD) signal that reflect regional or network activity within the brain. Imaging may take place while an individual is in the resting state (rs-fMRI, also known as task-free fMRI) or while performing an explicit task (task-related fMRI). Changes in functional connectivity in MCI and early AD have been detected using rs-fMRI, particularly within the default mode network (DMN), a network most active under resting conditions and involving many areas including regions within the medial prefrontal cortex, medial parietal cortex and medial temporal lobe (Yeo et al., 2011; Greicius et al., 2003). Sorg and colleagues (2007) observed significantly reduced DMN activity in amnesic MCI patients, particularly in the posterior cingulate cortex and hippocampus, which they hypothesized was an early marker of the specific functional connectivity changes observed in the DMN in AD. As rs-fMRI techniques have developed, widespread disruption of functional connectivity has been noted in amnesic MCI patients, both in areas of the DMN known to be associated with early amyloid deposition and in areas in which AD pathology is observed at a late stage of the disease (Minati et al., 2014).

Initial task-related fMRI studies involving episodic memory paradigms were previously suggested to demonstrate hyperactivation of the medial temporal lobe in MCI patients and hypoactivation in AD patients. However, a subsequent meta-analysis of 75 studies concluded that differential hypoactivation is detectable on task-based fMRI in MCI and AD, but that patterns of hyperactivation appeared similar in both, suggesting a possible compensatory mechanism to pathological connectivity changes in both MCI and AD (Li et al., 2015).

Mild cognitive impairment

Diffusion tensor imaging

Diffusion tensor imaging (DTI) uses the diffusion patterns of water molecules to map white matter tracts in the brain, and is interpreted often in terms of fractional anisotropy (the extent of directional restriction of diffusion) and mean diffusivity (the magnitude of diffusion). White matter tract damage and neuronal loss are thought to be reflected in decreased fractional anisotropy and increased mean diffusivity, both reflecting the increased movement of water within the tissues as barriers to diffusion are disrupted (B. Zhang et al., 2014). Such changes have been observed in the hippocampus and fornix to varying degrees in MCI and AD patients (Zhuang et al., 2013; Clerx et al., 2012; Zhuang et al., 2012).

Neuroimaging changes in MCI due to non-AD disorders

Vascular cognitive impairment

MRI changes suggestive of a vascular component to MCI include white matter hyperintensities, infarcts and haemorrhages (Hachinski et al., 2006). While the relative contribution of such MRI changes to a patient's MCI symptoms is poorly quantified, the presence of white matter lesions on MRI in older people, especially when of greater severity than appropriate for age, carries an adverse prognosis in terms of cognitive and functional decline and mortality (Inzitari et al., 2009). When considered in conjunction with vascular risk factors (such as hypertension, diabetes, and high cholesterol), white matter lesions on MRI predicted a 3.5-fold risk of progression of MCI to all-cause dementia and a 3.8-fold risk of progression to AD (Clerici et al., 2012).

Parkinson's disease

Atrophy in the temporal, parietal and frontal cortices has been reported in patients with MCI in Parkinson's disease (PDMCI) when compared to patients with PD and normal cognition (PDNC) (Klein et al., 2018; Mak et al., 2015; Melzer et al., 2012; Song et al., 2011). Other studies have observed subcortical atrophy, including the hippocampus, thalamus, and nucleus accumbens (Mak et al., 2015; Mak et al., 2014; Weintraub et al., 2011). However, the evidence to date for structural MRI changes in PDMCI remains conflicting, with one notable study of 148 PD subjects finding no significant differences in cortical volumes when comparing PDMCI and healthy controls (Pereira et al., 2012). Neuroimaging biomarkers for the risk of PDMCI conversion to PD dementia continue to be sought.

Lewy body disease

In an initial study of 75 patients with MCI, of which 48 had a clinical diagnosis of possible or probable MCI with Lewy body disease (MCI-LB), (^{123}I)FP-CIT SPECT imaging identified MCI-LB with a sensitivity of 54% and specificity of 89% (Thomas et al., 2019). Low tracer uptake in ^{123}I -metaiodobenzylguanidine (MIBG) cardiac scintigraphy has also been

Mild cognitive impairment

suggested in small case series as a potential predictor of progression from amnesic MCI to DLB (Fujishiro et al., 2012). The utility of both modalities of imaging as biomarkers in MCI-LB requires further investigation (Donaghy et al., 2015).

Frontotemporal dementia

Hippocampal atrophy is observed on MRI in patients with established frontotemporal lobar degeneration, with differing patterns of atrophy in its three main clinical subtypes: behavioural variant frontotemporal dementia, semantic dementia, and progressive non-fluent aphasia (van de Pol, 2006; Chan et al., 2001). Studies of genetic FTD have shown that atrophy predates symptom onset and that different atrophy patterns are associated with each mutation, though with a common network of affected regions including the insula, anterior cingulate gyrus, and orbitofrontal cortex (Cash et al., 2018). Of all measured regions, the insula was the first to exhibit volume loss (Rohrer et al., 2015).

A clinician's approach to MCI

History

Patients with MCI typically present with a concern about a decline in episodic memory. Unlike patients presenting with dementia, when insight may be compromised, affected individuals may be able to provide a detailed history of their cognitive difficulties. It is important to be aware that their subjective reporting of symptom severity may be enhanced (if there is underlying anxiety) or diminished (if early AD, i.e. 'forgetting what they have forgotten') and it is critical therefore that a collateral history is obtained from an informant, typically a close friend or relative, and that some objective cognitive testing is undertaken against which to compare the subjective history.

History taking should focus on the types of cognitive problems encountered. It is not uncommon for the patient's report of 'memory' decline to reflect not impairment of episodic memory but instead impairment of attention, naming, or familiar face recognition (prosopagnosia), which may point towards a non-AD diagnosis such as FTD. Questions used to probe episodic memory could include those about recollections of events from day to day, conversations, and appointments. By contrast, symptoms that might indicate a disorder of attention/working memory rather than episodic memory would include misplacing items, defective engagement in everyday functions (e.g. leaving the kettle on accidentally), or transient difficulty in remembering short-term information (e.g. going into a room to perform a task but forgetting what on arrival). There is increasing awareness that spatial navigation can be affected from the earliest stages of AD (e.g. Serino et al., 2014), possibly relating to the role of the hippocampus in spatial memory (Burgess et al., 2002; O'Keefe and Nadel, 1978), and this can be probed with questions about getting lost or impaired sense of direction when driving or walking.

Mild cognitive impairment

Executive function can be assessed with queries about problem-solving ability, multi-tasking, and organizational ability. Finally, as well as directed questions evaluating different cognitive functions, the onset (sudden vs gradual) and timescale (duration of symptoms, static vs progressive decline since onset) of cognitive change may be diagnostically informative.

Age-associated cognitive decline is commonplace, and as such the earliest stages of MCI can be difficult to distinguish from healthy ageing on clinical grounds alone. The difficulty of determining the presence of early stage neurodegenerative disease is further complicated by inter-individual differences in cognitive reserve, which leads to the relative preservation of cognition in the context of age and age-related diseases as a result of higher IQ, education, and lifestyle (physical, social, and intellectual) activities. Individuals with high cognitive reserve present a particular diagnostic challenge since they may have early AD but present with minimal cognitive symptoms and have very high scores on cognitive testing. In such instances, careful diagnostic workup, including use of biomarker-based tests, is warranted.

Outside of the cognitive assessment, everyday activities and functions should be evaluated.

A noticeable deficit in the basic activities of daily living (ADLs) would exclude a diagnosis of MCI, but one might elicit subtle deficits in instrumental ADLs (IADLs; Table 29.5). For example, baseline data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) reveals difficulties with remembering appointments, family occasions, holidays, and medications, or assembling tax records, business affairs, or other papers, to be 95% specific in differentiating controls (229 individuals) from a combined group of amnesic MCI (394 individuals) and AD patients (193 individuals) (Brown et al., 2011). While the aMCI patients reported a significantly greater number of functional IADL deficits than controls, the level of severity per deficit was not significantly different between MCI individuals and controls. Extracting this kind of information requires detailed questioning of both patient and informant, but the aim is to establish an overall picture, rather than focus on any single incident.

Table 29.5 Examples of basic and instrumental activities of daily living (ADLs).

Basic ADLs	Instrumental ADLs
• Washing • Grooming (e.g. brushing hair) • Dressing	• Housekeeping and cleaning • Financial management • Food preparation • Medication administration

Mild cognitive impairment

• Toileting and continence • Transferring and mobility • Self-feeding	• Grocery shopping • Navigational ability and local mobility (including driving and use of public transport) • Social functioning and communication (including phone or internet use, social interaction, and appointment keeping) • Care of children or pets

Additional questions should focus on sleep (duration of night-time sleep, apnoeic episodes, behavioural disorder during sleep, daytime somnolence), social behaviour, and neuropsychiatric symptoms.

Determination of anxiety is of particular relevance; while anxiety is a common cause of subjective cognitive impairment, it may also be a symptom of prodromal AD. A targeted systems review should be performed, including review of symptoms of the reversible causes discussed above, as well as neurological and psychiatric symptoms including behavioural or personality changes, hallucinations, gait or speech changes, visual or hearing loss, or focal neurological symptoms indicative of other neurological disease. The presence of urinary incontinence and gait disturbance might suggest normal pressure hydrocephalus. Non-AD degenerative disorders may be flagged up on initial history taking; for instance, behavioural, personality, or language change might indicate an FTD syndrome, while visual hallucinations or REM sleep behaviour disorder might suggest Lewy body pathology.

Overall health status should be assessed, including the past medical history and psychiatric history. This includes screening for reversible causes of cognitive impairment, such as depression, anxiety, thyroid disease, nutritional deficiencies, and alcoholism. Cerebrovascular disease, vascular risk factors (smoking, hypertension, diabetes mellitus, dyslipidaemia, and obesity), or cardiovascular disease may suggest an underlying vascular aetiology. A full medication history is necessary, including over-the-counter medications; anticholinergics, antihistamines, opiates, benzodiazepines, and other sedatives (e.g. zopiclone) are just some of the medications that may contribute to impaired cognitive performance. Any family history of young-onset dementia might indicate a genetic disorder whereas a history of late-onset dementia will help determine the level of risk of AD.

Examination

MCI due to AD is not typically associated with any abnormalities on general neurological examination. However, the latter is required to look for clinical signs that might indicate the presence of an alternative underlying cause, such as focal neurological signs or gait apraxia

Mild cognitive impairment

(cerebrovascular disease), extrapyramidal signs (Lewy body disease), eye movement disorders (tauopathy), and frontal release signs (FTD).

Cognitive testing

Objective evidence of cognitive impairment is a core component of the diagnosis of MCI, although at present there exists no consensus on the specific cognitive tests to be applied. Cognitive testing can be applied in the form of a general cognitive test, encompassing several cognitive domains; one example is the Addenbrookes Cognitive Examination III (ACE III) (Hsieh et al., 2013). Shorter screening cognitive tests, such as the Mini Mental State Examination (MMSE) (Folstein et al., 1975) or Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005) are often used in primary care or domiciliary settings but were designed more for detection of dementia. Caution therefore needs to be exercised in terms of their value in the diagnosis of MCI, as evidenced by a Cochrane review indicating that the MMSE score is a very poor predictor of progression from MCI to dementia (Arevalo-Rodriguez et al., 2015).

Tests of specific cognitive domains are often used to supplement screening general cognitive tests, especially in clinical services where neuropsychological support for memory clinics is available. Given that AD is the commonest underlying cause of MCI, tests of episodic memory are of paramount importance. These can vary in terms of duration and complexity, and current guidelines do not make recommendations for any particular test, though several are namechecked in the 2014 IWG-2 guidelines, notably the Free and Cued Selective Reminding Test (FCSRT) (Buschke, 1984), Paired Associates Learning (PAL) (Barnett et al., 2015) and the Rey Auditory Verbal Learning Test (RAVLT) (Rosenberg et al., 1984). Mention also is made of more recently introduced tests designed around theories of entorhinal cortex and hippocampal function, such as the 4 Mountains Test of spatial memory (Chan et al., 2016; Hartley et al., 2007) and the short-term memory binding test (Pertzov et al., 2012). This overlaps in part with the tests named in the 2011 NIA-AA guidelines, which refer to several verbal learning tests as well as the Logical Memory and Visual Reproduction subtests from the Wechsler Memory Scale (Wechsler, 1987). Tests assessing other cognitive domains include tests of attention and speed of information processing, naming, verbal fluency, and frontal executive function.

In all cases it is important to bear in mind that interpretation of test results needs to take into account background demographic information such as cultural background, premorbid IQ (if available), and years of education. The latter is particularly important, given that results on many cognitive tests are strongly correlated with levels of educational attainment.

In terms of the severity of impairment on cognitive testing required for the diagnosis of MCI, the Mayo Clinic criteria emphasize that diagnosis of MCI is a clinical judgment that neuropsychological tests can support; cut-

Mild cognitive impairment

off scores or thresholds for tests are not recommended and clinicians are encouraged to interpret objective test scores in the context of the case at hand. The NIA-AA criteria also do not specify cut-off scores for named cognitive tests, although suggest that as a guideline, MCI patients typically score 1 to 1.5 standard deviations below the mean for their age- and education-matched peers on culturally appropriate data. The DSM-5 criteria for mild neurocognitive disorder similarly indicate that performance typically lies between 1 to 2 standard deviations below the mean in diagnosed cases.

Investigations

Blood tests are performed to investigate possible underlying medical causes, including those that are potentially reversible. As a rough guide, these tests would include full blood count, renal function tests and electrolytes, liver function tests, glucose, thyroid function tests, vitamin B12 and folate, and lipid levels. Syphilis and HIV testing may be indicated in certain clinical contexts. Again, depending on context, more specialized blood tests could include tests for antibodies associated with autoimmune limbic encephalitis, paraneoplastic antibodies, and DNA testing for inherited dementias. Testing for susceptibility genes, such as Apoε4, is not currently recommended as a clinical test.

Brain imaging in the form of a CT or MRI scan is required in order to exclude structural causes of cognitive impairment, such as bleeds, neoplasms, or other space-occupying lesions. Patterns of cerebral atrophy or white matter changes may point towards particular degenerative diseases, although these may be subtle in MCI and qualitative radiological reporting in isolation is very rarely discriminative towards diagnosis in this respect.

Beyond this initial set of assessments and investigations, further testing will be performed at the discretion of the clinician and patient, in the context of local availability. Typically, second-line tests would involve either additional assessment with SPECT or FDG-PET if initial structural imaging is diagnostically uninformative, or biomarkers-based tests for underlying causes (ligand-PET or CSF amyloid/total tau/phosphorylated tau for AD; (¹²³I)FP-CIT or MIBG for DLB). Formal neuropsychological testing may be used to supplement initial clinic-based brief global cognitive testing, in order to look for cognitive profiles pointing towards specific neurodegenerative diseases, or non-degenerative aetiologies such as anxiety, as the underlying cause of MCI.

Management

Medication

To date, clinical studies of potential drug therapies for MCI have been largely negative. There is currently no pharmacological agent that is recommended to reverse MCI or slow its progression to dementia (Petersen, 2016). Cholinesterase inhibitors licensed for the treatment of

Mild cognitive impairment

AD dementia (donepezil, rivastigmine, and galantamine) overall have not been found to be efficacious when given in MCI (Doody et al., 2009; Feldman et al.; 2007, Winblad et al., 2008). Comprehensive systematic reviews of published and unpublished data for the use of cholinergic therapies in MCI (Raschetti et al., 2007), and pharmacological therapies at large (Ströhle et al., 2015; Cooper et al., 2013) found no significant difference in the probability of conversion from MCI to dementia between treated and placebo groups. Of non-cholinergic therapies, vitamin E and the anti-inflammatory agent rofecoxib also proved ineffective at slowing progression to dementia.

While reviews to date have concluded that there is no evidence to support the pharmacological treatment of MCI at present, this has to be taken in the context of limitations in terms of the design of previous MCI trials, including: i) the previous inclusion of patients diagnosed with MCI on clinical grounds alone, without biomarker evidence of underlying AD, resulting in an heterogeneous patient cohort; ii) short study durations so consequently low conversion rates from MCI to dementia; and iii) differences between trials in outcome measures used to assess treatment effect. More rigorous trial design and biomarker-based stratification of MCI patients will offset some of these limitations.

New pharmacological targets have emerged over recent years in the search for effective AD therapies, largely focused on β -amyloid given the amyloid hypothesis of AD. To date, phase I and II trials of β -secretase 1 (BACE-1) and γ -secretase inhibitors have proved negative (Mullard, 2017b). The monoclonal antibodies solanezumab, bapineuzumab, and gantenerumab, which bind β -amyloid directly, also missed their primary end points in phase III trials with AD patients (Mullard, 2017a). Aducanumab, had also initially not met its primary endpoints in its phase III trials, although a re-analysis of the trial data suggested that patients receiving a higher dose had a slower decline although at time of writing, this conclusion remains controversial. Nevertheless, Biogen, who own this agent announced plans to apply in early 2020 for regulatory approval for aducanumab in the U.S.

An alternative approach to targeting AD molecular pathology is intervention aimed at the physiological changes in AD. One such trial involved the food supplement, Souvenaid, containing compounds required for brain phospholipid synthesis and shown in animal models to promote synapse formation, cholinergic neurotransmission, and neurogenesis (Janickova et al., 2015; Cansev et al., 2015; Broersen et al., 2013). However, a Souvenaid trial in prodromal AD also did not demonstrate a significant treatment effect in terms of the primary outcome measure, a change in neuropsychological test battery performance at two-year follow up (Soininen et al, 2017).

Non-pharmacological measures

Mild cognitive impairment

Cognitive therapy

Epidemiological studies have shown that low levels of education and reduced engagement in cognitively stimulating activities are both independent predictors of subsequent dementia. As a result, there has been great interest in cognitive training strategies that might slow or halt progression of MCI to dementia. However, a systematic review of treatments for MCI (Cooper et al., 2013) found that existing cognitive therapy studies were consistently underpowered to detect differences. The interventions reviewed included computer-assisted cognitive training, and group psychological therapy (consisting of memory training; reminiscence, psychomotor, and recreational tasks; multisensory stimulation; and social interaction). Other reviews (e.g. Stott and Spector, 2011) have raised concerns about the poor methodological quality of cognitive therapy studies, limiting the conclusions that may be drawn from them. Overall, higher-quality, adequately powered studies are necessary to establish whether cognitive training is an effective treatment option for MCI.

Physical exercise

A meta-analysis of exercise interventions in six MCI studies involving 443 patients showed a modest benefit of exercise in slowing progression of MCI (Ströhle et al., 2015), with a further meta-analysis of combined cognitive and physical exercise training in MCI over ten studies also showing a modest improvement in global cognition scores (Karssemeijer et al., 2017). Results, however, remain conflicting: a high-quality randomized trial comparing a year-long programme of twice-weekly group exercise (moderate-intensity walking) with a low-intensity placebo programme (relaxation, balance, and stretching exercises) found no significant difference in cognitive performance in any domain although there was a significant difference in perceived quality of life (van Uffelen et al., 2007). Another high-quality, double-blinded, randomized controlled trial investigated the combined effect of lifestyle interventions in cognitively intact older adults at risk of dementia (Ngandu et al., 2015). There were 1,260 participants between the ages of 60–77 and without MCI, but at high risk of dementia as determined by the Cardiovascular Risk Factors, Aging and Dementia (CAIDE) Risk Score. There was a small but significant effect on cognition in the group randomized to a two-year programme of cognitive training, diet, exercise, and vascular risk-factor modification when compared to the control group. The preventative benefits of combined lifestyle-based interventions in those at risk of MCI and dementia continue to be investigated. As with other interventional MCI studies, the heterogeneity of the MCI study populations affects the interpretation of results, in that it remains unclear if any identified benefits relate to a non-specific cardiovascular benefit, rather than any disease-modifying effect on neurodegenerative pathologies.

Conclusion

From its inception in 1999 to the current day, there has been an evolution in the concept of MCI. Underlying the MCI concept is the notion that it may represent a transitional state between healthy ageing and dementia, and the awareness that it may be caused by a number of different underlying diseases. MCI, identified on clinical grounds alone, describes a heterogeneous patient group that includes those with non-degenerative conditions at low risk of future dementia, such as anxiety. The ability to predict progression from MCI to dementia is therefore dependent on the provision of ancillary information such as biomarker data.

Future years will likely see further refinement of the MCI concept, taking into account not only predictive biomarkers, but also its role in the spectrum from cognitively normal, through to subjective cognitive impairment and ultimately dementia. Greater understanding of MCI and other pre-dementia states will be crucial for the long-term management of the ageing population and the advent of interventions for delaying or preventing the onset of dementia.

DOI: 10.1093/med/9780198807292.003.0030

Introduction

Alois Alzheimer wrote his original report (Alzheimer, 1907) on a 51-year-old woman (Auguste D) who had suffered an illness involving cognitive impairment and other symptoms including delusions and hallucinations. At post-mortem he described the principal neuropathological features, senile plaques and neurofibrillary tangles, of what we now call Alzheimer's disease (AD). This eponymous term was coined by Kraepelin and was initially restricted to a presenile degenerative dementia. After several decades, Sir Martin Roth and colleagues recognized that older people with identical symptomatology and pathological features had the same disease and, in fact, formed the great majority of cases. AD therefore evolved to become a characteristic clinical syndrome that usually occurs in later life and which is associated with the neuropathological findings described in detail in Chapter 5. The young age of onset in Auguste D has prompted speculation as to whether there may have been an underlying genetic mutation in her case. A 2013 paper

Alzheimer's disease

suggested a presenilin 1 mutation, though this finding has not been subsequently replicated (Muller et al., 2013, Rupp et al., 2014).

AD as a clinicopathological entity has further evolved significantly, particularly in the past ten years. In particular, with the advent of early biomarkers and enhanced aetiological understanding for the basis of AD, there is now a recognition that AD has an extensive preclinical phase which can antedate the onset of dementia by many years.

Alzheimer's disease and the dementia syndrome

Diagnostic criteria for Alzheimer's disease: ICD-10, 11, and DSM-5 criteria

Having confirmed a patient has the dementia syndrome, the next stage is to try to establish the cause. Since AD causes over 50% of all dementia, it has come to be regarded almost as the model for dementia. As such, there was a tendency to diagnose AD by default rather than by the positive identification of the clinical syndrome though this should no longer be the case as biomarkers, imaging, and clinical description of the syndrome have become more sophisticated.

ICD-10 requires that dementia due to AD has an insidious onset and a gradual progression. AD cannot be diagnosed if there is a sudden onset, if there are neurological signs indicating focal brain damage or if the dementia can be explained by other brain or systemic disease. At the time of writing, there is an ongoing revision to ICD and the new DSM-5 diagnostic criteria have recently been published, although these are not the only recently described diagnostic criteria for AD (see Other AD criteria). A key difference between DSM-IV and DSM-5 has been the renaming of the category of the generic 'dementia' syndrome used in DSM-IV to that of 'major neurocognitive disorder'. This change in nomenclature has been driven in part by the ongoing debate of the utility vs pejorative associations of the word 'dementia' as well as the prior tendency to always associate 'dementia' with Alzheimer's when there are, of course, many causes of dementia (Sachdev et al., 2015). More specifically and relevant to this chapter, the DSM-5 criteria now include a diagnosis of major or mild neurocognitive disorder, of which AD is one subtype. Mild neurocognitive disorder is used in recognition that less severe cognitive impairment can occur and thus might allow for earlier diagnosis. In addition, mild cognitive disorder as an umbrella diagnosis can include cases where the cognitive impairment is non-progressive (e.g. due to head injury) rather than progressive. These criteria overlap with definitions of mild cognitive impairment (MCI) (Chapter 29) where patients are still maintaining their functional independence, although for a diagnosis of mild cognitive disorder due to probable AD, DSM-5 criteria demand that there has to be the presence of a causative AD-related genetic mutation given the high degree of uncertainty that exists in the diagnosis of AD in the very early stage. There are more flexible diagnoses for both major and mild neurocognitive disorder, i.e. possible AD is

Alzheimer's disease

accommodated if key criteria are not met, including lack of evidence of a decline in memory and learning as well as at least one other cognitive domain, unclear progression with either atypical declines or extended plateaus, or the suggestion that the cognitive impairment is secondary to mixed aetiologies.

DSM-5 includes the recognition that comorbidity is the norm and that having cerebrovascular disease does not preclude an individual also having AD, or vice versa. Indeed DSM-5 can accommodate mixed aetiologies (e.g. vascular and AD) by listing each under a separate diagnostic heading. Similarly, while typical presentations are amnesic, the new criteria accept that memory loss is not an absolute criterion for the major neurocognitive disorder due to AD; other presentations with prominent visuospatial deficits or logopenic aphasia are accepted variants. In addition, the separation between early and late onset that was present in DSM-IV has been removed, given the lack of scientific validity in this arbitrary distinction. Finally, criteria also consider the presence and absence of behavioural symptoms (e.g. depression, apathy, psychosis, etc.) as well as the severity of functional deficits that range from impairments in only instrumental activities of daily living (ADLs) (mild) such as managing money through to impairments in basic ADLs such as dressing/feeding self (moderate) and then to total dependency (severe).

ICD-10 was endorsed in May 1990. An early version of ICD-11 was released in June 2018 to allow preparation for transition with anticipated ratification in 2019 and changes to reporting from 2022. The advance online ICD-11 description for dementia retains many of the features from ICD-10 and describes a decline in previous level of function in at least two cognitive domains which significantly impairs independence or ADLs and arises from a condition affecting the brain. The conditions listed include trauma, which suggests the possibility of dementia encompassing relatively fixed deficits in contrast to the description of dementia being usually 'chronic or progressive' in ICD-10. The diagnostic description of Alzheimer's disease in ICD-11 recognizes the early appearance of memory symptoms and progression to include other cortical cognitive domains as well as the common occurrence of other mental and behavioural symptoms, many of which are included as sub codes.

Other recent Alzheimer's disease criteria

Both the ICD-10 and DSM-5 criteria for AD are related to the NINCDS-ADRDA (National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association) criteria. The original 1984 NINCDS-ADRDA criteria (McKhann et al., 1984) have been shown to have a sensitivity and specificity for AD of over 80% (Burns et al., 1990f; McKeith et al., 2000a) and have very good inter-rater reliability (Farrer et al., 1994), but they have now been superseded by the revised 2011 criteria (McKhann et al., 2011). In the intervening years since the original criteria, our understanding of the

Alzheimer's disease

pathophysiology and clinical progression has advanced and, as a result, there have been recent and, indeed, necessary reconsiderations of the diagnostic criteria for AD: the Working Group for New Research Criteria for the Diagnosis of Alzheimer's Disease led by Bruno Dubois (Dubois et al., 2007, 2010) and the revised McKhann criteria from the Alzheimer's Association (AA) and National Institute on Aging (NIA) (McKhann et al., 2011). While there are notable differences between these two diagnostic systems and ongoing debate regarding the most appropriate nomenclature, within these new criteria there is now an emphasis on how one defines Alzheimer's as a disease process and a focus on classification of Alzheimer's before the emergence of the dementia, with increasing prominence given to biomarkers from cerebrospinal fluid (CSF) and neuroimaging.

International Working Group for New Research Criteria for the Diagnosis of Alzheimer's Disease

The criteria proposed by Dubois and colleagues (2010) seek to establish a new nosological lexicon for AD by dividing it into three categories: 'preclinical stages of AD', 'prodromal stages of AD', and 'AD dementia'; these categories represent a continuum from individuals who evidence the presence of AD pathology as evaluated using biomarkers (coined 'symptomatic at risk'), or who have a genetic mutation that makes eventual AD dementia a certainty (defined as 'pre-symptomatic AD') but who do not currently have any cognitive or behavioural symptoms, through to individuals with mild symptoms and biomarker evidence of AD pathology but who do not reach the threshold for AD dementia diagnosis, and finally to those who have frank and symptomatic AD dementia. Chapter 29 describes in detail the 'preclinical stages of AD' and 'prodromal stages of AD', whereas the different lexical concepts of AD dementia including typical, atypical, and mixed AD dementia proposed by Dubois and colleagues (2007) are described here:

Typical AD: This refers to the most common clinical presentation of AD which is characterized by an early significant and progressive episodic memory deficit that remains dominant in the later stages of the disease, and is followed by or associated with other cognitive impairments (executive dysfunction, language, praxis, and complex visual processing impairments) and neuropsychiatric changes. The emphasis on episodic memory deficits or amnesic syndrome of the hippocampal type as a core feature arises from empirical evidence that the medial temporal lobes are typically the first structure affected by AD pathology before it cascades to other cortical areas. The criteria also allow for further support for the diagnosis of 'typical AD' by the presence of one or more AD biomarkers (Box 30.1).

Box 30.1 Alzheimer disease biomarkers

Alzheimer's disease

In the Dubois and colleagues (2007) criteria, biomarkers are divided into pathophysiological and topographical markers.

Pathophysiological markers relate to known degenerative processes that are associated with AD, including amyloid deposition

(particularly amyloid 1-42 beta) and the presence of abnormal tau.

Topographic markers relate to the subsequent impact of these cellular pathological changes, such as structural atrophy in the medial temporal lobe and reduced metabolism in temporoparietal regions on PET FDG imaging.

Reproduced with permission from Dubois, B., Feldman, H. H., Jacova, C. et al. Revising the definition of Alzheimer's disease: a new lexicon. The Lancet Neurology, 9(11): 1118-27. Copyright © 2010 Elsevier Ltd. All rights reserved. DOI:[https://doi.org/10.1016/S1474-4422\(10\)70223-4](https://doi.org/10.1016/S1474-4422(10)70223-4).

Atypical AD: This term is used to describe less common variants of AD, including syndromes such as progressive non-fluent aphasia, logopenic aphasia (characterized by slow speech and word-finding difficulties), frontal variant of AD, and posterior cortical atrophy; however, as these syndromes also map onto other differential diagnoses (e.g.

frontotemporal dementias) the criteria demand that the diagnosis of AD is supported by presence of amyloid in the brain (tested using, for example, amyloid labelled radioligands) or CSF changes characteristic of AD.

Mixed AD: This is used in the criteria to include individuals who meet the 'typical AD' criteria but who additionally have evidence (e.g. clinical, imaging, or biological) of other conditions that could be causing their dementia, such as cerebrovascular disease or Lewy body disease. Thus, one might consider mixed AD if there was a history of parkinsonism, gait disturbance, hallucinations, cognitive fluctuations, recent or past history of stroke, or evidence of small vessel ischaemic change or infarcts on neuroimaging. However, it is important to note that the presence of these symptoms or signs does not equate to an assumption of mixed aetiology. Indeed, Dubois and colleagues propose that, in the case of mixed AD and cerebrovascular disease, there must be both a history of stroke and imaging signs of cerebrovascular disease.

NIA/AA diagnostic criteria

The new NIA/AA guidelines for the diagnosis of AD, envisaged as a replacement to the 1984 NINCDS-ADRDA criteria (McKhann et al., 1984), are not dramatically different from the original criteria, although there is a recognition in that other forms of dementia such as dementia with Lewy bodies (DLB), vascular dementia (VaD), and frontotemporal dementia (FTD) have distinguishing and different clinical features that were not defined in the NINCDS-ADRDA criteria. As such, the NIA/AA guidelines have overarching diagnostic criteria for all dementias (defined as all-

Alzheimer's disease

cause dementia) as well as specific criteria for dementia caused by Alzheimer's. Finally, there is an awareness in the guidelines that genetics and biomarkers have a role in increasing the certainty of the diagnosis. Table 30.1 shows a summary of the classification of dementia due to AD by these guidelines. All-cause dementia is diagnosed (a prerequisite before considering the diagnosis of AD) when there are cognitive or behavioural symptoms that:

1. interfere with the ability to function at work or at usual activities;
2. represent a decline from previous levels of functioning and performing; and
3. are not explained by delirium or major psychiatric disorder.

Table 30.1 NIA/AA diagnostic criteria.

Probable AD dementia: Core clinical criteria	
	Meets criteria for dementia (discussed in text) and, in addition, has the following characteristics: A. Insidious onset. Symptoms have a gradual onset over months to years, not sudden over hours or days; B. Clear-cut history of worsening of cognition by report or observation; and, C. The initial and most prominent cognitive deficits are evident on history and examination in one of the following categories: i) Amnestic presentation: it is the most common syndromic presentation of AD dementia. The deficits should include impairment in learning and recall of recently learned information. There should also be evidence of cognitive dysfunction in at least one other cognitive domain, e.g. impaired reasoning and handling of complex tasks or impaired visuospatial ability) ii) Non-amnestic presentations: • Language presentation: the most prominent deficits are in word-finding. • Visuospatial presentation: the most prominent deficits are in spatial cognition, including object agnosia, impaired face recognition, simultanagnosia, and alexia.

Alzheimer's disease

	• Executive dysfunction: the most prominent deficits are impaired reasoning, judgment, and problem solving. <i>Note:</i> for each presentation, deficits in other cognitive domains should also be present. D. The diagnosis of probable AD dementia should not be applied when there is evidence of: i) substantial concomitant cerebrovascular disease, defined by a history of a stroke temporally related to the onset or worsening of cognitive impairment; or the presence of multiple or extensive infarcts or severe white matter hyperintensity burden; or ii) core features of DLB other than dementia itself; or iii) prominent features of behavioural variant FTD; or iv) prominent features of semantic variant primary progressive aphasia or non-fluent/agrammatic variant primary progressive aphasia; or v) evidence for another concurrent, active neurological disease, or a non-neurological medical comorbidity, or use of medication that could have a substantial effect on cognition.
Probable AD dementia with increased level of certainty	
Probable AD dementia with documented decline	Evidence of progressive cognitive decline on subsequent evaluations based on information from informants and cognitive testing in the context of either formal neuropsychological evaluation or standardized mental status examinations.
Probable AD dementia in a carrier of a causative AD genetic mutation	Evidence of a causative genetic mutation (in APP, PSEN1, or PSEN2) increases the certainty that the condition is caused by AD pathology.
Possible AD dementia: Core clinical criteria	

Alzheimer's disease

Possible AD dementia with atypical course	Atypical course meets the core clinical criteria in terms of the nature of the cognitive deficits for AD dementia, but either has a sudden onset of cognitive impairment or demonstrates insufficient historical detail or objective cognitive documentation of progressive decline.
Possible AD dementia with aetiologically mixed presentation	Meets all core clinical criteria for AD dementia but has evidence of: i) concomitant cerebrovascular disease, defined by a history of stroke temporally related to the onset or worsening of cognitive impairment; or the presence of multiple or extensive infarcts or severe white matter hyperintensity burden; or ii) features of DLB other than the dementia itself; or iii) evidence for another neurological disease or a non-neurological medical comorbidity or medication use that could have a substantial effect on cognition.
Probable AD dementia with evidence of the AD pathophysiological process	
	Diagnosis made in persons who meet the core clinical criteria for probable AD and who have biomarker evidence of AD pathophysiology, which increases the certainty that the basis of the clinical dementia syndrome is the AD pathophysiological process. Biomarkers include those described in Box 30.1
Possible AD dementia with evidence of the AD pathophysiological process	
	Reserved for people with clinical criteria for a non-AD dementia but who either have biomarker evidence of AD pathophysiological process or meet the neuropathological criteria for AD.
Pathophysiologically proved AD dementia	
	Meets the clinical and cognitive criteria for AD dementia outlined earlier in the text, and the

Alzheimer's disease

	neuropathological examination, using widely accepted criteria (Hyman and Trojanowski, 1997).
Dementia unlikely to be due to AD	
	A. Does not meet clinical criteria for AD dementia. B. i) Regardless of meeting clinical criteria for probable or possible AD dementia, there is sufficient evidence for an alternative diagnosis such as HIV dementia, dementia of Huntington's disease, or others that rarely, if ever, overlap with AD. ii) Regardless of meeting clinical criteria for possible AD dementia, both amyloid and neuronal injury biomarkers are negative.

Adapted with permission from McKhann, G. M., et al. The diagnosis of dementia due to Alzheimer's disease: recommendations from the National Institute on Aging- Alzheimer's Association workgroups on diagnostic guidelines for Alzheimer's disease. *Alzheimer's & Dementia*, 7(3): 263-9. Copyright © 2011 Published by Elsevier B.V. <https://doi.org/10.1016/j.jalz.2011.03.005>.

The guidelines suggest that the cognitive impairments should be diagnosed by taking a history from both the patient and an informant as well as carrying out an objective cognitive assessment. The NIA/AA guidelines demand that the cognitive or behavioural impairment includes a minimum of two domains (memory, executive, visuospatial, and language function; changes in personality, behaviour, or comportsment).

Summary: AD diagnosis

At the time of writing, we are currently in a state of flux with regard to how AD is diagnosed. This probably represents a 'paradigm shift' in how we clinically view the condition and how it will be treated in the future. Overall, there are significant overlaps between the new emerging diagnostic criteria, which share an emphasis on earlier diagnosis, that is, with a view to the development of disease-modifying treatments which would need to be given as early as possible in AD.

One challenge with the DSM-5 criteria is a lack of biological focus and no specific inclusion of biomarkers aside from family history and/or evidence of AD related genetic mutations.

Alzheimer's disease

Choice of which criteria are used may depend upon clinical speciality, local regulatory requirements, and familiarity, although overall while there are still differences between the various AD criteria, there is an increasing convergence of opinion (Morris et al., 2014). It seems likely that diagnostic criteria in the future will increasingly incorporate biomarkers as these are being continually refined with increased sensitivity and specificity.

Assessment

Regardless of whether we apply the ICD-10 or DSM-5 criteria, accurate assessment and diagnosis requires a systematic and thorough assessment: a full history (including from an informant), mental state examination, cognitive examination, physical assessment (including neurological examination), and investigations. The latter are important because alternative causes include both systemic diseases, e.g. vitamin B₁₂ deficiency and hypothyroidism, and brain diseases, e.g. normal pressure hydrocephalus and stroke. Box 30.2 shows a list of common investigations.

Box 30.2 Common investigations in dementia and Alzheimer's disease

- Full blood count
- Urea, creatinine, and electrolytes (including calcium)
- Liver function tests
- Thyroid function tests
- Vitamin B12 and folate
- Blood Glucose or HbA1c
- CT/MR scan of head to exclude other structural causes, to assess for level of vascular pathology, and to look for the extent and pattern of atrophy, looking particularly for medial temporal atrophy in AD

Additional investigations which may be appropriate in some cases include:

- Urinalysis
- HIV/syphilis serology
- Genetic testing for autosomal dominant genes leading to AD or those leading to other neurodegenerative diseases, e.g. FTD, CADASIL, or Huntington's disease
- Further imaging, including: SPECT hexamethylpropyleneamine oxime (HMPAO) or PET fluorodeoxyglucose (FDG) scan or Amyloid PET or ¹²³I-FP-CIT SPECT (FP-CIT SPECT) if DLB is a possibility.

Alzheimer's disease

- EEG
- Lumbar puncture including analysis for Alzheimer's proteins
- Detailed neuropsychological testing

Note: Conditions such as hypothyroidism and mild vitamin B12 deficiency are common and when they are detected by routine tests this does not necessarily indicate they are making a complete causal contribution to the cognitive problems.

The identification of C-11 labelled Pittsburgh Compound B provided the opportunity for in vivo identification of cerebral amyloid and therefore a possible biomarker for helping to diagnose AD (Klunk et al., 2004). Subsequently, more stable ligands have been identified which can do a similar job and studies in research participants have demonstrated potential usefulness as a diagnostic tool. However, a number of features make it more difficult to apply to clinical settings. One of these is that the incidence of positive amyloid scans increases with age. Half of those over 80 have a positive scan, but not all are demented (Rowe et al., 2010). There are also difficulties with 'false positives' in other dementing conditions (e.g. DLB) and also difficulty in distinguishing the exact nature of amyloid deposition. Nevertheless, this is a welcome potential extra tool in making what can be a difficult diagnosis, and consensus guidelines for use are beginning to appear (Johnson et al., 2013).

A further potential new diagnostic tool is analysis of CSF for A β 1-42, total tau (T-tau), and phosphorylated tau (P-tau). Amyloid concentrations in the CSF decrease with disease progression while tau and phosphorylated tau increase. This allows for the calculation of the ratios between these proteins to enhance diagnostic accuracy. Reported sensitivities and specificities have exceeded 90% and studies now include autopsy-confirmed cases (Engelborghs, 2008). However, much as with amyloid imaging, the specificity of CSF biomarkers decreases with age. Around a third of cognitively normal people aged 85 will have an abnormal result, and other degenerative diseases of the nervous system, including stroke and other forms of dementia, can also lead to an abnormal result. Clinical guidelines for these tests are also now emerging. For example, analysis of CSF for these proteins is included in the most recent NICE guidelines as an alternative to functional PET/SPECT scanning in cases where diagnosis is uncertain (<http://www.nice.org>).

Differential diagnosis

Historically, the biggest differential for AD among people with dementia was VaD. Understanding of the relationship between AD and VaD has evolved due to large pathological studies. These have demonstrated that vascular and Alzheimer pathologies become more common as we age and

Alzheimer's disease

increase the risk of dementia, but equally that some older people have pathologies associated with dementia, including AD, but do not show the clinical syndrome and so the correlation between pathology and dementia decreases with age (Saava et al., 2009). These pathological data correlate with the sensitivity of biomarkers and with clinical experience, so at younger age a relatively confident clinical diagnosis of dementia subtype can be made, but as age advances dementia is frequently mixed in origin. ICD-10 allows for a double diagnosis of AD and VaD, and new NIA/AA guidelines have a category of mixed dementia to include individuals who have cerebrovascular disease (stroke related to the onset/worsening of the dementia or evidence of severe white matter hyperintensities or infarcts on neuroimaging) but who also meet the core criteria for a diagnosis of AD dementia. As mentioned, the DSM-V criteria allow for an individual to have both a major/minor neurocognitive disorder due to AD as well as a major/minor neurocognitive disorder due to VaD.

Such a diagnosis should be made when there is clear evidence of each disease process contributing to the dementia, e.g. someone with AD who subsequently has a stroke and suddenly declines cognitively. However, a note of caution also needs to be given with the advance in neuroimaging methodologies, particularly magnetic resonance imaging: the mere presence of mild small vessel disease, lesions that are common even in non-cognitively impaired older people, should not be taken as evidence for a vascular contribution to the dementia. Indeed, in the AD criteria developed by Dubois and colleagues (2007), merely having white matter changes on imaging without any obvious neurological signs (e.g. motor or gait disturbance) cannot be used as a basis for making a diagnosis of mixed AD. Furthermore, more recent neuropathological studies have challenged the view that the changes regarded as being due to small vessel disease are purely vascular in origin, but instead might also relate to the Wallerian axonal degeneration that occurs in AD (McAleese et al. 2017).

A further major differential diagnosis for the dementia syndrome in older people is DLB, which is covered in Chapter 32. Post-mortem data suggest that DLB is a more common cause of dementia than previously appreciated, though the lower rates of clinical diagnosis (only some 7.5% of all dementia cases even in secondary care) suggests cases may be incorrectly attributed to other pathology (Rizzo et al., 2018). In the recently revised consensus criteria for DLB (McKeith et al., 2005, revised 2017), it can be diagnosed confidently (probable DLB) in the presence of at least two of the four core features (recurrent visual hallucinations, fluctuation, REM sleep behaviour disorder, and spontaneous parkinsonism), or one core feature plus one indicative biomarker (REM sleep without atonia as confirmed on polysomnography, dopaminergic abnormalities in the basal ganglia on functional neuroimaging, or abnormal (low uptake) of ¹²³iodine-MIBG on myocardial scintigraphy). However, when only one of these core features is found (without indicative biomarker evidence) or one or more of the biomarkers is

Alzheimer's disease

present but there are no core clinical features, possible DLB may be diagnosed (McKeith et al., 2017), although subjects may meet criteria for possible AD (McKhann et al., 1984) as well. Cognitive fluctuation can occur in AD (particularly in moderate and severe dementia) and visual hallucinations are also found (see Clinical features of Alzheimer's disease), so the presence of these features does not necessarily preclude a diagnosis of AD. The situation can often become clearer over time: the development of parkinsonism in the earlier stages favours a DLB diagnosis, but parkinsonism due to Alzheimer pathology in the substantia nigra is common in more severe dementia, whereas if delusions, hallucinations, apathy, and agitation are less persistent and improve (McKeith et al., 2000b,c) over time without treatment, this makes AD more likely. Making a diagnosis of DLB as opposed to AD has important clinical implications. For example, the former often responds better to cholinesterase inhibitors and DLB patients can have serious adverse reactions to neuroleptics.

In younger patients, FTD should be considered, especially if frontal features are prominent, e.g. primitive reflexes, disinhibition, marked apathy, or disproportionate impairments in executive compared to memory function. This is dealt with in Chapter 33.

Summary: AD diagnosis

The diagnosis of AD is a two-stage process. First, clinical evidence for the dementia syndrome is gathered, and other illnesses such as depression and delirium are excluded, and then the presentation is examined to see if it fits the above AD criteria of insidious onset and gradual progression in the absence of other possible causes with a common early hallmark of impaired short term memory. The two main other causes to consider in older people are VaD and DLB. Usually a careful assessment allows such distinctions to be made, but sometimes the clinician needs to wait patiently for further evidence as the disease progresses. Such distinctions are important because depression and delirium clearly merit a different kind of treatment from any cause of dementia.

Clinical features of Alzheimer's disease

Cognitive symptoms

These are central to the concept of dementia and AD. Cognitive symptoms and their assessment and treatment are dealt with in detail elsewhere (see Chapter 10, Chapter 35, and Chapter 36). Here we describe only the key symptoms and their progression as they are usually encountered in AD in clinical practice. (Note: here we use aphasia and dysphasia synonymously, although strictly speaking the former refers to complete impairment of language and the latter to partial impairment. The same applies *mutatis mutandis* to apraxia/dyspraxia, alexia/dyslexia, and agraphia/dysgraphia).

Alzheimer's disease

Amnesia

Memory impairment is the classic presenting complaint for AD, although other symptoms, e.g. apathy, subtle personality changes, and dysphasia, are often found early in the illness, too. The amnesia typically presents with a history of misplacing and losing objects, forgetting appointments, or repeatedly asking the same question. At this early stage, working memory (e.g. the ability to repeat back a few words or a list of numbers) is relatively unimpaired. However, the ability to recall such words or numbers a few minutes later is significantly impaired because the earliest deficits in AD are in the process of encoding or laying down new information in the memory stores. This probably results from damage to the hippocampal formation, which is the site of the earliest pathological damage in AD, hence the importance that is now attached to episodic memory dysfunction as a core feature in the newer diagnostic criteria for AD. Early hippocampal involvement is also behind early difficulties with spatial memory, remembering where items have been left, and navigating initially outside, but later in the disease also inside the home. Failure to lay down new memories can be demonstrated more clearly by tests in which a patient is read a short story and asked to recall it (logical memory tests) or when a long list of words is read and repeated attempts are made to learn the list, e.g. Rey Auditory Verbal Learning Test, and tests of verbal episodic memory are now part of National Institute for Health and Care Excellence (NICE) guidelines for the assessment of AD (NICE, 2018; <http://www.nice.org>).

In the early stages of AD, the recall of previously learned information remains good, showing that memory retrieval processes remain intact. This pattern results in the typical pattern of a failure of new learning (no memory for recent events) combined with clear memories of events earlier in life. Some individuals, particularly those with high intellectual reserve, can compensate for these deficits and others make use of memory prompts/cues such as diaries or making notes, and thus minimize, at least in the early stages, the impact of disease. However, as AD progresses, the memory impairment broadens to include retrieval of older memories and these are typically lost according to Ribot's law (more recent information is lost before more remote events), so the patient appears to live in the ever more distant past, for example, thinking that they still have young children or that their own parents are still alive. As well as these losses in episodic memory (personally related events occurring in a specific situation) there are accompanying losses in semantic memory (facts and vocabulary) and visuospatial memory.

Aphasia (dysphasia)

Deficits in cortical language production are usually present in the early stages of AD if the patient is examined closely. The earliest manifestation is with word-finding difficulties, where the patient struggles from time to time to find the correct words to complete sentences. Attempts to cover this up by using circumlocutions are common and may be cleverly

Alzheimer's disease

executed by intellectually more capable patients so the deficits are hidden. At this time there is also usually impairment in the naming of objects (nominal aphasia), which will initially be for the names of less common items rather than the more common objects that are frequently tested, e.g. pen or watch. Thus, pointing at objects in the room, e.g. a television, or parts of objects, e.g. the winder on a watch, may show some nominal aphasia that would not otherwise be revealed. As AD progresses, these deficits worsen and problems in the comprehension of language develop (receptive dysphasia) and expression of language shows syntactical errors, circumlocutions, and simplification of sentence structure. Phonemic (the substitution of similar sounding words) or semantic (the substitution of words with related meaning) paraphasias may be seen. Manifestation of language difficulties earlier in the presentation may raise the suspicion of alternative disease aetiologies, e.g. semantic dementia (see Chapter 33). Verbal perseveration, in which the patient repeats the same answer to consecutive questions, may now occur, too. The development of these deficits has serious consequences, as patients now increasingly struggle to understand what is going on around them and to communicate their confusion and distress clearly to others. It should not be assumed that a concurrent loss of all understanding occurs, as patients may still be sensitive to emotional and other nonverbal cues.

As the dementia becomes severe, marked poverty of the content of speech develops, with the repetition of short simple sentences on favourite themes and, eventually, mutism may occur. Some patients babble meaningless sounds or repeat words or part of words (palilalia and logoclonia) and phrases they hear (echolalia). Progression in language deterioration is not inevitable and many patients remain superficially fluent. They maintain a social discourse that can deceive the unwary about the true extent of their cognitive impairment. Careful attention to their language comprehension and production, however, will usually reveal a pattern of language impairment, including the deficits described.

Apraxia (dyspraxia)

Dyspraxia is the failure to carry out complex motor tasks due to deficits in the higher cortical control of movement, and *not* because of damage to the peripheral sensory or motor systems or in coordination. It typically occurs with cortical deficits in the dominant (usually left) parietal lobe, but as with other cognitive symptoms in dementia, dysfunction in other areas is also usually present. Ideomotor apraxia is the form usually elicited on examination and refers to the inability of the patient to carry out a motor task to command. Examples include: asking patients to wave; demonstrate how they brush their teeth; blow out a match; or show how they comb their hair.

Alzheimer's disease

Other common 'dyspraxias' described in clinical practice include dressing dyspraxia and constructional dyspraxia. Strictly speaking, these are not dyspraxias as they are not necessarily due primarily to higher motor failure. Dressing dyspraxia refers to the common difficulty patients have in putting their clothes on correctly due to faulty visuospatial processing, which results in them being unable to orientate their body properly in relation to their clothing. It is usually taken to indicate right (nondominant) parietal lobe damage. Constructional dyspraxia refers to the failure to adequately reproduce a two- (or three-) dimensional drawing, e.g. a star or a clock, or to the similar failure to assemble blocks into the required model. Like dressing, such tasks actually involve multiple cognitive domains (visual, spatial, executive, sensory, motor), but failure is usually taken to indicate right (non-dominant) parietal damage. All these dyspraxias have dire consequences for the patient's ability to carry out many ADLs. Cooking, cleaning, and general housework require the ability to carry out motor sequences, as do more basic activities such as eating and using the toilet. Failure in such domains is not primarily due to memory but to dyspraxic losses. Relatives may misunderstand why someone who appears healthy apart from an apparently mild memory impairment should struggle in such areas, and explaining the global nature of dementia can help them understand the situation.

Agnosia and visuospatial dysfunction

Agnosia is the failure to correctly interpret a sensory input in the presence of an intact sensory system and it is common in AD. Like apraxia, it is due to cortical damage and can occur in any sensory modality, though visual agnosia is the form usually met in clinical practice. In visual agnosia a patient sees an object but does not recognize it. Common agnosias include failure to recognize objects around the house, e.g. mistaking the kettle for the teapot or the dustbin for the toilet, and these, too, can have serious consequences for the patient. Perhaps the most well-known is prosopagnosia, in which the patient fails to recognize a familiar face, and when the face is that of a relative it can be very distressing for all concerned. Other variants include the 'mirror sign'—an inability to recognize oneself in the mirror—and there is considerable overlap between these misidentification phenomena and those more typically seen where the misinterpretations are elaborated by paranoid delusions (see Delusions).

Related to visual agnosia is the occurrence of visuospatial difficulties ranging from copying difficulties through to recognizing whole objects (agnosia). Right/left disorientation can also occur in AD and may be detected by asking the patient to obey commands such as 'point to the left ear with the right forefinger'. It is important to be aware that disproportionate visuospatial difficulties compared to the global cognitive state may be indicative of a non-AD presentation, e.g. posterior cortical atrophy or DLB (see Chapter 32).

Alzheimer's disease

Frontal-executive dysfunction

Damage to the frontal lobes has profound effects on personality, mood, and behaviour (discussed later). Cognitive effects include inflexibility in thinking and difficulties in problem-solving, abstraction, planning, and correctly sequencing behaviour. This is a complex area but one that should nonetheless be tested during assessment of dementia. It is dealt with in more detail in Chapter 10. Proverbs have traditionally been used to test how concrete and inflexible someone's reasoning is, but they are often very difficult to interpret. 'Similarities and differences' tests involve asking the patient what two objects (e.g. table and chair; shoe and boot) have in common and how they differ. Again, these can be difficult to interpret, but some attempt should be made, especially in someone who appears frontally impaired (e.g. markedly disinhibited). Easier to interpret are verbal fluency tests of frontal lobe function. These involve asking patients to name as many objects in a category in one minute (e.g. fruit or animals) or asking them to generate as many words as they can think of beginning with the same letter in one minute (e.g. F, A, and S in 'the FAS test'). As a rough guide, a normal subject should produce more than 15 words for each in a minute, and fewer than ten is clearly abnormal. A third kind of frontal test involves testing the subject's ability to shift from one item to another and this reveals perseverative problems. A sequence of alternating shapes or numbers may be written and the patient asked to continue the sequence. Motor perseveration can be demonstrated using the Luria two-step or three-step tests (in which the subject is asked to copy the examiner in alternately opening and closing the hand or making a fist, then an edge, and then a palm, respectively). In someone who shows any of these 'frontal' features physical examination can be undertaken for 'primitive reflexes' (see section Physical symptoms—neurological).

Executive dysfunction can arise early in the course of AD and is a common symptom with one study finding executive dysfunction in nearly two-thirds of AD patients (Swanberg et al., 2004). However, an early presentation of these symptoms in excess of memory difficulties, particularly in younger patients, should raise the suspicion of non-AD causes, such as FTD.

Other cognitive deficits

Corresponding to the aforementioned deficits in spoken language are impairments in reading (dyslexia) and writing (dysgraphia), which can be often identified with simple tests in AD using pen, paper, and reading material. Acalculia (more accurately anarithmetria) is the loss of the ability to do simple sums and can similarly be tested for in a straightforward way.

Alzheimer's disease

Neuropsychiatric and other non-cognitive symptoms

In his original report, Alois Alzheimer (1907) described both delusions and hallucinations in his patient Auguste D. The emphasis on the cognitive symptoms of dementia in making the diagnosis can distract from the fact that neuropsychiatric symptoms are very common; indeed, these symptoms tend to increase over time and almost all AD patients are affected by at least one neuropsychiatric symptom during their illness (Jost and Grossberg, 1996; Lyketsos et al., 2002; Steinberg et al., 2008; Zhao et al., 2015).

A systematic review and meta-analysis by Zhao and colleagues (2015) of 48 studies that reported prevalence data for the Neuropsychiatric Inventory (NPI) subscales (Box 30.3) found that the most frequent neuropsychiatric symptom was apathy, followed by depression, aggression, anxiety, and sleep disorder. Less common neuropsychiatric symptoms were irritability, appetite disorder, aberrant motor behaviour, delusions, and disinhibition, with hallucinations with euphoria the least reported symptom. One challenge from this meta-analysis was the wide variation in prevalence estimates between studies and differences in populations sampled with the majority being cross-sectional and clinic based.

Box 30.3 Prevalence of neuropsychiatric symptoms in Alzheimer's disease with 95% confidence intervals (in brackets)

Psychotic

Delusions 31% (27–35%)

Hallucinations 16% (13–18%)

Mood

Depression 42% (37–46%)

Anxiety 39% (32–46%)

Euphoria 7% (5–9%)

Behavioural

Apathy 49% (41–57%),

Aggression 40% (33–46%)

Appetite change 34% (27–41%)

Aberrant motor behaviour 32% (25–38%)

Disinhibition 17% (12–21%)

Alzheimer's disease

Sleep disorder 39% (30–47%)

Irritability 36% (31–41%)

Source: data from Zhao Q et al. (2015). The prevalence of neuropsychiatric symptoms in Alzheimer's disease: Systematic review and meta-analysis. *Journal of Affective Disorders*, 190, 264–71.

Overall lifetime rates of neuropsychiatric symptoms are much higher and the Cache County prospective longitudinal study (Steinberg et al., 2008) has provided up to five-year period prevalences for some of the major symptoms (Fig. 30.1).

Box 30.4 Pharmacological management of aggression, agitation, and psychosis in dementia

While this box focuses on the management of aggression, agitation, and psychosis in AD, many of these points are applicable to other neuropsychiatric and behavioural disturbances that are found in dementia.

- Consider, first, if nonpharmacological and social care interventions can solve the problem. In this context, taking a multidisciplinary approach and involving occupational therapy, nursing and social care staff can help.
- Always ask why is this patient presenting with this symptom now? Is there a treatable cause for his/her behavioural disturbance (e.g. pain, constipation, urinary retention)?
- Before instituting any pharmacological treatment always discuss with patients, carers and relatives the rationale for prescribing and discuss any potential harms associated with the medication (e.g. stroke and mortality risk with antipsychotics).
- Perform baseline assessment of the nature, frequency, and severity of the behavioural disturbance to compare against future changes in presentation.
- If symptoms persist or are severe in nature with a potential risk of harm (to themselves or others), consider a cautious trial of an antipsychotic.
- Benzodiazepines may be considered in certain specific circumstances if behaviour is severely disturbed and/or has an anxiety focus or if DLB is a diagnostic possibility, but be alert for excess sedation, worsening cognition and falls.
- Alternative medications include use of citalopram (possibly effective in agitation) or trazodone (possesses sedative qualities).

Alzheimer's disease

in addition to antidepressant effect which may help with some individuals with sleep difficulties (Camargos et al. 2014)).

- For all medications:
 - Start low and go slow
 - Review use of the drug regularly, balancing side effects and response
 - For antipsychotics, be aware that most neuroleptic reactions occur in the first two weeks, and if parkinsonism manifests consider a diagnosis of latent DLB and stop the antipsychotic
 - Do not prescribe drugs for prolonged periods. Regularly reassess the need for the drug; can alternative interventions be applied now the situation is containable? Antipsychotics can usually be stopped without re-emergence of behavioural disturbance.

However, accurately eliciting these mental state phenomena can be difficult in people with dementia and the figures quoted in following sections and in Box 30.3 and Fig 30.1 are derived from interviews with informants, who may overrate some symptoms (e.g. depression) compared with trained observers (Burns et al., 1990d). The rates of all the neuropsychiatric symptoms vary widely depending on, among other things, how the phenomena are defined, which patients are sampled, and the timeframe over which the survey is conducted. It is worth noting that

Alzheimer's disease

many of the studies were conducted before the accurate recognition of DLB was possible, which has a much higher rate of psychosis, and so the figures for AD are likely to be inflated by an admixture of DLB patients.

Associations between the manifestations of neuropsychiatric symptoms in AD with the level of cognitive impairment are not consistent, although some symptoms such as apathy (Onyike et al., 2007) and irritability (Craig et al., 2005) appear to be associated with the degree of cognitive decline. Other symptoms such as psychosis may predict accelerated cognitive decline (see Psychotic symptoms for further discussion).

Finally, it is important to recognize that other non-cognitive symptoms such as physical and neurovegetative symptoms have a profound impact upon patients with AD and their care.

Psychotic symptoms

Delusions

Delusional beliefs are common, can be very distressing to carers, and may contribute to early institutionalization. They are often understandable as attempts by patients to make sense of their situation and include beliefs that objects have been stolen, a spouse is unfaithful, or that intruders have been in the house. These beliefs commonly have a persecutory flavour and tend to lack the complexity and systemization of the delusions seen in schizophrenia. The delusions are often short-lived and can therefore be difficult to distinguish from confabulations. For hospital patients, the prevalence of delusions in published studies varies from about 25% (Cooper et al., 1991) to about 50% (Hirono et al., 1998). Burns and colleagues (1990b) studied a sample of AD patients in a catchment area and found 16% had delusions at some point in their illness and 11% had them in the previous 12 months. This figure is lower than most studies looking at clinically derived samples. Ballard and Walker (1999) systematically reviewed the literature and found a mean prevalence of delusions of 31% in all clinical settings and 23% in community settings, with Burns and colleagues (1990b) finding that delusions were three times more prevalent in men. Disease duration and age may be associated with an increased prevalence of neuropsychiatric symptoms, although this is by no means a consistent finding (Zhao et al., 2015).

Misidentification syndromes

Misidentification syndromes are sometimes called delusional misidentifications and might be better termed symptoms than syndromes. They are very common in AD, occurring in about 23–30% of patients at some time and in about 19% during a single year (Rubin et al., 1988; Burns et al., 1990c). They have been classified as delusions and as hallucinations depending on how the phenomena are understood. For example, the common assertion by patients with dementia that someone else has been in the house, when their family denies such a possibility, could be a paranoid delusional belief or a visual hallucination. In practice

Alzheimer's disease

it is often not possible to clarify the experience well enough to determine the exact form of the psychotic experience.

Another common kind of misidentification is the conviction that a relative or friend is someone else (which may be a Capgras syndrome if the misidentified person is accepted as looking exactly the same as his or her 'double', though this may be difficult to tease out in AD). Commonly, a spouse is misidentified as a son or daughter, or vice versa, but sometimes the patient believes the misidentified person is a stranger and this may provoke a strong reaction. Other symptoms include beliefs that people or events on the television are actually in the living room and the misidentification of the patient's own image in the mirror as another person. Wrongly believing strangers to have been in the house appears to be the commonest form of misidentification, being found in 12–17% of patients at some point; misidentifying people occurs in about 12%; misidentifying images from the television is found in 6–12%; and misidentifying a mirror image occurs in about 4–7% (Rubin et al., 1988; Burns et al., 1990c). Overall, studies show that misidentification occurs in 30% of people with AD (Ballard and Walker, 1999). Like delusions, these misidentification syndromes appear to be more likely to occur in men (Burns et al., 1990c).

Hallucinations

Hallucinations are less common than delusions and misidentification syndromes. However, study figures here may be underestimates reflecting an unavoidable bias in the way in which the symptoms are rated. The scores are informant based and informants will probably be unaware of the full extent of someone else's internal hallucinatory experiences while it seems reasonable to believe that delusions and misidentifications are almost certain to reveal themselves. Visual hallucinations are more common than auditory hallucinations and while olfactory, gustatory, and tactile hallucinations also occur in AD, they are much rarer. Studies in clinical settings have found prevalence rates for all hallucinations of between 10% (Mega et al., 1996) and 40% (Gilley et al., 1997) in AD. In their systematic review, Ballard and Walker (1999) found mean prevalence rates of 21% for all hallucinations (14% for visual hallucinations and 7% for auditory hallucinations) in clinical settings. Hallucinations may be more common in younger patients (Burns et al., 1990d) but, as with delusions, studies have not demonstrated this consistently (Zhao et al., 2015).

Management of psychosis in AD

Pharmacological (Box 30.4) and nonpharmacological interventions may both be of benefit, although use of the former needs to be considered in light of their benefit versus potential risks (particularly in the case of antipsychotics).

Alzheimer's disease

Nonpharmacologically, in addition to dealing with general health matters, treating the sensory deficits that may be exacerbating hallucinations, increasing the general level of stimulation, e.g. by arranging day care or attendance at a day centre, may be of benefit to someone who has hallucinations or misidentifications. Improved training to care providers to help their understanding of, and how to react to, people with dementia experiencing psychosis, aggression, and agitation is also important.

Mood changes

Alterations in mood are common in dementia, with depression being the most common. Here we are concerned with depression occurring during established AD; the relationship of depression to AD as a risk factor is considered in the section Risk factors for Alzheimer's disease and the concept of 'depressive pseudodementia' is dealt with in Chapter 39.

One problem is how we define the word 'depression'. Even separating studies looking at depressed mood, depressive symptoms, and depressive syndromes still leaves enormous variability, with rates varying from 0% to 87% for depressed mood (Knesevich et al., 1983; Merriam et al., 1988); from 0 to 89% for all depressive symptoms (Wragg and Jeste, 1989); and from 0% to 30% for depressive syndromes (Burns et al., 1990d; Teri and Wagner, 1991). These rates vary because different populations are sampled, different instruments are used, and different raters provide the rating. Problems in the assessment of depressive symptoms also occur because apathy can easily be mistaken for depression, while many depressive symptoms, e.g. poor appetite, weight loss, and sleep disturbance, are also common features of dementia itself. In addition, depressive symptoms in dementia tend to be associated more with psychotic symptoms and apathy, and less with negative cognitions such as hopelessness, suicidality, guilt, and low self-esteem (Olin et al., 2002; Rosenberg et al., 2005), and thus depression in dementia may represent a distinct syndrome with pathophysiological underpinnings that are different from the depression seen outside of dementia; this may have an impact on whether antidepressant medications are effective.

In a review of studies examining depressive syndromes diagnosed using standardized criteria, Ballard and colleagues (1996) found major depression to occur in 21% of dementia sufferers in clinical settings and 13% in the community. Depressive symptoms are also very common, with the Cache County Study reporting an initial prevalence of depressive symptoms of 29% at baseline (Steinberg et al., 2008). Over a five-year period, this study also noted that period prevalence for depression was very high at 77%. However, no clear association between depression and the severity of dementia has been found, with some studies showing depression to be more common in milder dementia and others showing the opposite. Depression decreases the quality of life of people with dementia, may reduce survival (Burns et al., 1991c), and so it would therefore appear to be important to treat it if possible.

Alzheimer's disease

Early small trials of selective serotonin reuptake inhibitors (SSRIs) (Nyth et al., 1992; Lyketsos et al., 2003), moclobemide (Roth et al., 1996), and tricyclic antidepressants (TCAs) (Petracca et al., 1996) reported evidence of benefit for depression in dementia, but TCAs should be avoided because they worsen cognitive impairment and have higher drop-out rates (Taragano et al., 1997). However, the quality of most of these studies is poor and several others were negative (Dudas et al., 2018).

Reinforcing this evidence for lack of efficacy are the results from the United Kingdom (UK) Health Technology Assessment Study of the Use of Antidepressants for Depression in Dementia (HTA-SADD) (Banerjee et al., 2011); this double-blind, placebo-controlled trial in a large cohort of probable or possible AD patients with depression found no treatment benefit with either sertraline or mirtazapine and increased adverse events were noted in those on these medications. The lack of efficacy and potential increased side effects of sertraline have also been confirmed by the Phase II of the Depression in Alzheimer's Disease Study (DIADS-2) (Rosenberg et al., 2010; Weintraub et al., 2010), which compared sertraline 100mg with placebo in depression in AD and found no significant difference in symptom change or response or remission rates at either 12 (Rosenberg et al., 2010) or 24 weeks (Weintraub et al., 2010). They also reported an increase in adverse events on sertraline and concluded that the evidence does not support the use of SSRIs in depression in AD. These individual studies and others have been the subject of a recent Cochrane systematic review, which concluded that there was not strong support for the efficacy of antidepressants for depression in dementia and good evidence that they have little or no effect on improving scores on depression rating scales (Dudas et al., 2018).

These findings now leave clinicians with difficult choices in managing depression in dementia. However, as with trials of antipsychotics, subjects in these studies were less severely depressed than many encountered in clinical practice. Antidepressants may therefore retain a role in the treatment of more severe and prototypical depressive syndromes, although the argument that patients with more severe depression may differentially respond to antidepressants has not been supported (Drye et al., 2011). Though evidence supporting the use of antidepressants in AD is poor, it should be kept in mind that the evidence for antidepressant use to treat depression in other contexts which are associated with dementia is stronger, for example, in post stroke depression (Mead et al., 2012). Thus, antidepressant treatments may be of relevance in more 'pure' VaDs.

Simple social interventions, e.g. befriending or a day centre, should be considered and it is important to note that even in the pragmatic HTA-SADD trial, there appeared to be a natural amelioration in depressive symptoms with time in the placebo group (who had treatment as usual). Furthermore, other agents such as cholinesterase inhibitors may also be useful and electroconvulsive therapy (ECT) remains a treatment option

Alzheimer's disease

for dementia patients, particularly for those with more severe depression, suicidality, or agitation/aggression. Although better studies are needed to clarify the safety of ECT and its efficacy, available case series are generally reassuring with regards to the use of ECT in people with dementia in terms of cognitive function (Rao and Lyketsos, 2000; Gauthier et al., 2010).

Elevation of mood in dementia is much less common and less frequently studied than depression. Burns and colleagues (1990d) found only one patient (out of 178) who reported manic symptoms and only six who had any observable evidence of mania. Similarly, point prevalence rates of euphoria and elation in the Cache County Study were less than 1% (Steinberg et al., 2008). Anxiety has been much less studied than even euphoria in dementia, but, consistent with clinical experience, it is a common symptom, with studies finding a rate ranging from 24% (Steinberg et al., 2008) to 50% (Patterson et al., 1990), and in the Cache County Study the five-year period prevalence of anxiety symptoms was 62% (Steinberg et al., 2008).

Behavioural symptoms

Apathy

Apathy is diminished motivation and manifests itself as a listlessness in which the patient has lost the drive to engage in goal-oriented behaviour and cognition (Starkstein and Leentjens, 2008). It is often confused with low mood and anhedonia, i.e. the loss of ability to enjoy previously pleasurable activities. Although they all may be present together, they are not the same phenomenon (Levy et al., 1998). The distinction is important because carers often think someone with AD is depressed when he/she has apathy as a part of the dementia. Apathy is probably the most common behavioural change in AD (Mega et al., 1996; Steinberg et al., 2008), although it is underdiagnosed. Apathy is common early in AD and it typically becomes more severe as the cognitive impairment worsens. At presentation, apathy is frequently a complaint given by relatives who often misunderstand it as laziness and become frustrated by it. Explaining that apathy is a feature of dementia can remove this misunderstanding and the tension it brings.

Previously apathy has been a somewhat neglected neuropsychiatric aspect of dementia, but more recently it has become a focus of academic and clinical interest. Although no formalized consensus criteria yet exist for apathy, a taskforce (Robert et al., 2009) has proposed that apathy be defined as 'a disorder of motivation that persists over time and meets the following requirements: i) the core feature of apathy, diminished motivation, must be present for at least four weeks; ii) two of the three dimensions of apathy (reduced goal-directed behaviour, goal-directed cognitive activity, and emotions) must also be present; iii) there should be

identifiable functional impairments attributable to the apathy; and iv) criteria are given to exclude symptoms and states that mimic apathy.'

Although there are no licensed pharmacological treatments available at the present time for apathy, a recent systematic review suggested that there is evidence that the cholinesterase inhibitors and memantine may be effective in treating this symptom, but there is less evidence for the efficacy of calcium antagonists and antipsychotics, and little or no evidence to support the use of antidepressants and anticonvulsants (Berman et al., 2012). Early small trials have reported positive results for stimulants such as methylphenidate, but the evidence is not robust enough for this treatment to enter mainstream clinical practice (Rosenberg et al., 2013). Nonpharmacological interventions such as exercise, multisensory stimuli, and pet therapy may also help, although rigorous data on their efficacy are lacking (Brodaty and Burns, 2012).

Overactivity and aberrant motor activity

Several overlapping phenomena involving overactive behaviour are commonly found in AD. The most well-known are agitation—which may be defined as painful inner tension associated with excessive motor activity (American Psychiatric Association, 1994) and often goes together with aggression (discussed in section Aggression and agitation)—and wandering. However, other 'aberrant motor behaviours' are recognized and sometimes measured, e.g. rummaging in drawers and repeatedly putting clothes on and then taking them off. Aberrant motor behaviour including wandering, purposeless hyperactivity, and rummaging appears to affect about a quarter of dementia patients (Gauthier et al., 2010). Other activities can include disrobing, intentional falling, hiding things, repetitive mannerisms, screaming/shouting, repetitive questioning, and making strange noises (Cohen-Mansfield et al., 1989)

The baseline rate for these behaviours in the Cache County Study was reported to be 7% and increased to nearly 30% after approximately five years, which is consistent with the notion that all such overactive behaviours tend to become more common with increasing severity of the dementia. As with other neuropsychiatric symptoms such as aggression and agitation, nonpharmacological environmental strategies may be helpful (see Chapter 19).

Aggression and agitation

Aggression and agitation are major problems in dementia. They occur commonly and can cause great distress to carers. They are a frequent reason for admission to hospital and transfer to residential care as well as leading to potentially faster cognitive and functional decline (Scarmeas et al., 2007). Aggression is open to different definitions and even when verbal aggression (shouting, swearing) is distinguished from physical aggression (punching, kicking, biting, pushing, pinching, etc.) there is still much scope for differences of opinion in each category about what

Alzheimer's disease

constitutes aggression. Burns and colleagues (1990e) defined aggression narrowly as behaviour liable to cause physical injury to others and still found 20% of their AD subjects to have aggression. Broader definitions naturally lead to higher figures and verbal aggression is usually found to be two to three times more common than physical aggression. Burns and colleagues (1990e) also found aggression to be much more common in men with AD. They also found that it became more common with increasing cognitive impairment, rising from 8% in mild AD to 24% in severe AD. Agitation, which overlaps with motor overactivity, has rates in dementia that are similar to aggression, with point prevalence rates of 13–24% in the Cache County Study (Steinberg et al., 2008), although rates may be higher (29–60%) in clinical samples (Bergh and Selbæk, 2012).

Treatment of agitation and aggression is often similar to that used for psychosis (see Pharmacological treatment of aggression, agitation, and psychosis in AD and Box 30.4) and often treatment trials not unreasonably assess these problems together (e.g. psychosis may be causing aggressive behaviour). For those with experience of running mental health wards for admission of the most disturbed patients, it is striking how behaviours can often improve following admission with minimal pharmacological intervention, and this may serve to highlight the importance of the right environment and level of resource to properly manage very complex patients.

Neurovegetative symptoms

Sleep

Sleep disturbance is another common feature of dementia which can have devastating consequences for carers and is dealt with in more detail in Chapter 48. It may take the form of frequent waking, reduced sleep quality, or a disturbance to circadian rhythms. More recent studies have suggested an increased prevalence of sleep apnoea in AD, although studies have not consistently found this (Duthie et al., 2011).

The well-recognized pattern of day-night reversal was found to occur in 28% of patients in one study (Reisberg et al., 1987) and all forms of sleep disturbance have been found in 45–70% of AD patients (Rabins et al., 1982; Merriam et al., 1988). Sleep deprivation can eventually lead to exhaustion for the spouse if it persists, especially when it is associated with night wandering. To reduce the strain from sleep disturbance the spouse may sleep in another bed or in another room. Respite care can be of great help, although placement in residential care may finally be needed.

Pharmacologically, psychotropic drugs (hypnotics and antipsychotics) are frequently prescribed, although caution needs to be applied as these drugs are associated with significant adverse effects (Box 30.5), e.g. falls and over-sedation, and the evidence base for their efficacy is limited. The

Alzheimer's disease

use of chronotropic agents, such as melatonin and bright light therapy have been investigated, with mixed results. A large well-conducted trial showed no beneficial effect of melatonin and this was confirmed by a recent Cochrane review that found no evidence to support the use of melatonin, but some evidence for the use of the sedative phenylpiperazine antidepressant trazodone, though this was based on a single small study (Singer et al., 2003, McCleery et al., 2016).

Box 30.5 Potential adverse effects of antipsychotics in dementia

- Worsening of cognitive function—equivalent to up to one year of cognitive decline
- Sedation and falls × 2 risk
- Extrapyrarnidal side effects
- Respiratory infections × 3 risk
- Prolonged QT_c and torsades de points × 2 risk
- Cerebrovascular event × 2 risk, although possibly × 9 risk in first week of antipsychotic use
- Mortality × 1.7–1.8 risk; may be higher with typical antipsychotics

Source: data from Kleijer, B. C. (2009). Risk of cerebrovascular events in elderly users of antipsychotics. *Journal of Psychopharmacology*, 23, 909–14.

Eating

Difficulties with feeding are common in dementia. These may progress from initial problems using cutlery with associated spillage of food through to complete dependence on others for feeding. In addition, there may be specific problem behaviours related to eating. Some patients refuse food, while others stuff food rapidly and clumsily into their mouths. The latter is common, occurring in 10% of people with AD (Burns et al., 1990e), and this figure is constant for all severities of dementia, although it is a more common feature of FTD and should raise this as a diagnostic option (see Chapter 33).

Sexual disinhibition

Sexual disinhibition is another problem that causes great distress to carers. It occurs in about 7% of people with dementia. It is rare in mild dementia and increases markedly with dementia severity (Burns et al., 1990e).

Alzheimer's disease

Personality changes

Alterations in personality are ubiquitous in dementia and changes in personality are inseparable from some of the behavioural changes already discussed, e.g. apathy and sexual disinhibition. However, it is important to note that changes in personality do occur very early in AD and 75% of people with mild AD show such changes (Rubin et al., 1987). These may precede the cognitive deficits and are often subtle in form, but nonetheless they are frequently recognized and commented upon by carers. Such information should be cautiously interpreted, as family and friends are often too closely involved to be able to comment accurately and dispassionately and may either exaggerate or deny any changes. As AD progresses these initially subtle personality alterations tend to become more evident.

Personality changes not included in the section Behavioural changes are suspiciousness and disengagement. Suspiciousness is common and was found in 25% of AD subjects (Patterson and Bolger, 1994). It may or may not eventually consolidate into frank paranoid delusions and can cause great friction, as repeated accusations are made about the motives and behaviour of well-meaning carers and relatives. Disengagement refers to the detached state of emotional indifference seen often in AD and which is associated with a loss of rapport with other people. Patients are no longer concerned about the feelings of others or affected by their attention or lack of it. Such disengagement can be upsetting to relatives and may overlap with apathy, but it needs to be distinguished from the low mood of depression.

Physical symptoms

Neurological

Early in AD, neurological examination is usually normal. Focal neurological signs suggest a VaD or other cause of focal damage, while extrapyramidal signs may indicate DLB. Primitive reflexes, however, may occur early in AD, although their frequency increases as the dementia worsens. Burns and colleagues (1991a) found the snout reflex was easily the most common, occurring in 41% of their clinical sample. The grasp reflex was identified in 7% and the palmomental reflex in 2.5%. As the disease progresses, non-specific changes occur in both gait and balance, and myoclonic jerks and other seizures may develop. In the late stage, bilateral non-focal signs (e.g. upgoing plantars) may be seen.

Incontinence

Urinary incontinence is a common and well-recognized feature of AD and has been found in 48% of AD subjects (Burns et al., 1990a), though this figure disguises its strong association with disease severity. Incontinence was found in only 8% of those with mild AD but in 94% of patients with severe AD (Burns et al., 1990e). This association has important implications in diagnosis as incontinence early in a dementia is

Alzheimer's disease

characteristic of other dementias, especially FTD and normal pressure hydrocephalus. Thus, the presence of urinary incontinence early in a dementia should lead to consideration of possible causes other than AD. It is also vital to consider and exclude other causes of incontinence, including urinary tract infections, especially in women or those with catheters, poor mobility, or failure to find the toilet in a strange environment (e.g. when someone has just been admitted to an inpatient unit).

General physical changes

AD is associated with a general physical deterioration in which the patient loses weight and develops a stooped posture associated with instability and gait abnormalities. AD patients are more prone to falls and this, combined with increased rates of osteoporosis, leads to enhanced likelihood of fractures compared to nondemented subjects (Duthie et al., 2011).

Weight loss may be an intrinsic feature of the disease process or secondary to progressive impairments, which can result in an inadequate consumption of food and fluids. Cronin-Stubbs and colleagues (1997) demonstrated that older people with AD lost weight at over three and a half times the rate of healthy age-matched controls, a rate of weight loss more severe than in older people with cancer. Weight loss was found to be more rapid in earlier stages of the disease and may occur prior to diagnosis, suggesting it is at least in part due to the disease process (LeBlanc et al., 2018). Whatever the cause, such marked weight loss is likely to contribute to the high mortality of AD.

Summary: Clinical features of Alzheimer's disease

While cognitive symptoms are central to the diagnosis of AD, neuropsychiatric and non-cognitive symptoms are arguably of more importance in management. Psychotic and mood symptoms are very common, a cause of distress to both patients and carers, and, in many cases, treatable in their own right. The behavioural disturbances, accompanying personality changes, and neurovegetative symptoms are also much more common than is usually recognized, can place great strain on carers, and their presence is a major risk factor for subsequent institutionalization.

Psychosocial interventions are usually necessary and should be the first consideration in treatment, though some of these (agitation, aggression, sleep disturbance, and psychosis) may respond to pharmacological treatment. The physical symptoms in AD remind us it is a debilitating condition requiring ongoing assessment and long-term palliative care.

Pharmacological treatment of aggression, agitation, and psychosis in AD

Alzheimer's disease

Before explicitly considering drug treatment, it is worth reiterating that the initial effort should be in understanding and treating any underlying cause other than dementia driving the behaviour (e.g. pain or delirium). Given their low propensity for side effects, non-pharmacological treatments should be tried, ideally before drug treatment.

Antipsychotics

Several studies have evaluated whether drug treatments are effective for non-cognitive symptoms in dementia, but there is controversy about the risk-benefit ratio of these drugs in AD, and in dementia in general. Empirically, antipsychotics have been used to treat agitation, aggression, and psychosis in AD. However, the evidence base for their use in AD psychosis is less clear, as studies have tended to be small and have focused on agitation and general behavioural disturbance as outcomes. Several larger randomized trials of atypical antipsychotics in AD have been reported, e.g. the National Institute of Mental Health (NIMH) Clinical Antipsychotic Trials of Intervention Effectiveness–Alzheimer's Disease (CATIE-AD) (Schneider et al., 2006b), and these, together with the smaller trials, have been subject to systematic review and meta-analysis (Sink et al., 2005; Ballard et al., 2006, 2011a; Schneider et al., 2006a). In summary, these reports suggest there is evidence for the efficacy, albeit of modest effect (effect size <0.5), for the use of certain antipsychotics (with the best evidence base being for risperidone, also the only drug to have a license for this indication in the UK) short term (fewer than 12 weeks) in the treatment of psychosis and aggression compared to placebo. The evidence for olanzapine is less clear, with contradictory findings reported, but there does appear to be a lack of benefit for quetiapine (Ballard et al., 2011a). However, many trials have tended to use very low, and therefore potentially suboptimal, doses of quetiapine. There is also little evidence that typical antipsychotics are efficacious for treating behavioural disturbance in dementia (although haloperidol may have some limited efficacy) and the evidence suggests increases in mortality are associated with these agents, too, at higher rates than for atypicals (see further later; see also Wang et al., 2005; Laredo et al., 2011) although rates of all-cause mortality seem to be similar across different atypicals (Farlow and Shamlan, 2017).

Evidence for the benefit of antipsychotics long term is also equivocal and withdrawal studies (e.g. the Dementia Antipsychotic Withdrawal Trial (DART-AD); see Ballard et al., 2009b) have failed to demonstrate worsening in neuropsychiatric symptoms after antipsychotic discontinuation, although many of the subjects in these studies were probably started on the drugs for milder degrees of symptoms; patients with higher baseline neuropsychiatric symptom scores may have higher relapse rates (Ballard et al., 2004). Most importantly, however, any benefit from antipsychotics in dementia needs to be weighed against the significant side effects associated with antipsychotic use (see Box 30.5), with numbers needed to treat about equal to the numbers needed to harm

Alzheimer's disease

(Lancot et al., 1998), and in particular the increase in mortality in dementia patients taking these agents.

Regulatory bodies in different countries have issued warnings about an increased risk of death and cerebrovascular adverse events in people with dementia taking atypical antipsychotics, e.g. the Committee for the Safety of Medicines in the UK (2004) and the Food and Drug Administration (FDA) in the US (2005), with an extension of the warnings to include typical antipsychotics in 2007 by the FDA. These warnings have been based on a number of case control studies and case register data. Initially most of the data were not publicly available, and consequently in an early meta-analysis (Schneider et al., 2005) on the risk of death with atypical antipsychotics of 15 eligible trials, nine were unpublished with data extracted from abstracts presented at research meetings. This report noted a statistically significant increase of about 50% in mortality in patients taking atypical antipsychotics and a similar increase in those on haloperidol. Overall, there appears to be a 1.5- to 1.8-fold increase in mortality with antipsychotic use (Ballard et al., 2009b). This risk may be substantially higher in the first week of medication administration (Kleijer et al., 2009) and it appears to be sustained; the DART-AD study (Ballard et al., 2009b), a long-term randomized controlled trial (RCT) study in AD patients on antipsychotics, noted a significant excess of mortality over 24–54 months in people randomized to continue antipsychotic medication compared to those randomized to discontinue antipsychotic medication.

Comparisons with typical antipsychotics are difficult due to the lack of randomized evidence, but a retrospective cohort study of 22,890 older subjects taking typical and atypical antipsychotics found the former group to have a higher mortality (Wang et al., 2005). This finding is supported by a veteran/war widow cohort study (Hollis et al., 2007), which found that haloperidol was associated with an increased risk of death compared with individuals on olanzapine, although chlorpromazine had comparable levels of risk to atypicals. Another concern has been whether the use of antipsychotics hastens cognitive decline in dementia (McShane et al., 1997), and an analysis of the effect of atypical antipsychotic use (olanzapine, quetiapine, and risperidone) on cognitive function from the CATIE-AD trial (Vigen et al., 2011) found that AD patients who received an antipsychotic in the two weeks prior to cognitive testing had an average decline 2.46 points greater on Mini-Mental State Examination (MMSE) than placebo patients, although in this study it could not be determined whether this was a permanent and enduring effect on cognition or more related to the acute administration of these agents, e.g. enhancing sedation. The CATIE-AD study used an innovative endpoint of time to discontinuation as a proxy measure of the balance between efficacy and tolerability. Patients taking risperidone and olanzapine were less likely to discontinue medication due to lack of efficacy, but were more likely to discontinue due to side effects. The balance between these two aspects meant that the overall time to discontinuation was not

Alzheimer's disease

significantly different between drug and placebo, again highlighting the close balance between benefit and harm for these medications.

Overall, it is clear that there are reasons for concern about the use of antipsychotics in dementia. They are associated with increased mortality and risk of cerebrovascular events, as well as possibly worsening cognition. There is also little doubt they have been overprescribed despite the modest benefits they appear to confer. For example, in the UK, it has previously been estimated that around 180,000 people with dementia are on antipsychotic medications in any one year, which equates to an additional 1,800 deaths and an additional 1,620 cerebrovascular adverse events (Banerjee, 2009). Increased understanding and awareness of this problem does seem to have caused a decline in total antipsychotic prescribing in this context, at least in the UK, mostly due to a decline in the use of first-generation drugs, and some evidence for positive changes in terms of lower rates of prescribing being temporally related to changes in guidelines and national warnings. (Stocks et al., 2017). It is worth noting, however, that patients entering the clinical trials were often much less psychotic and disturbed than many seen in clinical practice. Thus, in those with persistent and severe psychosis and associated agitation or aggression their use may be justified, especially given the even weaker evidence for alternative treatments (Thomas, 2011).

Antidepressants, mood stabilizers, and benzodiazepines

Trials using antidepressants to treat agitation have suggested that these agents may help. Two studies by Pollock (Pollock et al., 2002, 2007) examined the efficacy of citalopram. The later study compared citalopram with risperidone and found that both agents reduce agitation and psychotic symptoms to a comparable level. This conclusion has subsequently been supported by the CitAD study (Porsteinsson et al., 2014). This was a randomized controlled study of 186 patients with Alzheimer's disease and agitation, and showed that citalopram led to significant improvement in the primary endpoints of agitation and secondary endpoints of caregiver stress and total NPI with a number needed to treat of around seven. However, side effects included decreased cognition and increased QTc, albeit with no significant differences in serious adverse events or adherence between treatment and control groups. The dose used was 30mg (greater than the maximum recommended dose for the elderly in the UK). These data from this study have been further examined to suggest that the differences may be mediated by sedation, that the effect of citalopram treatment was not observed for the first three weeks of treatment, and that response was most likely in those with less severe dementia and agitation (Newell et al., 2016; Weintraub et al. 2015; Schneider et al., 2016). In addition, citalopram may also have benefits in remediating other psychiatric symptoms (Leonpacher et al., 2016).

Alzheimer's disease

There have been a number of small studies examining the use of valproate for the treatment of agitation and aggression in AD. Baillon and colleagues (2018) noted that the benefits of valproic acid derivatives were equivocal and indeed were associated with significant adverse side effects. The evidence for divalproex sodium is no better; a large RCT (Tariot et al., 2011) confirmed the findings of previous RCTs in that divalproex sodium treatment had no effect on the emergence of agitation or psychosis (or slowing of cognitive impairment) and indeed was associated with significant toxic side effects. This is on top of a report of accelerated brain atrophy and cognitive impairment in patients with mild to moderate AD treated with divalproex sodium (Fleisher et al., 2011). As a result, sodium valproate cannot be recommended for use in the context of AD, a point made explicit in current UK NICE guidelines.

The potential benefit for carbamazepine remains unclear; two small reports have suggested benefit from carbamazepine in agitation and aggression (>300 mg/day) (Tariot et al., 1998; Olin et al., 2001), with effect sizes potentially greater than that seen with antipsychotics (Ballard et al., 2009a). Larger studies are needed, particularly as the potential toxicity of carbamazepine in AD may be an issue that limits the use of this agent. At time of writing, the efficacy of carbamazepine in the treatment of agitation was being examined in a UK-based clinical trial (SYMBAD study, <https://clinicaltrials.gov/ct2/show/NCT03031184>).

Benzodiazepines impair cognition (Tannenbaum et al., 2012) and may increase the risk of AD in themselves (Billioti de Gage et al., 2014). Data on their efficacy remain limited, and as such do not support the routine use of these agents for neuropsychiatric symptoms (Tampi and Tampi, 2014) though they may have some utility in emergency situations, where concern over the possibility of DLB diagnosis makes treatment with antipsychotics even less attractive.

Cholinesterase inhibitors

The fact that cholinesterase inhibitors improve cognition and function in AD is well established. However, their use in the treatment of aggression and agitation is less clear; any improvements have been noted in secondary analyses of datasets whose primary outcome was an improvement in cognition and/or function (Sink et al., 2005; Gauthier et al., 2010). Specific studies examining the effects of cholinesterase inhibitors on agitation or aggression have been disappointingly negative. For example, the UK multicentre, double-blind, placebo-controlled trial CALM-AD examined the efficacy of donepezil in treating agitation over a 12-week period, but it failed to find any significant improvement in its primary outcome measure of agitation (Howard et al., 2007).

Nevertheless, it is possible that there are potential benefits of cholinesterase inhibitors in ameliorating other neuropsychiatric domains in AD, e.g. apathy, excess motor activity (Gauthier et al., 2010), and possibly depression. In addition, judicious use of cholinesterase inhibitors

Alzheimer's disease

early in the course of AD may delay or prevent the emergence of behavioural changes that occur with disease progression (Cummings et al., 2004).

Memantine

As with cholinesterase inhibitors, on the basis of post hoc analyses of previous RCTs, memantine has been suggested to have positive effects on agitation and aggression (Wilcock et al., 2008). Specific RCTs designed to investigate the impact of treatment with memantine on demented patients with agitation have failed to demonstrate benefit. For example, one large trial comparing memantine against placebo in AD patients with agitation found no improvements on the primary outcome measure (Cohen-Mansfield Agitation Inventory) albeit with some unspecified improvements on the neuropsychiatric inventory score (Fox et al., 2012). Other memantine trials have also been inconclusive (Schneider et al., 2011; Herrmann et al., 2013).

Newer potential treatments

Finding alternative and new agents for the treatment of agitation, aggression and psychosis as well as other neuropsychiatric symptoms in AD is topical at present. Examples include a phase-2, randomized, multicentre, double-blind, placebo-controlled trial of dextromethorphan hydrobromide–quinidine sulfate (a drug with complex actions including non-competitive NMDA antagonism, serotonin and norepinephrine reuptake inhibition, sigma 1 agonism, and nicotinic alpha3/beta4 antagonism) in AD found that this improved agitation and aggression with benefits seen in global measures and some carer measures and this agent appeared to be well tolerated (Cummings et al. 2015). Additionally, yokukansan—a Chinese herbal remedy featured in a meta-analysis of five RCTs—suggested small, but significant benefits on hallucinations, delusions, hallucinations, and agitation/aggression subscales on the neuropsychiatric inventory (Matsunaga et al., 2016).

A recent large double-blind RCT of Pimavanserin, a selective 5-HT_{2A} receptor inverse agonist and antagonist (approved in US for the treatment of Parkinson's disease psychosis), in nursing home patients with AD demonstrated a small- to medium-sized reduction in psychotic symptoms at six weeks in the treatment group, although the efficacy signal disappeared at 12 weeks (Ballard et al., 2018). Nevertheless, the drug was well tolerated and did not negatively affect cognition.

More robust evaluation of medications with anecdotal or only a limited evidence base in the treatment of agitation and aggression is also currently underway. For example, as mentioned, a large RCT is currently underway in the UK (the SYMBAD study) investigating carbamazepine and mirtazapine as treatment for agitation in dementia (<https://clinicaltrials.gov/ct2/show/NCT03031184>).

Alzheimer's disease

Summary: Pharmacological treatments in AD

While helpful, such summaries of evidence hide many of the difficulties in interpreting studies and applying the evidence base to clinical practice. For example, atypical antipsychotic studies that were carried out in nursing homes often only included people with moderate to severe dementia (MMSE scores of less than 15), raising the issue of whether these findings can be generalized to less cognitively impaired and physically frail patients. Conversely, patients able to give consent to enter randomized studies tend to be less disturbed than many patients encountered in clinical practice. Finally, it is difficult to interpret what changes of a few points on rating scales mean in clinical practice.

As a general clinical approach, in patients with psychosis, agitation, or aggression, it is important to ask whether any agitation and aggression is being caused by undiagnosed or undertreated pain, constipation, hunger, or dehydration; indeed, the benefits of adequate analgesia for agitation in nursing home resident dementia patients have been highlighted in a recent cluster trial (Husebo et al., 2011). Environmental factors, caregiver interaction, and social stimulation (either too much or too little) also need to be considered.

Nonpharmacological approaches may be helpful, although the evidence for such interventions is often weak (Livingston et al., 2005) (see Chapter 19 for details). For example, the use of Melissa (lemon balm) aromatherapy has been advocated in treating agitation/aggression, although a recent rigorous double-blind study failed to show that aromatherapy was better than a cholinesterase inhibitor or placebo in treating agitation in AD patients (Burns et al., 2011). One systematic review identified person-centred care, dementia care mapping, and music and sensory therapy as being helpful in agitation (Livingston et al., 2014). A recent Cochrane review of music therapy concluded that there may be benefits in depression and overall behaviour but not specifically for aggression (Van der Steen et al., 2018).

If a nonpharmacological approach fails, then citalopram could be considered (Seitz et al., 2011), particularly if the agitation is mild or moderate. If the behavioural disturbance is more severe, treatment with an antipsychotic, specifically risperidone, should be considered. In view of the risks discussed in the section Antipsychotics, the clinician should explain his reasons for such treatment to patients and, if appropriate, their next of kin.

Risk factors for Alzheimer's disease

Identifying risk factors for AD is important for two main reasons. First, identification of risk factors and protective factors enables possible new treatments or public health interventions to be developed. Second, these aetiological factors may throw light on the pathogenesis of AD, stimulating new research that can further our understanding of the

Alzheimer's disease

disease process, leading in turn to new treatment opportunities. Box 30.6 summarizes our present state of knowledge about the aetiological factors involved in AD.

Demographic risk factors

Age

It is easily forgotten that old age is the most important risk factor for AD, with AD's prevalence rising rapidly after 60, and approximately doubling every five years. But for how long does such a rise continue? It is still not clear whether the increase continues indefinitely (i.e. everyone would develop AD if they lived long enough). However, dementia is not always an inevitable consequence in the oldest old (Arosio et al., 2017).

Smoking

Sensory deprivation

Possible protective factors

Apolipoprotein E2 allele

High intelligence/education

Consistent findings from studies in the oldest old are lacking, partly given the limited number of individuals that can be recruited from these age groups, challenges in developing appropriate cognitive measures in these populations given their often-significant sensory impairments and also problems in early studies with the use of appropriately operationalized diagnostic criteria. Early studies reported that the prevalence of dementia appeared to plateau for people in their 90s and may even drop in the very old (Fichter et al., 1995; Ritchie and Kildea, 1995) and indeed, in centenarians, if dementia does ensue, its onset is clinically delayed to an average of 92 years (Arosio et al. 2017). Incidence studies are a better measure of whether age itself is a causal factor in AD and dementia, and several studies (Matthews and Brayne, 2005) have countered the above findings, instead suggesting that dementia incidence continues to rise

Alzheimer's disease

exponentially, with one US-based study reporting annual incidences of dementia of over 20% in 95-to 99-year-olds and greater than 40% in centenarians (Corrada et al., 2010). However, another prospective incidence study found that, while dementia incidence continues to increase beyond age 85, the rate of increase appears to slow relative to that of 65- to 85-year-olds (Hall et al., 2005). Overall, further work remains to be done to: i) clarify the role of ageing in dementia; ii) establish why there is a lack of an association between AD and apolipoprotein E (APOE, see Apolipoprotein E polymorphism) in the oldest old; and iii) explain the finding that up to half of the oldest old with dementia do not have obvious cerebral pathology to account for their cognitive deficits while some of those without clinical symptoms of dementia may carry significant pathological burden, for example, in terms of amyloid load. This suggests that the pathophysiological processes that dictate when an individual develops dementia, or more specifically AD, may vary considerably with age (Juva et al., 2000; Kawas and Corrada, 2006).

Sex

It is well recognized that AD is more common in women, but is female gender an independent risk factor? It could simply be that women live longer than men and consequently are at higher risk or live longer with the illness. As with studies examining age as a risk factor, sex differences in the incidence of AD have been reported in some but not all studies; one meta-analysis found women to have a higher incidence of AD than men but not a higher incidence of dementia in general (Gao et al., 1998). However, three more recent large longitudinal studies (Barnes et al., 2003; Corrada et al., 2010; Katz et al., 2012) found similar rates between men and women, even in the very old.

Nevertheless, others have reported that women have poorer cognitive outcomes than men (Laws et al., 2018). Such sex-related differences could be related to postmenopausal changes in oestrogens, genetic polymorphisms of sex-related genes, or an interaction of sex with APOE genotype (Gao et al., 1998). Of these possibilities most work has been done to investigate a possible role for sex hormones. Early systematic reviews and meta-analyses of cohort and case-control studies (Yaffe et al., 1998; LeBlanc et al., 2001; Nelson et al., 2002) reported oestrogen use to be associated with a reduction in the risk of developing AD of 29–34%. However, randomized trials, e.g. (Henderson et al., 2000; Mulnard et al., 2000; Wang et al., 2000) have failed to find any clinically meaningful evidence of benefit in treating patients with mild to moderate AD with oestrogen.

A large primary prevention trial, the Women's Health Initiative Memory Study (WHIMS), examined the possible benefit of HRT/ERT in reducing the frequency of, or time of, onset of dementia in postmenopausal women, but adverse outcomes led to both arms being terminated early (treatment led to increased rates of stroke, coronary heart disease, venous

thromboembolism, and breast carcinoma). The use of unopposed oestrogen over seven years was associated with a nonsignificant increased risk of dementia (hazard ratio (HR) = 1.49; 95% CI 0.83–2.66) (Shumaker et al., 2004), and treatment with combined oestrogen and progestin over four years led to a doubling of dementia risk (HR = 2.05; 95% CI 1.21–3.48) (Hays et al., 2003). Combining these two groups, there was a highly clinically and statistically significant increase in dementia in women taking HRT (HR = 1.76; 95% CI 1.19–2.60) (Shumaker et al., 2004).

However, it has been suggested that there may be a 'critical window' around the perimenopausal or early postmenopausal period, in other words, before significant Alzheimer's neuropathology has developed, during which oestrogen therapy may be beneficial in enhancing cognition, whereas later oestrogen treatment has negative effects. Support for this hypothesis was demonstrated in an observational cohort study (Whitmer et al., 2011) involving 1,524 women, which found that those who took hormone therapy at midlife had a 26% decreased risk of getting dementia compared to those who never took hormone therapy, whereas those taking hormone therapy only in late life had a 48% increased risk and women taking hormone therapy at both midlife and late life had a similar risk of dementia. However, as with similar studies of AD, risk factors confounded by indication (healthier, better-educated women with lower risk for dementia take HRT) might explain these findings.

Efforts have also been made to look at the potential protective effect of marriage. At least one systematic review has found that married people are less likely to develop dementia than lifelong single people or widows, though this finding may be confounded by differences in physical health and education and is not an effect of marriage per se (Sommerlad et al., 2018).

Ethnicity, race, country, and culture

It is estimated that the majority of people with dementia in the world live in developing countries (60% in 2001, rising to 71% by 2040 as a result of changing demographics; see Ferri et al., 2005). However, an outstanding issue is whether the inherent incidence of AD differs across the world and in different ethnic or racial groups.

A large number of studies have been published, although the findings have been contradictory and difficult to interpret. In a between country and race comparison Chandra and colleagues (2001) found a lower incidence of AD in older persons living in rural India (4.7/1000 person years) compared to a predominantly white population in the US (17.5/1000 person years). However, different social expectations of older people in the Indian cohort meant that individuals with cognitive decline may not have met functional impairment criteria for dementia, thus underestimating the true level of dementia in the Indian sample. A within-

Alzheimer's disease

country comparison (Manhattan, US) of AD incidence between different racial groups by Tang and colleagues (2001) demonstrated that African-Americans had a greater risk for AD than white people (for 65- to 74-year-olds, incidence rate per person-year was 1.7% for African-Americans vs 0.4% for Caucasians and 4.4% vs 2.6%, respectively, for 75- to 84-year-olds), even adjusting for confounders such as education and vascular disease. However, the Cardiovascular Health Cohort (Fitzpatrick et al., 2004) only found marginal differences between African-Americans and white people, and these authors were cautious about the differences due to concerns about ascertainment methods applied during the data collection. A recent systematic review examining incidence and prevalence of dementia in the US among different racial and ethnic groups found higher prevalence rates among African-American and Caribbean-Hispanic populations, although there is large within population heterogeneity and use of current race/ethnicity classifications may be too crude to delineate specific race/ethnic risk factors (Mehta and Yeo, 2017).

Ethnicity, which encompasses shared culture, religion, language, geography, diet, and so on, may be a more powerful contributor to AD risk than race, given commonalities in life experience and environment between people of the same ethnic background; thus, epidemiological studies comparing different ethnicity despite similar race may give clues about risk or protective factors, and indeed provide an insight into the underlying pathophysiology of AD.

An important example was the Indianapolis-Ibadan Dementia Project which used identical assessment methods in Nigeria and Indianapolis, and reported an increased incidence of dementia and AD in African-Americans compared to Nigerians (Hendrie et al., 2001). One possible explanation for this finding was the observation that APOE ϵ 4 occurrence in the Nigerian cohort does not appear to be associated with increased AD risk (Gureje et al., 2006), suggesting that some protective mediating factor, potentially environmental, has a role in reducing risk in the Nigerian cohort. However, it should be noted that a more recent follow-up study from Nigeria reported a higher incidence rate of dementia than previously thought (Gureje et al., 2011) and thus the reported difference in the original study by Hendrie and colleagues (2001) may have related more to an underestimation of dementia incidence.

Overall, there remain significant problems with examining AD incidence across different races, cultures, ethnic groups, and countries, including problems with diagnostic classification, imprecise diagnostic instruments, imprecision in defining ethnic/racial groups, and different social expectations in certain cultures. In addition, even with better assessment and screening methodologies, the true prevalence and incidence of AD cannot be established without post-mortem confirmation of diagnosis. Until there are clear biological biomarkers for AD that can be easily applied in both high- and low-tech environments, we will remain

Alzheimer's disease

uncertain as to the true variability in AD incidence across different racial, ethnic, and cultural groups.

Genetic risk factors

Family history

It has long been recognized that AD is more common in relatives of people with AD. Classic twin studies demonstrated a significantly higher concordance in monozygotic vs dizygotic twins (e.g. Pedersen et al., 2004). Meta-analysis suggests that those with a first-degree relative (parent, sibling, child) with AD have a 3.5-fold increase in their risk of developing AD (van Duijn et al., 1991). Generally, those with an early onset of the disease (before 65 years) show a stronger familial risk, although early-onset AD only accounts for 1–5% of all AD cases; conversely, the increased risk is very much reduced for those whose relatives develop AD in very old age. Nevertheless, the genetic contribution to AD is increasingly being revised upwards and new risk genes are continually being identified, with recent estimates suggesting a potential genetic contribution of up to 70% in AD (Pedersen et al., 2004; Gatz et al., 2005; Ballard et al., 2011b) (see Chapter 8 for a more detailed discussion of AD genetics).

Down's syndrome

Virtually all people with Down's syndrome have the neuropathological features of AD by the age of 40 years (Mann et al., 1986) and this is probably due to having an extra copy of the amyloid precursor protein gene located on chromosome 21. However, the prevalence of dementia in people with Down's is much less than 100%, even by age 50, although it is clearly markedly elevated for age (Zigman et al., 1996). The reason for this discrepancy between pathology and function (though it also mirrors some findings in the non-Down's syndrome elderly population) is not understood and complex interactions between maternal age and frequency of the APOE ϵ 4 allele (see next section) have been proposed. In addition, the added difficulties of making an accurate clinical diagnosis in this group are likely to contribute to the variable findings. Dementia in Down's syndrome is dealt with in detail in Chapter 47.

Autosomal dominant gene mutations

Three genetic loci have been identified with mutations conferring an autosomal dominant pattern of inheritance for AD with almost complete penetrance. These are mutations in the amyloid precursor protein gene on chromosome 21, in the presenilin 1 gene on chromosome 14, and in the presenilin 2 gene on chromosome 1. While all are associated with early-onset AD (before 65 years) they account for less than 2% of all AD cases (Farrer et al., 1997) and indeed do not seem to be present in even the majority of early-onset familial AD cases (Cruts et al., 1998). Their importance lies in the clues they may give about the pathogenesis of AD. For example, these mutations all lead to an excessive production of the

Alzheimer's disease

pathogenetic long chain form of the amyloid beta protein (amyloid beta 42) (Hardy, 1997), and the presenilin 1 gene codes for an important enzyme (gamma secretase) involved in producing amyloid beta 42 protein (De Strooper et al., 1999; Saftig et al., 1999). More recently, a gene which had been identified as a potential risk gene in genome-wide association studies (GWAS) (sortilin related receptor 1, SORL1, involved in the endocytosis of low-density lipoprotein) has been identified as possibly having pathogenic variants resulting in an autosomal dominant pattern of inheritance (Pottier et al., 2012). Identification of families with deterministic mutations has also allowed the study of the development of the disease as members of these families can be identified and examined many years before an accurately predicted date of symptom onset. Studies of this sort have shed light on the length of time Alzheimer's pathology develops over and what the early changes might be. For example, such studies have demonstrated subtle cognitive, structural, and pathological changes many years (in some cases decades) prior to symptom onset (Bateman et al., 2012).

Genes that increase risk of Alzheimer's disease

There are many methods which can be employed to identify genes which increase the risk of a disease. These include linkage studies, candidate gene approaches, GWAS, meta-analyses of GWAS, pathway analysis, analysis of rare variants, approaches looking at changes in copy numbers, and whole genome analysis. These approaches have been applied to AD and in addition to the identification of autosomal dominant genes a number of other genes which increase the risk of AD have been identified. Whilst this wealth of data is welcome, it has resulted in a large number of genes being identified, some likely incorrectly, and some, where association does not necessarily relate to causation. This section focuses on those genes that have been identified and proven to be associated with AD in replication studies.

Apolipoprotein E (APOE) polymorphism

APOE is a plasma protein involved in lipid transport. The gene coding for APOE is located on chromosome 19 (19q13.2). It has three common alleles— $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$ —which in the normal population have allele frequencies in white people of about 7%, 77%, and 16%, respectively (Zannis et al., 1993). Many studies have shown the $\epsilon 4$ allele to be much more common in AD subjects, occurring in 30–50% of patients (Roses, 1996). The estimated age-adjusted odds ratios for AD are 2.6 for $\epsilon 2/\epsilon 4$ heterozygotes, 3.2 for $\epsilon 3/\epsilon 4$, and 14.9 for $\epsilon 4/\epsilon 4$ homozygotes (Farrer et al., 1997). Thus, APOE $\epsilon 4$ alleles have a dose-dependent effect in increasing the risk for AD and notably there is a dose-dependent relationship between APOE $\epsilon 4$ expression and worse performance on episodic memory tasks in people with AD (Van der Vlies et al. 2007). Other studies have demonstrated that the increased risk conferred by APOE $\epsilon 4$ is related to it bringing forward the time of onset of AD (Roses, 1996). However, these striking findings need to be put in context. Up to

Alzheimer's disease

50% of those who are homozygous for $\epsilon 4$ live to beyond 90 without developing AD and about two-thirds of those who develop AD have no $\epsilon 4$ allele (Henderson et al., 1995). It should also be noted that there is evidence the $\epsilon 2$ allele may be protective, as Farrer and colleagues (1997) found an odds ratio for AD of 0.6 for the combined $\epsilon 2/\epsilon 2$ and $\epsilon 2/\epsilon 3$ genotypes. Of all non-deterministic risk genes, APOE is by far the most robustly replicated and implicated in terms of risk of AD, and whilst it might account for a significant proportion of the heritability of AD, other genes are clearly contributory.

Other risk genes for Alzheimer's disease

The search for other risk genes using the techniques outlined earlier, including large GWAS meta-analysis of tens of thousands of cases and controls (Lambert et al., 2013), has been intensive and resulted in what is almost a surfeit of data: more than 500 genes have been suggested as potentially contributing to risk of AD. Discussion of all of these is beyond the scope of this chapter. Studies of this sort have been expanded to incorporate pathway analysis to identify commonly implicated biological processes including cholesterol metabolism and inflammation (Jones et al., 2010). This underlines the importance of studying the genetics of AD as this has allowed the development of novel patho-aetiological models, for example, galvanizing research focus on the role of inflammation and immunity as being important pathogenic processes in AD, and this is now translating in to new therapeutic strategies and ultimately trials (see Potential disease-modifying drugs for Alzheimer's disease).

Genes apart from APOE and SORL1 which are consistently implicated as risk genes for Alzheimer's disease include CLU (clusterin, a heat shock protein involved in apoptosis), PICALM (phosphatidylinositol binding clathrin assembly protein, involved in endocytosis), and TREM2 (triggering receptor expressed on myeloid cells 2, involved in white blood cell mediated immune response). Interest is also increasing in looking at 'resilience' genes, which reduce the risk of dementia, e.g. the A673T variant in amyloid precursor protein (APP) (Jonsson et al., 2012). These genetic findings are covered in greater detail in Chapter 8 and interested readers should consult the online meta-analysis website <http://www.alzgene.org> for up-to-date information.

Education, intelligence, mental activities, and cognitive reserve

Education, intelligence, and mental activities have all been mooted to modify the risk of incident AD. A common element uniting these factors is the notion of cognitive reserve, a hypothesis that compensatory processes or strategies, related to either brain function and structure (e.g. people with higher levels of education may have more synaptic connectivity and can therefore tolerate more neuronal loss before clinical deficits emerge) protect against the risk of dementia. Beyond this is the concept that mental engagement and activities, such as belonging to a social group, reading, and playing games, help build upon cognitive reserve and lessen

Alzheimer's disease

the risk of dementia (this is discussed in more detail in Physical, cognitive, and social activity).

Valenzuela and Sachdev (2006) carried out a review of published data on the effects of premorbid IQ, education, occupation, and engagement in mental activities on incident dementia, and noted that the majority of studies indicated a protective effect of education (ten out of 15 studies), occupational attainment (nine out of 12), high premorbid IQ (two of two), and mental activities (six of six). Combining these as markers of cognitive reserve, Valenzuela and Sachdev (2006) suggested that individuals with high reserve had a decrease in AD risk of 46% compared to those with low reserve.

Individuals with higher cognitive reserve as measured by the proxies of education, occupational achievement, or engagement in leisure activities appeared to have a more rapid decline once the diagnosis of AD was made; this may be because people with greater cognitive reserve have higher levels of pathology at the 'point of inflection' where memory function begins to decline (for discussion, see Stern, 2009). In support of this, a functional neuroimaging study showed regional cerebral blood flow to be lower in better educated subjects in the parietal and temporal lobes compared with more poorly educated subjects who had been matched for the severity of their dementia, indicating they had more advanced disease (Stern et al., 1992).

What is not clear is how factors such as intelligence and education affect the risk of incident AD. Is it a case that these factors lead to more efficient use of brain networks and better synaptic transmission, the development of compensatory cognitive strategies, or allow one the ability to recruit alternative brain networks in the face of disease, and so the dementia presents later, or not at all if death supervenes?

Alternatively, do intelligence and education affect performance on objective cognitive tests so that people with poor education or lower intelligence fall below the threshold for dementia more easily and better educated/more intelligent people are better able to 'cover up' their deficits on testing?

There is evidence for the former; autopsy studies (Bennett et al., 2005; Roe et al., 2008) found that education (and brain volume) interacts with AD pathology to predict cognitive performance, and a longitudinal study (Roe et al., 2011) found that in individuals with normal cognitive function but high levels of CSF tau and phosphorylated tau at baseline (biomarkers for AD) the time to incident cognitive impairment was moderated by education and brain volume. Interestingly, one of the earlier religious orders studies which had followed a group of nuns for many years showed not only that those nuns with lower verbal ability in early life (a proxy measure of intelligence) had poorer cognitive functioning and a higher rate of AD, but also that at post-mortem all of those with neuropathological evidence of AD had low verbal ability (Snowdon et al., 1996). Therefore, higher intelligence may also possibly

Alzheimer's disease

protect against the pathological process of AD itself. However, a biomarker study (Vemuri et al., 2011) observed that the association between cognition and the American National Adult Reading Test (a measure of premorbid IQ) was found to be additive rather than interactive with biomarkers of AD pathology. Clearly, further work is required to clarify the exact relationships between education, intelligence, cognitive reserve, and AD.

Depression as a possible risk factor for AD

It is generally agreed that in the early stages of the dementia process, people often seem to have symptoms of depression, and indeed their dementia may present initially with depression rather than overt cognitive changes. But is depression an independent risk factor for developing dementia or AD? Several case-control and cohort studies have examined this and a thorough meta-analysis (Ownby et al., 2006) identifying studies in which a specific diagnosis of depression (rather than depressive symptoms) found 20 good-quality published studies and reported that any history of depression doubled the risk of developing AD (odds ratios of 2.03 (95% CI: 1.73–2.38) for case-control studies and 1.90 (95% CI: 1.55–2.33) for cohort studies).

However, as there is often quite a short period between the episode of depression and the onset of dementia, it is not obvious whether the depression is an intrinsic feature of the dementia or a true risk factor for dementia. Nevertheless, a recent prospective study based on the Framingham cohort (Saczynski et al., 2010) found that depression was associated with double the risk of dementia and AD in older men and women over a 17-year follow-up period, supporting the hypothesis that depression is a risk factor for dementia, rather than the other way around.

It is not, however, clear how depression mediates its effect, although its associations with high cortisol levels, chronic inflammatory markers (e.g. tumour necrosis factor- α), and hypothalamic-pituitary-adrenal axis activation have been suggested as mediating processes. Depression may also have its effect via lifestyle factors; reduced physical activity and social engagement occur in depression and these are both factors associated with an increased risk of dementia. Alternatively, increased vascular pathology associated with depression (Thomas et al., 2004) could provide the missing link, as vascular factors are associated with increased AD. Against this argument is the finding from the Framingham study (Saczynski et al., 2010) that even controlling for major vascular risk factors did not alter the AD risk level associated with depression.

Vascular risk factors

Over recent years the debate about the relationship of AD to VaD has been complicated or clarified (depending on your view) by evidence that vascular disease may directly contribute to the pathology of AD. The so-called angiogenesis hypothesis proposes that elevated blood pressure

Alzheimer's disease

leads to small vessel damage and inflammation with secondary increases in amyloid and neural loss (Kuller and Lopez, 2011). In fact, this is far from a new idea, as in his original paper Alois Alzheimer (1907) described vascular pathology at post-mortem in Auguste D. This finding has been confirmed by more recent pathological data showing that AD patients have a high level of white matter lesions and small grey matter infarcts. Both APOE and homocysteine (discussed in Homocysteine, vitamin B₁₂, and folate) are also vascular risk factors and may exert their pathogenic effects in AD via vascular disease. It has been proposed that a history of hypertension, as long as ten and 15 years before the onset of dementia, increases the rate of AD (Skoog et al., 1996), and therefore that treatment of systolic hypertension in older people might reduce the rate of dementia and AD (Forette et al., 1998). However, a review of longitudinal studies (Daviglus et al., 2011) failed to find any significant difference in the incidence of AD between subjects with and without hypertension, and pooled analyses examining the treatment effect of antihypertensives on the incidence of AD have also found no statistically significant effect (RR: 0.90, 95% CI: 0.79–1.03) (Guan et al., 2011). Specific trials of antihypertensives in established disease, even those with multiple putative disease modifying mechanisms, have been negative (Lawlor et al. 2018).

Unfortunately, research into the potential risk reduction effects of antihypertensives is hampered by the fact that studies have focused on older individuals and therefore may have 'missed the boat' in terms of preventing any vascular changes and thus consequent amyloid formation. These studies also have several other problems, including: i) inconsistent diagnostic criteria for dementia; ii) different definitions of hypertension; iii) focusing on vascular endpoints rather than on dementia; and iv) probable bias due to survivor effects, i.e. patients who would normally have died with cerebrovascular disease but remained alive because of successful control of their hypertension may be the people with the highest levels of vascular damage (therefore the highest risk of AD according to the angiogenesis hypothesis), thereby actually increasing the overall incidence of AD (Kuller and Lopez, 2011).

Therefore, the benefits of blood pressure reduction on dementia risk remain unclear at the current time. Even considering the treatment of hypertension earlier on in midlife may not be helpful for reducing AD. The Uppsala Longitudinal Study of Adult Men, which started in 1970 when subjects were 50 years old and has followed subjects for up to 40 years, failed to find any association between vascular risk factors and AD incidence (Rönnemaa et al., 2011). However, high systolic blood pressure did appear to be a risk factor for all types of dementia, in particular VaD and mixed dementia, so antihypertensive treatment may be more beneficial for these dementias than for AD.

Beyond hypertension, other manifestations of vascular disease, including ischaemic heart disease, heart failure, renal failure, atrial fibrillation, and previous cerebrovascular disease, are associated with an increased risk of

Alzheimer's disease

dementia of all types including AD (Bunch et al., 2010; Dublin et al., 2011).

Elevated total cholesterol in midlife, an established risk factor for coronary heart disease and stroke disease, has been associated with an increased risk of developing dementia in cohort studies (Kivipelto et al., 2001; Whitmer et al., 2005), although there is a lack of association between high cholesterol in late life and AD (Anstey et al., 2008). Reduction of cholesterol using statins has been proposed to modify AD through several mechanisms, in addition to the headline effect of cholesterol lowering, including antioxidative effects, inhibition of butyrylcholinesterase, and increasing the trafficking of amyloid precursor protein (Darvesh et al., 2004). Two cross-sectional analyses have reported a reduction in dementia in people taking statins (Jick et al., 2000; Wolozin et al., 2000). However, concern was expressed about 'bias by indication' in these studies (i.e. healthier, better educated people are more likely to take statins), and this view is supported by the finding in a five-year prospective study that, while on cross-sectional analysis, statin use was inversely associated with dementia, statins did not reduce incident dementia risk (Zandi et al., 2005). Further caution about the potential benefits of statins in reducing AD and dementia arises from the findings in two large randomized placebo-controlled trials of two different statins—simvastatin in the Heart Protection Study (Heart Protection Study Collaborative, 2002) and pravastatin in the PROSPER study (Shepherd et al., 2002)—which both failed to find any benefits of statins on cognitive function or in reducing dementia risk.

Other vascular risk factors that may increase the risk of AD are the metabolic factors obesity and diabetes. Diabetes doubles the risk of VaD and, more specifically, AD (Ahtiluoto et al., 2010), with the risk increased in APOE ϵ 4 carriers. A systematic review by Biessels and colleagues (2006) noted that a majority of cohort studies have suggested that diabetes is associated with an increased risk of incident AD, although limitations in studies such as different diagnostic criteria for diabetes, lack of information on duration of the diabetes, and the quality of glycaemic control make it difficult to determine what elements of diabetes contribute to increasing the risk of AD.

Obesity in midlife is linked with an increased incidence of AD with risks in the order of 2–5 times in individuals with body mass indexes (BMI) more than 30 (Gustafson, 2008; Fitzpatrick et al., 2009); increased waist-to-hip ratios may also be a specific risk factor (Gustafson et al., 2009). However, obesity is often co-associated with vascular and metabolic disturbances (e.g. hypercholesterolaemia, hyperglycaemia, hypertension, hypertriglyceridaemia, and reduced levels of high-density lipoprotein, i.e. the 'metabolic' syndrome), which in themselves have been associated with AD risk, making it difficult to disentangle the unique contribution of obesity to AD risk. Indeed, these vascular/metabolic risk factors may be additive in their effects. For example, in one study, combining obesity with hypertension and high cholesterol led to a much larger combined

Alzheimer's disease

risk (OR 6.2) (Kivipelto et al., 2005), and in another prospective study (over 5.5 years) diabetes, smoking, hypertension, and heart disease all increased the risk of AD, but their combinative effect was much stronger, increasing the risk by over threefold (Luchsinger et al., 2005).

This section raises the attractive possibility that lifestyle modification might decrease the risk of Alzheimer's disease. Studies have been completed to identify the impact of single lifestyle interventions but have had disappointing results. More recently multi-interventional studies have been reported, which have again been largely disappointing, though the FINGER study did show benefits in cognition for those at high risk assigned to multiple intervention addressing diet, exercise, cognitive training, and vascular risk (Ngandu et al., 2015).

Head injury

A meta-analysis of 15 case-control studies of head injury (with loss of consciousness) showed it to be associated with an increased risk of AD (OR 1.58, 95% CI 1.21–2.06) (Fleminger et al., 2003) and this risk appears to be specific to men. However, one major criticism is that early studies used retrospective assessments from relatives, raising the risk of recollection bias. Interestingly, however, a study using a prospective historical cohort design of Second World War veterans who had documented nonpenetrating head injuries demonstrated that both moderate and severe head injury were associated with a significant risk of AD (Plassman et al., 2000).

Further evidence for head injury effects on AD risk come from pathology in that head injury leads to a disturbed balance between amyloid beta genesis and catabolism, leading to an increase in amyloid beta deposits. Indeed, amyloid deposition has been reported to occur within hours of the injury (Johnson et al., 2010). The potential increased risk following repeated minor head injury has become a topic of interest in the UK following the suggestion that there is an increased risk of dementia in football players who have repeatedly headed a heavy football. This has led to funding to investigate this possible link in footballers and the results of these studies are awaited. In the US there are concerns around the safety of American football (see Mez et al., 2017) with evidence of players having traumatic encephalopathy. Whether this means it causes an excess of dementia, and whether it associates with AD, are separate entities.

Sensory deprivation

Case control studies, systematic reviews, and meta-analyses have been consistent in identifying hearing loss as a risk factor for dementia, though whether it is a specific risk factor for AD is less clear (Livingston et al., 2017; Loughrey et al., 2018). The interest in this is enhanced by the fact that this risk factor may be modifiable by correcting hearing difficulties, though we do not yet know whether such intervention is beneficial. The role of visual impairment is not as well studied, but results from the

Alzheimer's disease

recent ProVIDe study in the UK found a high incidence of visual impairment among those with dementia, much of which could be corrected by providing the right prescription spectacles (Bowen et al., 2016). This highlights the importance of not overlooking what may seem to be simple interventions (for example, getting the right spectacles) but which might make rapid and significant improvements to quality of life.

Other possible risk factors

Metals

Studies some years ago showed increased aluminium in the brains of subjects with AD and suggested that aluminium is neurotoxic (Crapper et al., 1973; Trapp et al., 1978). This led to the suggestion that it may play a role in the causation of AD, supported by some epidemiological evidence of higher rates of AD in areas with high aluminium content in the drinking water (Doll, 1993). However, other studies have not confirmed these early findings and it is clear aluminium is neither necessary nor sufficient to cause AD (Walton, 1991).

More recently, attention has switched to other metals including iron, zinc, and copper, whose levels in the brain appear to be raised and whose homeostasis is disordered in AD. This has led to the hypothesis that these metals may increase oxidative damage and the formation of amyloid beta plaques (Maynard et al., 2005). However, the role of metallobiology in the pathogenesis of AD is far from resolved, as research findings are often controversial and contradictory (Schrag et al., 2011).

Smoking

It has been hypothesized that smoking increases nicotinic receptors in the cortex and this could counteract the cholinergic deficit in AD, and smoking has been firmly identified as a protective factor in Parkinson's disease (Gigante et al., 2017). The role of nicotine as a potential neuroprotective agent in AD has received support from the finding that nicotine treatment reduces beta-amyloid deposition in mice (Hellstrom-Lindahl et al., 2004). In addition, early case-control studies suggested that smokers had a 20% reduction in AD (Graves et al., 1991). However, a meta-analysis of 19 prospective studies (Anstey et al., 2007) with at least 12 months of follow-up has refuted the argument that smoking may be protective for AD: current smokers had an incident risk of 1.79 (95% CI: 1.43, 2.23) for developing AD (with a comparable level of risk for incident VaD) compared to non-smokers. Incidence risks were similar when comparing current vs former smokers (pooled RR = 1.70; 95% CI, 1.25–2.31). But the view that nicotine may be neuroprotective has received support from randomized trials reporting benefits of nicotine therapy on cognition (e.g. Newhouse et al., 2012), although whether it reduces the development of AD or dementia remains to be demonstrated.

Alzheimer's disease

Homocysteine, vitamin B₁₂, and folate

Cognitive impairment is associated with deficiencies in folate and vitamin B₁₂. Homocysteine is an amino acid intermediary in methionine metabolism and its blood levels increase with deficiencies in folate and B₁₂ because its elimination is dependent on these vitamins, and the risk of cognitive impairment and dementia associated with their deficiencies may be related to raised homocysteine levels.

High homocysteine levels appear to occur in AD compared to healthy older people, although a meta-analysis of prospective data has not provided conclusive evidence that homocysteine enhances the risk of developing AD (Ho et al., 2011). In addition, systematic reviews of intervention studies have found no evidence for any benefit on cognition or dementia using B₁₂ with and without folate even when associated with a lowering of homocysteine or for B vitamin supplementation more broadly (Malouf and Grimley Evans, 2009; Ford and Almeida, 2012; McCleery et al., 2018).

Frailty and weight loss

Reduced muscle strength and general frailty have been associated with an increased risk of dementia, and while midlife obesity with high BMI is associated with dementia risk, this situation reverses in old age, with low BMI being associated with incident AD (Fitzpatrick et al., 2009); however, it is possible that these factors are actually markers of dementia pathology rather than being causative, and thus are not true risk factors.

Alcohol

Previous meta-analyses of alcohol use have suggested there may be a 'U-shaped' relationship between alcohol consumption and dementia risk (Anstey et al., 2009; Weuve et al., 2012). Higher levels of alcohol intake are likely to increase the risk of dementia, possibly through well-established neurotoxic pathways such as Wernicke-Korsakoff syndrome, which may be underdiagnosed in heavy drinkers as well as direct neurotoxic effects leading to particularly cerebellar and frontal cortex deficits. It has been asserted that individuals who drink mild to moderate amounts of alcohol have a lower risk of AD and all types of dementia. Part of this effect is thought to be mediated through the indirect effect on cardiovascular health or as part of antioxidant process (e.g. high levels of antioxidants are present in red wine), although the exact neurobiological underpinnings are not known. More recently, however, the protective effects of moderate drinking on the brain has been questioned (e.g. Topiwala et al., 2017) in that non-drinking groups may contain a lot of people who have physical ill-health and their lack of alcohol consumption may be related to this. Thus, the relationship may be more 'J-shaped'.

Protective factors

Alzheimer's disease

Anti-inflammatory medication

A review of case-control studies has suggested arthritis, nonsteroidal anti-inflammatory drugs, and steroids to be protective factors for AD, reducing the risk by about 50% (McGeer et al., 1996). This fits with current views that AD is associated with an inflammatory response in the brain because senile plaques are associated with prominent astrogliosis and microglial activation (Dickson et al., 1988) and pro-inflammatory cytokines are increased in the brain in AD subjects (Wood et al., 1993), as well as the association for genes involved in inflammatory pathways with AD. A dampener for enthusiasm about the role of inflammation in AD is that all RCTs using anti-inflammatory drugs, including ibuprofen, prednisolone, naproxen, and COX inhibitors, in established AD have been negative (Aisen et al., 2000; Aisen et al., 2003; Imbimbo, 2004; Reines et al., 2004; Lyketsos et al., 2007).

Vitamins, antioxidants, and nutritional supplements

Oxidative stress is thought to be important in the development of dementia and neurons are especially vulnerable to oxidative stress because the brain has a high oxygen consumption and a lack of antioxidant enzymes, e.g. superoxide dismutase (SOD-1), compared with other organs (Esposito et al., 2002), and is more dependent on dietary antioxidants, including tocopherols, ascorbic acid, carotenoids, vitamin A, and flavonoids. Although using vitamins as antioxidants has been frequently claimed to be protective against AD, cross-sectional and cohort studies have reported mixed findings on the possibility of nutritional and/or supplementary dietary antioxidants reducing the risk of dementia (Engelhart et al., 2002; Morris et al., 2002; Tabet et al., 2002; Larrieu et al., 2004; Engelhart et al., 2005). It is possible the characterization of oxidative stress as an exclusively negative cellular event may be simplistic. Reactive oxygen species may have physiological cellular roles to play, for example, as signalling molecules, including the induction of pathways protective against neurodegeneration (Underwood et al., 2010).

A randomized trial of vitamin E supplementation in AD involving moderately impaired subjects reported that after adjustment for baseline MMSE (but not before), vitamin E delayed time to a composite endpoint by 230 days (Sano et al., 1997). However, there were no differences in a range of secondary outcome measures including ADAS-Cog and MMSE. Another randomized trial of 769 subjects compared progression to possible or probable AD in subjects with amnesic MCI (Petersen et al., 2005). Subjects were randomized to vitamin E (2000 IU), donepezil (10mg), or placebo for three years and no difference in outcome was observed, casting doubt on the benefits of antioxidant treatment in preventing or slowing the development of AD. Similarly, a large RCT of 6,377 older women on 600 IU of vitamin E on alternate days (Kang et al., 2006) found no difference between treatment and control groups on measures of cognitive function after 5.6 years and 9.6 years of treatment.

Alzheimer's disease

In summary, there is no good evidence to support vitamin E supplementation to either treat or prevent AD.

Omega-3 fatty acids, frequently obtained from fish oils, have been similarly mooted to have a range of health benefits mediated by their modulatory effects on inflammatory pathways. However, their potential effect on the incidence of AD has not been conclusively established (for discussion, see Daviglus et al., 2011).

General dietary changes may, however, offer some benefits in reducing the risk of AD. Emerging evidence has suggested that medium-to-high fruit and vegetable intake or adherence to a Mediterranean diet may reduce the risk of AD occurrence (Daviglus et al., 2011) and this is generally supported in systematic review, although caution needs to be applied to the findings of these dietary studies as individuals who take additional nutritional supplements and/or eat healthily also tend to be better educated and more physically fit (see Physical, cognitive, and social activity).

Once a risk factor has been identified, a sensible idea is to try to correct that risk factor in a hope of preventing disease or slowing decline once disease is established. One nutritional supplement which is now commercially available is Fortasyn Connect (also known as Souvenaid), a mixture of nutrients designed to maximize neuronal and synaptic function. RCTs have suggested benefit on cognitive tests in those with mild AD, though no benefit was seen in the primary outcome for those with MCI (Soininen et al., 2017).

Physical, cognitive, and social activity

The cardiovascular benefits of physical activity are well established and, given the putative linkage between vascular risk factors and AD as well as evidence in transgenic animal studies that physical activity reduces AD pathology, it is not unreasonable to hypothesize that physical activity may reduce AD risk. A meta-analysis of nine cohort studies (Daviglus et al., 2011) found that higher levels of physical activity were associated with lower risk of incident AD (HR = 0.72; 95% CI, 0.53–0.98). However, such studies often relied on self-reports of physical activity rather than objective measures, associations were not always statistically significant, and in some studies physical activity appeared to increase the risk of AD (Daviglus et al., 2011). Nevertheless, a subsequent Australian prospective study of older individuals (50+ years) randomly allocated to an education and usual care group or to a 24-week home-based programme of physical activity demonstrated sustained benefits of the exercise intervention up to 18 months, in terms of improvements in global cognition and delayed recall (Lautenschlager et al., 2008). Sadly, this benefit has not been replicated in further good-quality RCTs and methodological differences make meta-analysis challenging (Du et al., 2018).

Alzheimer's disease

Cognitive engagement and leisure activity involvement may also have protective effects, perhaps by improving cognitive reserve, although the evidence base is still limited. Studies in this area suffer from the inevitable inclusion of individuals who tend to be better educated and healthier, factors (as already discussed) that in themselves reduce AD risk. Furthermore, it may be that in individuals with prodromal AD, the direct effects of the disease cause early social disengagement and reduced motivation and drive, which may accentuate the apparent 'difference' between healthy individuals who are socially and cognitively active compared to those who go on to develop AD.

Recent large epidemiological studies have examined the incidence of dementia in both the US and UK and have found fewer cases than expected. Retrospective analyses to identify the potential reasons for this are difficult, but both improvement in vascular health and education have been suggested, with the decline in expected cases in the Framingham study being seen only in those with high school diploma education or better (Satizabal et al., 2016, Matthews et al., 2016). Whether increasing social mental activity can bring benefit after the condition is manifest is even less clear, though there is some early evidence that social events such as 'singing for the brain' or computerized 'brain training' may help, whereas conversely loneliness may increase risk of dementia (Savulich et al., 2017; Osman et al., 2016, Rafinsson et al., 2017). Further work is required to understand better both the positive and negative impacts of social, physical, and environmental factors; challenges to this include the necessity to look at these lifestyle factors well before the emergence of dementia. Studies such as the UK PREVENT study are taking this long view perspective (<http://www.preventdementia.co.uk>).

Prognosis of Alzheimer's disease

The natural history of Alzheimer's disease

Every old age psychiatrist is familiar with the considerable variability in the pattern and progress of AD. All the studies following the natural history of the disease bear this out as they show substantial variations in symptomatology and rates of decline. The practical consequence of this for the clinician is that it is very difficult to give accurate predictions to patients or their families about the likely progress of the disease after the diagnosis has been made. However, despite these uncertainties, patients and relatives will continue to seek information on prognosis, and two of the most common outcomes of interest are time to institutionalization into residential or nursing home care, and time to death.

Institutionalization

Data compiled by the National Alzheimer Coordinating Centre (Spackman et al., 2011) have suggested annual probabilities of institutionalization of 1.2, 3.4, and 6.6% for mild, moderate, and severe AD dementia, respectively. A higher overall annual incidence of 11.84% was observed in a two-year prospective French study (REAL-FR (Gillette-Guyonnet et al.,

Alzheimer's disease

2011)), thus highlighting the wide range of progression evident even in reasonably powered studies. Established predictors of institutionalization include the presence of behavioural symptoms, severe impairments in ADLs and cognition, having a paid (versus family) carer, living alone, and depression (Knopman et al., 1988, Habermann et al., 2009). Caregiver factors also probably have a significant role in predicting early nursing home placement. For example, a prospective study (Gaugler et al., 2003) identified that older age of carers (more than 80 years) and high perception of care burden by the carers themselves predicted higher early institutionalization. This study and other evidence show that there is a complex interaction between patient and caregiver factors that influences the course of the pathway to nursing care. This underlines the fact that it is always important to consider the needs of caregivers in the assessment of management of patients with dementia (Gaugler et al., 2011).

Death

Time from diagnosis to death is highly variable, with the length of survival from diagnosis ranging from one year up to 20 years. This is highly dependent on how early the diagnosis is made, although certain other factors, e.g. age at onset and comorbidity are also important. The median life-expectancy after diagnosis appears to be about five to ten years for patients diagnosed with AD in their 60s and 70s (equivalent to approximately 70% reduction in expected median lifespan) but only between three to four years if patients are in their 90s (an approximate 40% reduction in expected median lifespan) (Xie et al., 2008; Zanetti et al., 2009). Unsurprisingly, the mildest patients at outset tend to show the longest times to both institutionalization and death. A recent large naturalistic UK-based study arrived at a mean time of survival of around seven years from diagnosis to death (Price et al., 2017).

The cause of death in AD can be difficult to determine. As with other chronic diseases in older people, many people will die *with* the disease rather than *from* it. A Swedish autopsy study based on data from 1974–2004 found that the most common cause of death in AD patients was bronchopneumonia (47.3%) (Brunnstrom and Englund, 2009). Difficulties in the terminal stages with feeding and poor airway protection may be contributory. Since AD is associated with marked weight loss and physical decline (Cronin-Stubbs et al., 1997), these are likely to contribute in their own right to death in many people with advanced disease, although frequently AD may not be mentioned on the death certificate (Burns et al., 1990a).

Whether AD directly causes death is less certain, although it seems plausible as some patients do simply fade away without any other obvious cause for death occurring. Many others develop other complications of immobility and physical debilitation and die of a combination of causes.

Alzheimer's disease

Measuring rates of decline

Two kinds of instrument (global rating scales and cognitive scales) have been used to try to measure the rate of decline in AD. Global measures, e.g. the Clinical Dementia Rating Scale (CDR) (Hughes et al., 1982), tend to change very slowly over a few years and so are not useful measures of change clinically. Cognitive scales can show significant changes over the course of a year. Some of these are in common use and familiarity with the data derived from research may help a clinician to see how rapidly any patient is declining compared with these norms and therefore aid the prediction of progress and outcome, although the substantial variability should always be borne in mind. The annual rate of change in the MMSE (Folstein et al., 1975) is about 2.5 points a year for moderately affected patients, with higher rates for more severely affected patients and lower rates for milder cases (Salmon et al., 1990). The REAL-FR study (Cortes et al., 2008) noted that after two years 11% of patients lost more than nine points on the MMSE, 66% lost between three and nine points, but a substantial minority (23%) remained stable or improved, highlighting the heterogeneity in cognitive decline among AD patients as well as evidence of plateauing.

Two more comprehensive instruments are the CAMCOG (the cognitive component of the Cambridge Mental Disorders of the Elderly (CAMDEX)) and the ADAS-Cog (the Alzheimer's Disease Assessment Scale—cognitive subscale). Burns et al. (1991b) used the CAMCOG to follow the progress of 110 AD patients. They found a drop of about 12 points in the first year (maximum score 107 with 80/79 as the cut-off for dementia). This included change in every main subsection, but many of the scores were already near the floor at baseline and this instrument appears less useful in more advanced dementia. Older studies have used the ADAS-Cog (maximum score 70, higher scores = worse performance) and have shown an annual rate of increase of between eight and nine points (Kramer-Ginsberg et al., 1988; Yesavage et al., 1988). A more recent finding from the REAL-FR study reported a slower rate of progression of an average of a 4.5 point gain per year on the ADAS-Cog over a four-year period (Gillette-Guyonnet et al., 2011), which may reflect changes in management of AD (memory clinics and availability of symptomatic drugs) over the past 15–20 years.

Predicting rates of decline

Within the rough framework of the above figures for rates of decline and time to institutionalization and death, are there any clinical features that can help sharpen the prediction in individual cases? Certainly, the more severe the dementia the more rapid is the rate of decline (Morris et al., 1993). Consistent with this, the decline is nonlinear, being slower at the milder stage but accelerating as the dementia progresses (Teri et al., 1995).

Alzheimer's disease

In some studies, the level of education has been demonstrated to be a predictor of decline (see discussion in Physical, cognitive, and social activity).

Extrapyramidal symptoms appear to predict more rapid deterioration in AD (Lopez et al., 1997), although results are complicated by the likely admixture in earlier studies of patients with AD and DLB and that the prognosis of DLB is significantly poorer in studies that directly compare the two conditions (Miller et al., 1991, Price et al., 2017). Gait apraxia may also be a marker of poor survival (Paradise et al., 2009), although whether gait apraxia is a reflection of or due to more severe brain disease, and thus shorter survival, or that it leads to survival-shortening falls or immobility is not clear. Several studies have found psychotic symptoms to predict more rapid deterioration, although when groups have been matched for severity of AD at outset the findings have been mixed. Some studies have found that psychosis does still predict rate of decline (Chui et al., 1994; Stern et al., 1994), but not all (Reisberg et al., 1986; Chen et al., 1991). One longitudinal study has not found depression to predict decline (Lopez et al., 1990), but, unsurprisingly, it has been shown to be associated with greater impairment on ADLs (Pearson et al., 1989).

Other factors that have been investigated without a clear conclusion include sex, age of onset, APOE genotype, and concomitant cerebrovascular disease. Data (see previous sections) on oestrogen replacement, lipid-lowering agents, vitamins (B₆, B₁₂, E), omega-3 fatty acid supplementation, and NSAIDs have not indicated that they alter the rate of decline.

The effects of drug treatment on prognosis

Antipsychotic drugs, both typical and atypical, appear to worsen cognitive decline in dementia (McShane et al., 1997; Ballard et al., 2005; Vigen et al., 2011) and, as discussed earlier, are associated with increased mortality (Schneider et al., 2005). They have also been shown to adversely affect patients with DLB (Dickson et al., 1988; McKeith et al., 1992; Ballard et al., 1998). It appears that while these widely prescribed drugs do show benefits in the short term for specific symptoms, there is a danger they may worsen patient status overall.

Whether treatment with either cholinesterase inhibitors or memantine delays time to institutionalization is an important one for individuals and from a health economics perspective, but is a difficult one to answer with certainty, though evidence exists that suggests such benefits are seen with both groups of drugs (Feldman et al., 2009, Lachaine et al., 2011). Similarly, there is evidence that use of cholinesterase inhibitors and to a lesser extent memantine is associated with prolonged survival, though not time spent in institutional care. It is possible therefore that any extra life associated with use is spent at home, an idea which is likely to appeal to patients, although other studies have reported conflicting results (Tan

Alzheimer's disease

et al., 2018; Wattmo et al., 2016, Kazmierski et al., 2018; Zhu et al., 2013).

Potential disease-modifying drugs for Alzheimer's disease

All current treatment for Alzheimer's disease is symptomatic rather than disease modifying, i.e. it does not slow down the underlying pathological disease process. As Alzheimer's is a disease largely of old age, delaying its onset and progression may have significant personal, societal, and economic benefits. For example, one study estimated that delaying progression to frank dementia by five years would result in a 41% lower prevalence and 40% lower cost of AD in 2050 (Zissimopoulos et al., 2014).

Efforts at disease-modifying treatment have targeted the pathogenic proteins associated with the disease and, in particular, beta amyloid. Enthusiasm for these treatments has been enhanced by the possibility to visualize amyloid in vivo and therefore the possibility of having a readout of target engagement in conjunction with clinical outcomes. Most trials of this sort have used passive immunization to varying species of beta amyloid using monoclonal antibodies. Results have been mixed. Early studies of bapineuzumab suggested that cerebral amyloid load as measured by Pittsburgh compound B PET scanning was decreased (Rinne et al. 2010). Disappointingly, early results from phase III trials of solanezumab and bapineuzumab failed to show significant cognitive or functional benefit from treatment despite replicating the earlier PET findings and there were safety issues with regard to cerebral oedema (Salloway et al., 2014; Doody et al., 2014). Possible reasons for failure of these studies including treating too late in the disease course, though sadly a trial of gantenerumab in prodromal disease was also discontinued due to futility and a further large trial of solanezumab in mild disease also failed to reach significance in its primary endpoints (Ostrowitzki et al., 2017; Honig et al., 2018). More hopeful results for a monoclonal antibody targeted to soluble amyloid fibrils (BAN2401) in mild disease demonstrated dramatic reduction of amyloid load on PET and improvement in cognition. Further studies of this antibody are awaited. Immunotherapy has also been targeted against tau, and early studies have reported promising immune responses to an active vaccine (Novak et al., 2017).

An alternative approach targeting amyloid involves inhibition of the enzyme beta secretase. This is one of the enzymes required to cleave amyloid precursor protein in to the toxic 40-42 amino acid species that aggregates in AD, and as such is suitable target for drug action. In a story that echoes that of the anti-amyloid monoclonal antibodies, early readouts looking at decreased levels of amyloid in the CSF looked promising, but this has failed to be replicated in large phase three clinical trials, for example, the recently reported failure of verubecestat to improve cognition or function in mild-to-moderate disease (Egan et al., 2018).

Alzheimer's disease

A further approach is to target protein aggregation and one drug long touted as an antiaggregant of tau is leuco-methylthioninium, a derivative of methylene blue, though this drug may also have other beneficial effects involving tau phosphorylation and mitochondrial function. A recently published large clinical trial demonstrated no benefit on cognition or function of this drug compared to placebo overall. Intriguingly there did seem to be improvement in those patients taking it as monotherapy but no benefit to those taking it concomitantly with acetylcholinesterase inhibitors, despite it having no known effect as a cholinesterase inhibitor itself (Gauthier et al., 2016). Results of further investigation are awaited.

The similarity shared by many dementing illnesses, for example, protein misfolding and aggregation leading to cellular dysfunction and ultimately neuronal death, raises the possibility of applying therapeutic strategies that tackle these processes identified in other diseases. Examples include up-regulation of autophagy (a natural cellular process which clears misfolded proteins), inhibition of chronically activated unfolded protein response (another natural cellular response to the production of misfolded proteins), or targeting of neuronal death or inflammatory responses (Boland et al., 2018; Hughes and Mallucci, 2019). These alternative therapeutic approaches are beginning to be reflected in early clinical trials (Scheltens et al., 2018; Underwood et al., 2017). Other drugs are being trialled as a result of the overlap between AD and other diseases; for example, diabetes where more than one large trial is underway of the long acting GLP-1 agonist liraglutide. The overall picture provides reasons to be optimistic in a field that has had problems with repeated disappointment. Firstly, the sheer diversity of therapeutic approaches is encouraging—if the underlying therapeutic strategy of the current trials was the same then overall failure would be perhaps more likely. While diversity of approach to tackling the disease is welcome, attempting to make trials more uniform in their outcome measures will help in evaluating different approaches and to this end recent attempts to provide a consensus on outcome measures are welcome (Webster et al., 2017). Secondly, the translation of excellent basic science into clinical studies coupled with investment to connect patients and research initiatives such as the Clinical Research Network, Join Dementia Research, and dementia drug discovery institutes in the UK means that high-quality, large-scale clinical studies are possible and being performed. Together these changes are intended to bring forward the realization of a disease-modifying drug that could be rapidly available for widespread clinical use.

Conclusion

The pattern and progression of AD is highly variable. Predictors of decline include severity of illness, which predicts a more rapid course, and extrapyramidal and psychotic symptoms, which probably also do so. While antipsychotic drugs are of benefit in the short term in treating some non-cognitive symptoms, their long-term use may worsen the prognosis; cholinesterase inhibitors, on the other hand, improve

symptoms in the short term, but their effects in the longer term on the disease are unclear. There remains a pressing need to develop new symptomatic therapies in AD as well as viable disease-modifying agents.

Vascular and mixed dementia

Chapter: Vascular and mixed dementia

Author(s): Robert Stewart

DOI: 10.1093/med/9780198807292.003.0031

Introduction

Vascular disorders have been established as the most important 'environmental' risk factors for late-life dementia in Western settings because of their high prevalence and potential for modification. Historically, however, 'vascular dementia' (VaD) as a construct has attracted substantially less research than Alzheimer's disease (AD). This is partly because it falls between traditional clinical specialties, being seen as the province of stroke researchers by those interested in dementia, and vice versa, but more fundamentally because its validity as a 'diagnosis' has remained elusive. Research diagnoses tend to prioritize reliability over validity (since the former is more easily established) and can sometimes fail to keep up with accumulating knowledge about a clinical condition, or fail to reflect changing presentations. VaD has been a good example of this failure.

Vascular and mixed dementia

Definitions of vascular dementia

Changing fashions for ‘lumping’ or ‘splitting’ dementia are fundamental to the problems underlying VaD as a diagnosis. Throughout the first half of the twentieth century, later-onset (‘senile’) dementia was viewed as an inevitable consequence of ageing and, since atherosclerosis was a popular substrate for ageing, most dementia was assumed to be ‘vascular’. Seminal post-mortem studies in the 1960s and early 1970s challenged this by demonstrating the importance of Alzheimer pathology—previously assumed only to underlie rare early onset (‘presenile’) syndromes. However it was evident that multiple cerebral infarctions were also responsible in some cases of cognitive decline, and a second ‘diagnosis’ of multi-infarct dementia arose, later to be subsumed under the more broad category of VaD.

One of the first structured assessments for VaD to come into widespread use in research settings was the Hachinski Ischemic Scale (Hachinski et al., 1975), although this was never intended as a diagnostic instrument and was simply a checklist of 13 features of ‘arteriosclerotic psychosis’ from a widely read textbook (Mayer-Gross et al., 1969); some refer to the course of the dementia (e.g. abrupt onset, stepwise deterioration, fluctuation), some to symptoms (e.g. nocturnal confusion, depression, somatic complaints), and some to the likely presence of or risk for cerebrovascular disease (e.g. history of strokes or hypertension, focal neurological signs). No attempt was made to validate the instrument or to investigate its scaling properties or the validity of the different weights given to some items. Despite this, it was found to have the highest inter-rater reliability in an independent evaluation of case identification instruments for VaD (Chui et al., 2000), probably because it primarily seeks to ascertain whether significant cerebrovascular disease is present in the context of dementia, rather than whether it is deemed to be causally related.

Considering the standard current classification systems for clinical practice, DSM-IV criteria required the presence of dementia and either focal neurological signs/symptoms, or evidence of cerebrovascular disease judged to be aetiologically related (American Psychiatric Association, 1994); this was having dropped the requirement for an early step-wise course of decline after DSM-III-R. For DSM-5 major and mild neurocognitive disorders (American Psychiatric Association, 2013), the classification of ‘vascular’ is recommended in individuals with clinical features suggestive of a vascular aetiology (mentioning onset following a cerebrovascular event and/or decline in complex attention and frontal-executive functioning) where there is evidence of cerebrovascular disease from history, examination, or neuroimaging. Probable and possible categorization is applied depending on number of these criteria fulfilled. The former bring the construct closer to VaD defined by ICD-10 criteria, which require both evidence of focal brain damage and evidence of

Vascular and mixed dementia

cerebrovascular disease judged to be aetiologically related, as well as an uneven distribution of cognitive deficits.

Probably the most widely used criteria in research settings to date have been those developed in a 1991 workshop of the Neuroepidemiology branch of the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN, (Román et al., 1993). A diagnosis of VaD using NINDS-AIREN criteria rests on evidence of cerebrovascular disease (both clinical and from neuroimaging), and an observed relationship between cerebrovascular disease and dementia (such as an onset within three months of an acute stroke or an abrupt deterioration in cognitive functioning, or a fluctuating or stepwise deterioration). A 'probable' diagnosis using this system requires all three of these criteria to be present while a 'possible' diagnosis can be made in the following situations: i) where dementia is accompanied by focal neurological signs in the absence of neuroimaging data; ii) in the absence of a clear temporal relationship between clinical stroke and dementia; iii) 'in patients with subtle onset and variable course of ... cognitive deficits and evidence of relevant CVD' (Román et al., 1993).

The system of subdividing dementia based on assumed underlying causation therefore continues to be enshrined in current diagnostic schedules. However, several changes over the 30–40 years since the first criteria were developed highlight problems with this approach when it comes to conceptualizing VaD:

- 1. *Changing cohorts.*** Older people dying in the 1960s lived through times when there was little opportunity to prevent or control cerebrovascular disease. More severe and florid pathology would have been observed at post-mortem than would be expected (in developed nations) today and was more clearly a primary cause of a dementia syndrome. However, people with dementia known to clinical services are now frequently in their ninth and tenth decades where underlying pathology is much more likely to be mixed. Most people in these age ranges will have at least mild levels of cerebrovascular disease which may be coincidental, or at least not a single causal factor.
- 2. *Advances in neuropathology.*** Early studies predominantly focused on multiple cortical infarctions. Other more subtle forms of cerebrovascular pathology, e.g. lacunar infarction, white matter disease, vascular amyloid deposition, and microangiopathy, have subsequently been highlighted. These may increase the risk of dementia but may not in isolation be sufficient to cause the clinical presentation; instead, a combination of pathological processes may be necessary.
- 3. *Advances in neuroimaging.*** Clinical diagnostic criteria for multi-infarct or VaD traditionally relied on a history of vascular risk factors, a history suggestive of recurrent strokes, and evidence on clinical examination of neurological deficits indicative of cortical

stroke. Subsequent technological advances allow in vivo identification of much more subtle changes, e.g. white matter hyperintensities and alterations in patterns of perfusion and connectivity. However, these are all common in unaffected people in old age and cannot be assumed to be causal when they are seen in someone with dementia.

Problems with 'vascular dementia' as a diagnosis

The validity of VaD as a diagnosis rests on the demonstration of a discrete syndrome (dementia) with a clear primary cause ('vascular'), and with good clinical and clinico-pathological reliability. Considering routine diagnostic practice, it is important to be aware that these criteria are problematic in a number of respects:

1. The clinical course of dementia (i.e. 'stepwise' vs 'gradual deterioration') is a poor predictor of pathological findings (Fischer et al., 1990).
2. Dementia following clinical stroke frequently shows a gradual deterioration and has been found to occur without further infarction in many, if not the majority of, cases (Kokmen et al., 1996; Tatemichi et al., 1994). Consistent with this, post-stroke dementia was found to be more strongly predicted by medial temporal atrophy and thalamic infarcts rather than NINDS-AIREN neuroimaging criteria (Firbank et al., 2012), or white matter hyperintensities (Firbank et al., 2007).
3. Risk factors for stroke have long been recognized to be risk factors not only for VaD but also for clinical AD (Stewart, 1998).
4. Dementia in community samples is frequently associated with mixed rather than discrete pathology (Holmes et al., 1999) and cerebrovascular disease seems to be rarely associated with dementia in the absence of Alzheimer pathology (Hulette et al., 1997).
5. Research diagnostic criteria poorly reflect underlying pathology. Although cerebrovascular pathology is likely to be present in cases with a previous diagnosis of VaD, it is also frequently present in people with other clinical diagnoses (Fernando et al., 2004; Holmes et al., 1999; White et al., 2005).
6. Clinical diagnostic criteria for VaD have poor inter-rater reliability (Chui et al., 2000; Lopez et al., 1994). Highest agreement is found where criteria simply estimate the degree of cerebrovascular disease in people with dementia (Hachinski et al., 1975), and unsurprisingly much lower agreement is found if a judgment is required as to whether dementia was actually caused by cerebrovascular disease. Different diagnostic schedules also show poor agreement with each other (Chui et al., 2000).
7. Operational definitions of dementia have been criticized for focusing excessively on memory impairment and for poorly reflecting cognitive impairment relating to vascular disease which more often affects non-memory domains such as executive function (Bowler and

Vascular and mixed dementia

Hachinski, 2000), although this has been addressed to some extent in DSM-5.

The principal reason that dementia categorization has persisted is because of potential utility in AD research. If risk factors for a particular pathological process are to be identified, there is some rationale for excluding people with evidence of any other pathology. This can be readily carried out for AD since levels of vascular pathology can be reasonably estimated (and screened out) by clinical examination or neuroimaging, although neuropathologically 'pure' AD is less common than diagnostic criteria would suggest (Fernando et al., 2004). The same is not true for VaD. The only means of defining 'pure' VaD is to establish a temporal relationship between stroke episodes and cognitive decline, and then to exclude cases with evidence of gradual decline in between strokes. This process relies heavily on retrospective and potentially inaccurate information.

The implications are becoming increasingly problematic. If VaD as a diagnosis poorly reflects underlying pathology and relies on a differentiation from AD, which involves a large degree of subjective judgment and 'guesswork', then research attempting to apply these criteria is fraught with methodological shortcomings. Prevalence studies will be difficult to interpret if between-site equivalence cannot be assumed. Furthermore, any observed between-site differences in prevalence (or in the proportion of dementia defined as 'vascular') may simply reflect underlying differences in stroke incidence or local clinician diagnostic practice. Case control studies become difficult if all VaD cases have evidence of cerebrovascular disease by definition (or if it is absent or minimal in the case of AD) since they will differ from controls by definition.

One of the most important consequences of the 'diagnosis problem' has been that the role of vascular factors in dementia has historically been underestimated. If vascular factors are not often associated with dementia in isolation (i.e. other coexisting pathology is required), this does not mean that they are not important risk factors. The following sections review some of the evidence for this and discuss potential causal pathways, before considering potential implications for the treatment and prevention of dementia.

Specific 'vascular dementia' syndromes

If VaD and AD are not clearly distinguishable disorders, the continued usefulness of a sub-categorizing diagnostic system is questionable. However, this primarily applies to older age groups where overlapping pathology is likely. People who develop dementia relatively early (for example, in their seventh decade or younger) are much more likely to have a single underlying cause, and it therefore remains appropriate to sub-categorize dementia in younger-onset cases. Furthermore, there are particular syndromes within the 'VaD' category that can reasonably be

Vascular and mixed dementia

considered as discrete diagnoses. These include genetic disorders such as 'cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy' (CADASIL), a familial disorder manifesting as recurrent strokes (most often lacunar infarcts) usually in the fourth to sixth decades, occurring in the absence of vascular risk factors and associated in most cases with a subcortical dementia and pseudobulbar palsy. The principal underlying pathology is an abnormality in basal smooth muscle cells, predominantly in the media of small cerebral arteries; and underlying mutations were successfully identified in the *Notch3* gene on chromosome 19 (Joutel et al., 1997). Other syndromes of familial VaD have been described (Box 31.1) and it is likely that, as with AD, further discrete disorders exist that may be explained by specific mutations.

Box 31.1 Examples of specific vascular dementia syndromes

Genetic disorders

Sickle cell disease

CADASIL

Hereditary cerebral haemorrhage with amyloidosis—Dutch and Icelandic types

Familial British dementia with amyloid angiopathy

Homocystinuria

Fabry's disease

Hereditary endotheliopathy with retinopathy, nephropathy, and stroke (HERNS)

Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)

Strategic infarct dementia

Conditions associated with cerebrovascular pathology and secondary dementia:

Subdural haematoma

Systemic lupus erythematosus

Polyarteritis nodosa

Buerger's disease

Polycythaemia rubra vera

As well as genetic disorders, cases of dementia have been described that appear to have been caused by specific single ‘strategic’ infarctions (Tatemichi et al., 1992), most often within thalamic structures, the angular gyrus, or deep frontal lobe structures; these may also be considered as discrete diagnoses (Thal et al., 2012) because of the apparent single sufficient cause. In addition, of non-cardiovascular disorders causing secondary dementia, several do so through their effects on the vasculature (Box 31.1), although such disorders cause only a very small proportion of dementia cases.

Frequency of dementia occurring after stroke

Defining dementia after stroke presents semantic challenges—for example, in how to refer to a single major stroke that has caused substantial and permanent loss of cognitive function. However, these issues, and the limitations of VaD as a diagnosis, should not obscure the importance of vascular disorders as risk factors for dementia. There has been a helpful tendency for ‘post-stroke dementia’ research to consider all cognitive decline occurring after a stroke and accept that this encompasses a range of processes, from the *de novo* development of dementia as a result of the event to people whose stroke may be exacerbating pre-existing cognitive decline (vascular or otherwise).

Consensus estimates suggest that people with a history of stroke have a dementia prevalence of around 30%, representing a four- to sixfold increased risk. Prevalences following stroke range from 7% in community samples with first-onset stroke and excluding those with pre-stroke dementia, to 41% in clinical samples of recurrent stroke (Kalaria et al., 2016), although some level of persisting cognitive impairment is detectable in around 80% of cases (Jokinen et al., 2015; Mahon et al., 2017). A study following 355 older people (mean age 80 years) who were dementia-free at three months after stroke found an incidence of dementia prior to death in 23.9% over an average follow-up of 3.8 years (Allan et al., 2011)—considerably higher than the 2–3% per year incidence that would be expected in a community sample of that age range (Launer, 1998). The Framingham Study estimated a twofold increased risk over a ten-year period (Ivan et al., 2004), and this was found to remain raised over at least two decades after an index stroke (Kokmen et al., 1996). The twofold increase was supported by estimates from a systematic review (Savva et al., 2010), which also concluded that this was not accounted for by demographic factors or vascular risk profile. One study suggested a stronger association with cognitive impairment in the absence of dementia (Srikanth et al., 2004), but this may reflect differences in deciding the point at which mild cognitive impairment is distinguished from dementia (i.e. when it is believed to be affecting activities of daily living) in the context of a previous stroke.

Vascular and mixed dementia

Selective mortality (in people with stroke who are at risk of developing dementia) is likely to be a diluting factor and to explain a stronger association in younger compared to older people (Ivan et al., 2004; Savva et al., 2010). High levels of variation between studies in reported prevalences of post-stroke dementia and appear to be due to differences in methodology: for example, whether the sample was hospital or community based and how rigorously pre-stroke dementia was ascertained and excluded. Over 90% of the variation was accounted for by methodology (Pendlebury and Rothwell, 2009).

Risk factors for post-stroke dementia

Clearly, any risk factor for stroke is also a risk factor for dementia caused by stroke (whether the stroke is the sole underlying cause or precipitates the clinical onset of dementia associated with other pathology). However, less is known about the factors that predict whether or not someone experiencing a stroke will go on to develop dementia. The first consideration is the nature of the index stroke itself. Although strategic infarct dementia syndromes have been identified, as described earlier, population-based studies have often failed to demonstrate a consistent association between stroke location and risk of dementia: for example with respect to arterial territories of cortical infarctions (Censori et al., 1996; Desmond et al., 2000; Pohjasvaara et al., 1998) and the location (or number) of lacunar infarctions (Loeb et al., 1992). Higher overall levels of cerebrovascular disease tend to predict development of dementia following stroke injury; these include the presence of previous stroke, multiple infarctions, silent infarcts, and white matter hyperintensities; however, predictors also include non-vascular brain lesions on neuroimaging, such as medial temporal lobe and/or global atrophy (Kalaria et al., 2016), again strongly implicating pre-stroke causal processes in many cases.

Other factors identified as being associated with risk of dementia following stroke (albeit not always consistently) are increased age, lower levels of education, previous stroke disease, and vascular risk factors such as diabetes, recent smoking, and atrial fibrillation (Barba et al., 2000; Censori et al., 1996; Desmond et al., 2000; Pohjasvaara et al., 1998). The role of blood pressure level is uncertain: although hypertension is clearly a risk factor for stroke, and therefore for stroke-caused dementia, many studies report no association between blood pressure at the time of stroke and subsequent dementia risk. Instead, risk of dementia has sometimes been associated with lower blood pressure and orthostatic changes (Pohjasvaara et al., 1998). Disorders associated with hypoxia and ischaemia (such as seizures, arrhythmias, and pneumonia) have also been found to be associated with higher risk of dementia after stroke (Moroney et al., 1996). A recent review concluded that there was supportive evidence for the following factors predicting post-stroke dementia: i) older age, female sex, and lower education among demographic characteristics; ii) pre-stroke cognitive decline and/or physical impairment; iii) haemorrhagic stroke, supratentorial stroke,

Vascular and mixed dementia

dominant hemisphere stroke, and recurrent stroke; iv) infection, delirium, or early seizures following stroke; and v) imaging indicative of cerebral small-vessel disease, cortical atrophy, and medial temporal lobe atrophy (Mijajlovic et al., 2017).

Although prospective studies following a major stroke have been important in understanding dementia associated with cerebrovascular disease, they may not be generalizable to situations where multiple smaller infarctions have occurred. An early study with a different design investigated factors associated with dementia in a sample of people all of whom had multiple cerebral infarctions (Gorelick et al., 1993). Independent risk factors were: increased age, lower educational attainment, previous myocardial infarction, recent smoking, and lower systolic blood pressure. CT findings associated with dementia were: more severe stroke, left cortical infarction, and diffuse enlargement of the lateral ventricle suggesting cerebral atrophy (Gorelick et al., 1992).

Clinical features of post-stroke dementia

As mentioned, many cases of dementia following stroke appear to follow an Alzheimer-like clinical course and to occur without further episodes of infarction (Honig et al., 2003; Kokmen et al., 1996; Tatemichi et al., 1994). Pre-stroke cognitive decline is evident in many cases (Kase et al., 1998), and is associated with atrophic changes on neuroimaging, rather than early cerebrovascular disease (Pohjasvaara et al., 1999). In addition, not only does stroke predict cognitive impairment, but cognitive impairment is also associated with a raised risk of future stroke (Ferucci et al., 1996), and dementia following stroke predicts further stroke episodes (Moroney et al., 1997).

Taken together, this evidence suggests that there is a close (although potentially complex) interrelationship between stroke and primary degenerative changes underlying many cases of apparent VaD, and that the stroke itself may be a relatively late event in an ongoing process of insidious cognitive decline. One study found that the clinical picture shifted from one consistent with AD over the first two years after a stroke to a more classic 'VaD' picture over years two through four (Altieri et al., 2004). This is consistent with a process in which the stroke episode precipitates dementia in people with pre-existing Alzheimer pathology. Those without this vulnerability maintain their cognitive function initially, but remain at risk of further strokes and of dementia occurring at a later stage as a result of these.

A nested neuropathological follow-up in the cohort study reported by Allan and colleagues (2011) concluded that 75% fulfilled current VaD criteria. In this case, the exclusion of dementia at three months after stroke may have removed most of the 'precipitated AD' cases in favour of a more vascular picture. However, one should bear in mind that a neuropathological diagnosis is simply describing the relative extent of different pathological features, and conclusions are inevitably limited

Vascular and mixed dementia

regarding which *one* of these actually caused the *ante mortem* clinical syndrome.

Taken together, these findings do suggest at least that Alzheimer pathology may be directly responsible for a reasonable proportion of dementia developing after a stroke and is consistent with estimations from clinical follow-up (Hénon et al., 2001). A post-stroke cohort is likely to yield high levels of cerebrovascular disease, which might be present in a person in the same age range who did not develop dementia, so causation should not be assumed from co-occurrence. Comparisons of neuropathological features between participants who did or did not develop dementia after stroke identified microinfarctions and medial temporal lobe atrophy as distinguishing features (Allan et al., 2011).

Vascular risk factors and dementia

Although clinical stroke is strongly associated with dementia, it does not appear to be the initiating event for cognitive decline in many cases. As discussed, pre-stroke dementia is detectable in a substantial minority of people with stroke, and milder pre-stroke cognitive decline may be more common still. A large body of complementary evidence now strongly suggests that risk factors for cerebrovascular disease are also risk factors for dementia—both due to AD and VaD, as estimated clinically.

Mid-life hypertension

Hypertension, a powerful risk factor for cerebrovascular disease, has long received attention as a risk factor for dementia (Stewart, 1999). However, it has taken time for consistent findings to emerge from prospective studies. These studies have had to involve large community cohorts (usually with at least 1000 participants) and at least ten to 15 years follow-up to demonstrate a risk effect, although even now there remain areas of variation, illustrated in the range of associations summarized in Box 31.2. Although most studies have analysed mid-life blood pressure as an exposure against late-life cognitive impairment or dementia as an outcome, it appears that it is a decade-plus interval between blood pressure measurement and dementia ascertainment that is important for demonstrating an association, rather than a younger age at blood pressure measurement, since delayed risk associations (over a 15-year follow-up) have also been found for late-life systolic blood pressure (SBP) and diastolic blood pressure (DBP) (Skoog et al., 1996).

Box 31.2 Examples of prospective associations between blood pressure and later cognitive impairment/dementia

Associations with worse late-life cognitive function

- Progressively higher mid-life diastolic blood pressure (DBP) (Kilander et al., 1998),

Vascular and mixed dementia

- Raised mid-life systolic blood pressure (SBP) (≥ 160 mmHg compared to <110 mmHg) in men (Launer et al., 1995),
- Progressively higher mid-life SBP and DBP in people who had not received antihypertensive treatment (Elias et al., 1993),
- Persistently high SBP (≥ 140 mmHg) over a 38-year period (Swan et al., 1998),
- High SBP (≥ 160 mmHg compared to <140 mmHg) but not DBP (Kivipelto et al., 2001a).

Prospective associations with dementia

- Raised mid-life SBP and DBP ($\geq 160/95$ mmHg) in men for both dementia and AD, but only in those not previously receiving antihypertensive agents (Launer et al., 2000),
- Higher SBP at age 70 and higher DBP at age 70 and 75 for AD aged 85 (Skoog et al., 1996),
- Mid-life high SBP (≥ 160 mmHg compared to <140 mmHg) but not high DBP for AD (Kivipelto et al., 2001b),
- Both hypertension and 'pre-hypertension' (SBP/DBP $>120/80$ mmHg but not fulfilling hypertension criteria) defined by blood pressure levels and/or antihypertensive treatment (Gottesman et al., 2018),
- Orthostatic hypotension in people aged 80+ with hypertension (Peters et al., 2018).

Late-life hypotension

Cross-sectional surveys, on the other hand, have tended to find that people with dementia have lower blood pressure than those without, although this is not universally reported. Two large surveys in Sweden and US (Guo et al., 1996; Morris et al., 2000) found lower SBP and DBP in participants with dementia compared to those without. The first of these studies reported on both all dementia, and AD specifically (Guo et al., 1996), and the second just used AD as an outcome (Morris et al., 2000). On the other hand, one large survey of AD in Finland did not find any difference in blood pressure by dementia status (Kuusisto et al., 1997) and a survey in Japan found no difference in hypertensive blood pressure levels between participants with and without AD (Ueda et al., 1992).

Low blood pressure is common in older people and (for both SBP and DBP) known to be associated with adverse consequences (Boshuizen et al., 1998; Mattila et al., 1988; Satish et al., 2001). Hypotensive orthostatic blood pressure changes have also been found to be associated with dementia, in particular a reduced SBP response to standing (Vitiello et

Vascular and mixed dementia

al., 1993), confirmed in prospective follow-up of an 80+ year old sample with hypertension (Peters et al., 2018). In a Swedish cohort without dementia, frontal and parietal atrophy was associated with lower SBP and parietal atrophy with lower DBP; those in the cohort with AD had lower SBP and DBP, and those with VaD had lower DBP (Skoog et al., 1998). Findings from several studies suggest that, for people with dementia, lower blood pressure level is also associated more advanced stage of the disease (Guo et al., 1996; Hogan et al., 1997; Skoog et al., 1998), suggesting that there may be effects of neurodegenerative disorders on blood pressure levels.

From those studies investigating *change in* rather than *level of* blood pressure, the following findings have been reported: i) an association between 30-year decline in SBP and worse psychomotor speed (Swan et al., 1998); ii) cognitive decline over a three-year period being associated with a 10mmHg SBP decline over the same period (Zhu et al., 1998); iii) dementia in women associated with a reduced level of SBP increase and a higher level of DBP decline over a ten-year period (Petitti et al., 2005); iv) dementia and AD associated with SBP and DBP decline over the previous three years (Qiu et al., 2004); v) dementia associated with a slower increase in SBP over the previous 15 years and consistently lower levels of DBP (Wagner et al., 2018); and vi) a 30-year cohort study of Japanese-American men finding that incident dementia at the end of the study associated with a greater previous increase in SBP from middle to late life and a more pronounced decline in SBP over a three- to six-year period prior to the clinical onset (Stewart et al., 2009).

Taking the above two sections together, there is therefore robust evidence that dementia is predicted by higher blood pressure ten to twenty years earlier, but that blood pressure undergoes an exaggerated decline in people with dementia over perhaps five years or so before the clinical onset of the condition. These observations appear to be exaggerations of changes expected with age (a rise in blood pressure up to and including midlife followed by a decline in later life) and, although evidence is less substantial, tend to be also observed for other vascular risk factors as described below.

Dyslipidaemia

Raised lipid levels have received less attention than blood pressure as risk factors for dementia and results are also conflicting. Some studies, predominantly from Scandinavian populations, have suggested that raised mid-life total cholesterol is associated with later dementia (Kivipelto et al., 2001b; Kivipelto et al., 2002; Kivipelto et al., 2005; Notkola et al., 1998). However, others have found over shorter periods of follow-up that higher total cholesterol levels are associated with lower risk of dementia (Mielke et al., 2005) or show no association at all (Reitz et al., 2004).

Vascular and mixed dementia

In general, evidence supports associations between mid-life total cholesterol levels and risk of AD, but does not suggest associations with late-life cholesterol levels (Anstey et al., 2008) and findings from three studies have suggested an exaggerated decline in cholesterol levels from midlife to late life in people with dementia compared to controls (Mielke et al., 2010; Notkola et al., 1998; Stewart et al., 2007). However, this is not always found: another study found no trajectory differences for cholesterol sub-fraction or triglyceride levels (Wagner et al., 2018).

Diet and obesity

A large amount of attention has focused on dietary risk or protective factors for dementia. With many measures to choose from and a sizeable risk of false positive findings from multiple analyses, it is difficult to draw firm conclusions; however, there are several reports that an atherogenic diet is associated with increased risk (Kalmijn et al., 1997; Luchsinger et al., 2002), and a Mediterranean diet with lower risk (Féart et al., 2009).

As with cholesterol and blood pressure, the association between obesity and dementia has been complicated by the observation of changes in the risk factor (in this case, accelerated weight loss) prior to the clinical onset of dementia (Stewart et al., 2005). Initial studies suggesting that mid-life obesity measured by body mass index is a risk factor for dementia (Gustafson et al., 2003) were supported by a systematic review (Gorospe and Dave, 2007) and subsequent research (Hassing et al., 2009), including studies measuring central obesity (Whitmer et al., 2008). However, a large 26-year follow-up of an Icelandic sample found no association between mid-life obesity and a range of outcomes, including brain infarcts or microbleeds, total brain or white matter lesion volume, or dementia (Albanese et al., 2015).

Diabetes and metabolic syndrome

Type 2 (non-insulin-dependent) diabetes has also been found to be a risk factor for dementia, both VaD and AD (Ott et al., 1999; Peila et al., 2002). Selective mortality is likely to be important, reducing the co-occurrence of the two conditions, which may explain some negative findings (MacKnight et al., 2002). Strong interactions were reported between hypertension and diabetes as predictors of cognitive impairment in the Framingham Study (Elias et al., 1997). However, much of the effect of diabetes on risk of dementia appears to be independent of cerebrovascular disease and may involve other non-vascular pathways or common underlying factors (Stewart and Liolitsa, 1999). Indeed, the hypothetical links between the two conditions have been substantial enough for AD to be proposed as 'type 3 diabetes' (Steen et al., 2005).

Several studies have also reported associations between risk of dementia and the pre-diabetic state of insulin resistance or 'metabolic syndrome', either estimated through vascular risk factor clustering (Kalmijn et al., 2000) or directly measured hyperinsulinemia (Luchsinger et al., 2004). One study, however, found that both low and high insulin were associated

Vascular and mixed dementia

with later dementia (Peila et al., 2004). In people with diabetes, there is some evidence for profiles associated with higher risk of cognitive decline and/or dementia. In one study, insulin treatment was associated with a higher risk of dementia (Ott et al., 1999) and mild cognitive impairment in another (Roberts et al., 2008), the latter study also finding associations of cognitive impairment with longer duration, earlier onset and complications. Possibly consistent with the association between insulin treatment and dementia risk, another study following a large cohort of people with type 2 diabetes found a higher risk associated with one or more hypoglycaemic episodes (Whitmer et al., 2009). However, another study found that dementia risk was predicted by both lowest and highest average glucose levels over five years (Crane et al., 2013) and there is evidence emerging implicating fluctuations or peaks in glucose levels in cognitive decrements, as well as diabetes complications such as macro- and microvascular disease (Biessels and Despa, 2018).

Smoking

Smoking has been implicated as a risk factor for dementia in numerous systematic reviews (Anstey et al., 2007; Hersi et al., 2017; Peters et al., 2008; Zhong et al., 2015). For example, Zhong and colleagues (2015) reported a risk ratio of 1.3 for all-cause dementia associated with current smoking, similar risk ratios for AD and VaD, a 34% increased risk for every 20 cigarettes per day smoked, and no increased risk of dementia outcomes for former smokers. A recent systematic review found a weak association between passive smoking and increased dementia risk (Stirland et al., 2017). Finally, it is worth noting a review concluding that studies with tobacco industry affiliation were more likely to report a protective effect for dementia and less likely to report a risk effect than studies without such affiliation (Cataldo et al., 2010).

Other vascular risk factors

Other vascular factors associated with dementia include ischaemic ECG changes (Prince et al., 1994), and atrial fibrillation (Ott et al., 1997), as well as measures of peripheral and carotid atherosclerosis (Hofman et al., 1997). Several studies have found that people who are more physically active (Laurin et al., 2001; Rovio et al., 2005; Yoshitake et al., 1995) or with higher cardiorespiratory fitness (Kurl et al., 2018) have a lower risk of dementia, which may or may not be mediated through effects on the vasculature.

Mechanisms of association

What is becoming increasingly apparent is that people at increased risk for stroke are also at increased risk for dementia, whether this is defined clinically as VaD (i.e. with evidence of significant comorbid cerebrovascular disease) or AD. The apparent associations with AD have not been clearly explained by missed infarctions (Ott et al., 1999) or by dementia with primary vascular pathology being misclassified as AD (Hulette et al., 1997), although these possibilities are difficult to exclude

Vascular and mixed dementia

absolutely. Neuropathological studies of community populations have found very high prevalence of mixed vascular and Alzheimer pathology (Fernando et al., 2004), particularly in oldest age groups (Brayne et al., 2009; Corrada et al., 2012). An explanation therefore probably lies in links between vascular factors and AD. These may involve four possible pathways, which need not be mutually exclusive.

Interactions at a pathological level

Cerebrovascular pathology in dementia is reviewed elsewhere in this book (see Chapter 5). There are numerous theoretical ways in which vascular processes might induce or accelerate Alzheimer pathology, including amyloid deposition as a response to ischaemia, links through inflammatory pathways, blood-brain barrier disturbance secondary to cerebrovascular disease, and for diabetes, abnormal protein glycation secondary to prolonged hyperglycaemia.

These processes predict that people with vascular disease will have higher levels of Alzheimer pathology—a hypothesis that is difficult to test except in the rare instances where neuropathological follow-up has been carried out in people without dementia. An early study found that increased Alzheimer pathology was associated with hypertension or coronary artery disease in people without previous dementia (Sparks et al., 1995; Sparks et al., 1996). Elevated mid-life blood pressure was also associated with decreased brain volume and Alzheimer pathology in a cohort study with a relatively large pathological follow-up (Petrovitch et al., 2000). The same study also found associations between diabetes and increased Alzheimer pathology (Peila et al., 2002), although associations were found with a protective rather than atherogenic lipid profile (Launer et al., 2001), a finding which requires further clarification.

Associations were reported between smoking and neuritic plaques in a neuropathological follow-up nested within a large cohort study (Tyas et al., 2003), suggesting direct influences on AD for this exposure. Consistent with this, associations have been observed between smoking and PET amyloid positivity in vivo (Zhang et al., 2018); however, associations with reduced cerebral perfusion have also been reported (Siennicki-Lantz et al., 2008) in addition to the well-recognized adverse effects of smoking on cerebrovascular disease.

Not all studies have found consistent evidence for these types of associations—one community study found that raised blood pressure was associated with microinfarcts but not with other pathological changes (Wang et al., 2009) and another found less Alzheimer pathology among people who had been treated for hypertension compared to normotensive individuals (Hoffman et al., 2009). The large MRC CFAS community neuropathological study similarly found no associations between vascular risk factors and Alzheimer pathology burden, but instead implicated

Vascular and mixed dementia

microinfarcts as the key underlying pathological pathway (Richardson et al., 2012).

As mentioned, a range of hypothetical links between diabetes and AD have attracted particular interest, besides the role of diabetes as a vascular risk factor. The concept of AD as 'type 3 diabetes', for example, rests on the following observations: brain insulin resistance and cognitive impairment caused by type 2 diabetes mellitus; disturbances in brain insulin and insulin-like growth factor signalling mechanisms as early abnormalities and potentially underlying AD lesions; experimentally induced 'brain diabetes' in animal models resulting in cognitive impairment and disturbed acetylcholine homeostasis; and responsiveness of these experimentally induced changes to insulin sensitization (de la Monte and Wands, 2008).

Clinical/symptomatic interactions

As well as acting directly on the progression of Alzheimer pathology, vascular disorders may also accelerate the onset of symptomatic dementia at relatively early stages of comorbid AD. In an early US study of elderly nuns who were screened in late life and followed to post-mortem, a lower level of Alzheimer pathology was observed in association with dementia if infarction was also present, suggesting that the infarction had accelerated the onset of dementia (Snowdon et al., 1997). Similar findings were observed around that time in the Oxford OPTIMA study, where early Alzheimer pathology was associated with much greater cognitive impairment if cerebrovascular disease was also present (Esiri et al., 1999). In another study using a community-derived sample, significant interactions were found between the presence of cerebral amyloid angiopathy and Alzheimer pathology in their association with previous level of cognitive impairment (Pfeifer et al., 2002). Other neuropathological follow-up studies of community samples have suggested a predominance of mixed pathology (Fernando et al., 2004), with independent influences of Alzheimer and non-Alzheimer pathology on cognitive function (White et al., 2005) or on the likelihood of dementia at death (Matthews et al., 2009).

One way in which vascular factors may influence AD is that memory impairment secondary to early Alzheimer pathology may be more likely to be noticed as 'dementia' if other cognitive domains are also affected. White matter disease may be important in this respect since subtle disruption of fronto-subcortical pathways may result in impaired executive function. White matter hyperintensities on magnetic resonance imaging are common in older age groups and are associated with vascular risk factors, particularly hypertension. Although they are more common in dementia and, across a population, are associated with relative cognitive impairment (Breteler et al., 1994), at an individual level they may be severe without any apparent clinical manifestations (Fein et al., 1990). They do not therefore appear to be sufficient in themselves to

Vascular and mixed dementia

cause dementia but may precipitate this in the presence of other pathology—i.e. in effect, reduce the age of dementia onset.

Common underlying factors

An association between vascular disease and AD may be explained by a common underlying risk factor. Both vascular status and dementia have causal processes operating across the life-course with ample opportunity for interaction at many stages (Table 31.1). However, most research fails, or is unable, to take this into consideration and is potentially limited by focusing at a very late stage in long-term evolving processes. Vascular risk factors such as hypertension and diabetes are commonly classified as 'environmental' risk factors for dementia. However, they are known to have a substantial familial aetiology and it is possible that common genetic factors explain some of their association with AD. Lifestyle factors such as diet, physical activity, and personality could also potentially underlie later associations.

Table 31.1. A life-course model of the relationship between vascular factors and dementia

Infancy and childhood	Genetic factors determining later vascular risk and cognitive impairment Environmental stressors affecting both vascular risk (e.g. blood pressure, proneness to obesity) and cognitive function (level of attainment in childhood and/or vulnerability to later neurodegeneration)
Early adulthood	Level of 'attained' cognitive function set determining risk of later impairment ('reserve') Socioeconomic status influencing vascular risk profile, and risk behaviour (smoking, diet, physical activity)
Midlife	Vascular risk factors becoming manifest (hypertension, obesity, dyslipidaemia) Possible subtle early cognitive changes secondary to vascular damage; also very early Alzheimer and vascular pathological changes Continuing manifestation of lifestyle-related risk factors (diet, smoking, exercise)
Late life	Impact of clinical cerebrovascular disease (stroke, TIA) on cognitive function Co-occurring or consequent AD Metabolic changes associated with frailty (e.g. weight loss, decline in blood pressure) possibly exaggerated in pre-clinical and clinical dementia

Vascular and mixed dementia

	Chronic effects of raised vascular risk (e.g. diminished blood pressure reactivity) Selective mortality (survivors with vascular risk factors potentially at lower risk due to other unknown protective factors)

‘Mendelian randomization’ studies attempt to identify causal associations through investigating genetic propensity to a risk factor as the exposure to, rather than the presence of, the risk factor itself. A recent review of such studies in dementia research concluded that the most convincing causal evidence was for shorter telomere length associated with AD, with only tentative evidence for smoking quantity, vitamin D, homocysteine, SBP, fasting glucose, insulin sensitivity, and high-density lipoprotein cholesterol; however, the key deficiency appeared to be in the size and quality of source studies (Kuzma et al., 2018). Both cognitive function and risk of vascular disease are determined by socioeconomic status from childhood onwards and at least part of the overlap in later life may reflect long-standing social inequalities—a mechanism which has tended to be ignored in preference to biological links.

Effects of Alzheimer’s disease on the vasculature

As well as vascular influences on Alzheimer pathology or its expression, it is also possible that AD induces or exacerbates cerebrovascular pathology. Even long-duration prospective studies cannot conclusively demonstrate the direction of causation if pathological processes begin one or two decades before clinical symptoms become manifest. Deposition of amyloid occurs in cerebral blood vessels as well as the brain parenchyma in AD. This ‘cerebral amyloid angiopathy’, described in detail in Chapter 5, is associated with both cerebral haemorrhage and small infarctions (Olichney et al., 2000), and is a common and apparently parallel pathology to parenchymal amyloid deposition (Keage et al., 2009). Abnormalities in capillary structure have also been reported in AD (de la Torre and Mussivand, 1993). It is therefore possible that the presence of AD may exacerbate or accelerate vascular pathology, or render the brain more vulnerable to further insults. Early cognitive decline may also affect factors such as diet, exercise, and adherence to prescribed medication, which, in turn, may influence the risk of cerebrovascular events.

Vascular risk factors and dementia treatment—clinical implications

In theory, clinical implications should be numerous since vascular disease is one of few potentially modifiable risk factors for dementia. However, although research attention is increasing in this area, there is woefully little direct evidence at present for any intervention to prevent or treat dementia through modifying vascular risk. Despite this, there are particular issues which can be addressed to some extent.

Vascular and mixed dementia

Treatment of dementia through modifying vascular risk

If vascular disease were to cause dementia through damaging the brain directly, or through accelerating the progression of Alzheimer pathology, then it is likely that these processes would continue to contribute to the progression of disease after diagnosis. Interventions to halt or slow the progression of vascular disease could therefore be expected at least to prevent further cognitive decline, and possibly even improve cognitive function.

However, there has been little research into potential interventions. Even for aspirin, despite recent enthusiasm from animal models (Chandra et al., 2018) few randomized trials in dementia have been attempted. A pilot study in multi-infarct dementia reported improvement in cognitive scores and cerebral blood flow, although the protocol did not involve a placebo and participants were not blind to their allocation (Meyer et al., 1989). Another study found that men at high risk of cardiovascular disease who had received warfarin or aspirin had better cognitive function at the end of a five-year trial period than those receiving placebo, although cognition had not been assessed at baseline (Richards et al., 1997). A report of two further trials of aspirin in AD raised a concern of increased intracerebral haemorrhage, which was not balanced by any demonstrable effects on cognition (Thoonsen et al., 2010), and a systematic review concluded no proven benefit (Jaturapatporn et al., 2012).

Apart from drug treatments to reduce vascular burden, other lifestyle changes have received at least some consideration. There is randomized controlled trial evidence, for example, of a benefit of aerobic against anaerobic exercise on cognitive function in sedentary men (Kramer et al., 1999) and a beneficial effect of a six-month exercise programme over an 18-month follow-up period in participants reporting memory difficulties (Lautenschlager et al., 2008). However, recent trials have found no benefit of exercise in people with dementia on function, quality of life or carer burden (Lamb et al., 2018) or on global cognition or executive function (Toots et al., 2017), although a systematic review concluded that there was evidence of exercise training having benefit on depression in people with dementia (Barreto et al., 2015) and a subsequent trial of a hospital-based exercise programme reported benefits on agitation and lability (Barreto et al., 2015).

Considering treatment of vascular risk factors in dementia, a small randomized trial of different glucose control regimes in people with diabetes and dementia reported the best outcomes in the middle ranking intervention (i.e. better than the group receiving diet and exercise only, and better than those receiving assertive glycaemic control with oral medication and/or insulin; see Chen et al., 2017). However, the conclusion of a 2014 review of antihypertensive treatment in dementia concluded a lack of firm evidence for either benefits or harm, and recommended further research but caution in the meantime (van der Wardt et al., 2014). Further caution is warranted following the recent report of lower blood

Vascular and mixed dementia

pressure during antihypertensive treatment being associated with accelerated cognitive decline, as well as higher mortality, in people aged 85+ (Streit et al., 2018).

Prevention of stroke in dementia

It is therefore uncertain whether modification of vascular risk in people with established dementia has an impact on the course of cognitive decline. However, there is also little evidence at present that such measures are contraindicated, aside from the need for caution inherent in any medication use for older and higher-frailty populations. The prescription of aspirin or the treatment of hypertension in a patient with dementia and cerebrovascular disease might be carried out not only in the hope of preventing further cognitive decline, but also to prevent stroke.

Complex ethical issues surround the question of how intensively to treat comorbid disease in individuals with clinical dementia, particularly when the dementia itself is at an advanced stage. In addition, although there may be no upper age limit for stroke prevention (Staessen et al., 2000), the effectiveness of interventions such as blood pressure control has not been adequately assessed in the context of comorbid multiple infarctions and dementia. However, it is important to bear in mind that, while some may consider an acute fatal stroke to be a preferable alternative to end-stage dementia, a non-fatal episode may lead to a lengthy period of disability and suffering, which might have been prevented. It is now accepted that intensive screening for preventable risk factors should take place in people with single or recurrent strokes. There is no good reason why people who happen to have dementia should be excluded from that process, although an undoubted problem with VaD has been its 'falling between stools' and the risk for people with this diagnosis receiving sub-optimal attention from both stroke and dementia services.

Treatment of dementia in people who have cerebrovascular disease

Although there is no good research evidence to suggest that 'VaD' and 'AD' can be adequately separated as distinct disorders, the persistence of the two diagnoses in clinical parlance has led to their incorporation in inclusion/exclusion criteria for clinical trials and, hence, to the perception that diagnosis determines treatment 'eligibility'. Although there is some trial evidence for a beneficial effect of acetyl-cholinesterase inhibitors in people with 'VaD', this is most evident for the sub-group with potentially mixed disease (Erkinjuntti et al., 2002) and a meta-analysis concluded uncertain benefit in the disorder as a whole (Kavirajan and Schneider, 2007). This may reflect previous findings suggesting that cholinergic deficits in pure VaD are not present, or are less strong than those in AD or mixed dementia (Perry et al., 2005; Sharp et al., 2009).

However, people with 'pure' VaD have also been very hard to identify, and the lack of detectable cognitive decline in the placebo group over the course of a standard trial means that treatment effects are hard to

demonstrate. The danger is that difficulties encountered in applying diagnostic criteria (which are predictable given the lack of evidence to support their applicability) limits enthusiasm for further trials in people with cerebrovascular disease and dementia resulting in an impoverished evidence base. Recommended indications for future treatments will be limited to AD alone because of a lack of evidence in other disorders. If dementia with cerebrovascular disease is classified as ‘vascular’ in clinical practice, then people with AD may fail to receive treatment on the basis of comorbidity.

Vascular risk factors and dementia—implications for prevention of dementia

The implications of current research for the prevention of dementia are substantial, whether vascular risk factors directly induce dementia pathology, or accelerate the onset of the clinical syndrome. However, effects may be difficult to demonstrate in conventional clinical trials because of the potentially long period over which risk factors exert their action, and the changed relationships between risk factor levels and dementia, closer to the clinical manifestation of cognitive decline. Furthermore, most interventions may be well established as beneficial for other reasons (e.g. preventing cardiac disease and stroke), so that it may not be possible ethically to have a placebo group, or to retain a double-blind placebo comparison, for a sufficient time period to test an impact on dementia incidence.

All of these issues may explain, for example, the frequently negative results for trials of antihypertensive agents on dementia as an outcome. A review of observational studies and trials combined concluded that there was suggestive evidence for benefits associated with calcium channel and renin-angiotensin system blockers (Rouch et al., 2015). This was supported by a later review of observational studies examining antihypertensives as a group and all-cause dementia as an outcome (Xu et al., 2017), and a recent trial of intensive blood pressure lowering showed benefits in secondary outcomes of mild cognitive impairment alone or combined with dementia, although the primary dementia outcome fell marginally short of statistical significance potentially because of early study termination (SPRINT MIND Investigators for the SPRINT Research Group et al., 2019)—another common challenge for preventative trials.

However, an alternative explanation for the lack of trial evidence for benefit is that observational evidence is broadly flawed for medications conferring benefits because of ‘confounding by indication’ (i.e. people receiving those medications having other protective factors). This may explain the lack of trial evidence for non-steroidal anti-inflammatory drugs, despite promising observational evidence for dementia risk reduction (Wang et al., 2015), as well as similar negative conclusions for statins in dementia prevention (McGuinness et al., 2016). Furthermore, as mentioned regarding blood pressure lowering, what is a beneficial intervention in midlife cannot necessarily be assumed to retain a positive

Vascular and mixed dementia

benefit-risk ratio into later life, and further research is particularly needed in the most advanced age ranges where empirical evidence is least available.

If conventional cohort studies of vascular risk management are flawed (because of confounding by indication) and if adequately designed trials are unlikely to be feasible (because of the long period of observation required), it is possible that evidence will always be lacking on the scope for preventing dementia. However, it is worth at least considering imputation from parallel sources of evidence.

Specifically, if vascular disease is a risk factor for dementia then it can be hypothesized that populations with high levels of vascular risk will also have higher dementia risk. This has been supported in findings from UK African-Caribbean elders in whom dementia prevalence was raised 70% than UK-born counterparts and who also had higher prevalences of diabetes (Livingston et al., 2001). It is also supported by a recent national dementia survey carried out in Trinidad and Tobago, a nation known to have high rankings in diabetes and hypertension mortality, and where dementia prevalence was substantially raised, particularly in the 70–90 age range (Davis et al., 2018). It can also be hypothesized that improving vascular risk in a population over time will be reflected in subsequent decline in age-specific dementia prevalence and incidence, which again has received at least some support in Western settings (Matthews et al., 2013). Clearly there are other potential explanations for differences in dementia prevalence and incidence geographically and over time; however, there may be scope, with more evidence of this nature, to model the potential impact of moving a population from one level of risk to another in a way that is not currently possible with traditional research designs.

Conclusion: What is vascular dementia?

Vascular disease has long been recognized as an important cause of dementia. Current evidence supports this, even though vascular disorders are frequently not a single cause in isolation, but instead interact with other neuropathological processes. Renewed recognition of this and of the potential for prevention or treatment of dementia has resulted in welcome but long-overdue research interest and advice for those affected. VaD as a research field is therefore alive and well.

However, there remain major drawbacks with sub-categorizing dementia, 'VaD' being particularly problematic. Its continued usefulness is doubtful although there is uncertainty as to what should replace it. 'Vascular cognitive impairment' achieves a shift away from a memory-focused view of dementia. Even so, retaining the word 'vascular' still assumes that cerebrovascular disease can be separated out and identified as a single underlying cause of cognitive impairment. For clinical purposes, it may be most valid to consider dementia as the principal diagnosis and to include vascular disease as one of several potential predisposing, precipitating, or

maintaining factors. This approach is at least in keeping with the tradition of the diagnostic formulation and with the reality of multiple, interacting, and overlapping disorders (and causes for disorders) in older age groups.

DOI: 10.1093/med/9780198807292.003.0032

Historical background

In 1817, James Parkinson described the clinical features of what he designated the shaking palsy, later renamed Parkinson's disease by Charcot. However, he did not describe a dementia syndrome in his patients, but stated that '... the intellect and senses are uninjured' (Parkinson, 1817). Fritz Heinrich Lewy (1885-1950) discovered in 1912 the intraneuronal eosinophilic inclusions, later named Lewy bodies, during his research on parkinsonism. In 1923 Lewy described 43 patients with parkinsonism of whom 21 were demented (Alafuzoff et al., 2009; Rodrigues e Silva et al., 2010), but dementia with Lewy bodies (DLB) was only first recognized as a neurodegenerative entity in 1961 when Okazaki described two clinical cases with dementia, disorientation, hallucinations, and profound motor symptoms with rapid

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

progression with Lewy-body pathology (Okazaki et al., 1961). The triad of dementia, parkinsonism, and psychosis was considered the core syndrome, and later fluctuating confusion, frequent falls, neuroleptic sensitivity, and syncope were added. In 1998 α -synuclein (α S) was identified as the main constituent of Lewy bodies, designating a new group of neurodegenerative disorders named the α -synucleinopathies (Mueller et al., 2017; Spillantini et al., 1998) (see Table 32.1).

Table 32.1 α -synucleinopathies.

Name	Characteristic features
Dementia with Lewy bodies (DLB)	Dementia with parkinsonism, visual hallucinations, fluctuations, and/or REM sleep behaviour disorder (RBD)
Parkinson's disease (PD)	Tremor, rigidity, akinesia, and/or gait disturbance
Parkinson's disease dementia (PDD)	Dementia after more than one year of parkinsonian motor symptoms, i.e. Parkinson's disease.
Multiple system atrophy	Autonomic dysfunction, parkinsonism, and ataxia
Idiopathic REM sleep behaviour disorder	Acting out dream content during REM sleep
Pure autonomic failure	Orthostatic hypotension, constipation, urinary incontinence, sweating, and impotence

Nomenclature and clinical diagnostic criteria for dementia with Lewy bodies

Alzheimer's dementia (AD) pathologies such as tau-inclusions and in particular amyloid plaques are present in DLB, although usually to a lesser extent than in AD. Uncertainty regarding the contribution of underlying pathology to the clinical picture resulted in different groups designating different names for the same clinical phenomenon; diffuse Lewy body disease (Kosaka et al., 1984), dementia with cerebral Lewy bodies (Eggertson and Sima, 1986), or senile dementia of Lewy body type (Perry et al., 1990). The importance of Alzheimer pathology was stressed by other groups suggesting names like AD with Parkinson's disease

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

changes (Ditter and Mirra, 1987), AD with incidental Lewy bodies (Joachim et al., 1988), and Lewy body variant of AD (Hansen et al., 1990).

In the early 1990s, both the Nottingham group (Byrne et al., 1991) and the Newcastle group (McKeith et al., 1992) proposed clinical diagnostic criteria for what later became DLB. In 1995 an international consortium developed the first consensus criteria for a clinical diagnosis of DLB (McKeith et al., 1996) characterized by dementia accompanied by the core features fluctuating cognition and consciousness, spontaneous features of parkinsonism, and recurrent complex visual hallucinations. Additional supporting features such as frequent falls, syncope, and transient loss of consciousness, systematized delusions, and severe sensitivity to treatment with antipsychotic drugs were listed. In the revised version of the criteria from 2005, suggestive features like REM sleep behaviour disorder (RBD) and a positive [(123)I]beta-CIT (2beta-carbomethoxy-3beta-(4-iodophenyl)tropane), SPECT(Single Photon Emission Computed Tomography (CIT-SPECT), or PET(Positron Emission Tomography) scan and neuroleptic sensitivity were added to the diagnostic criteria (McKeith et al., 2005). In the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), major and mild neurocognitive disorder with Lewy bodies have been included alongside the other dementias corresponding to dementia with Lewy bodies and DLB-MCI, although without specific diagnostic criteria (American Psychiatric Association, 2013). In June 2017 the fourth consensus report from the DLB Consortium was published to include updated diagnostic criteria for DLB. These criteria now include core and suggestive clinical signs and symptoms, and additionally indicative and suggestive biomarkers. Hypersomnia and hyposmia are included in the supportive clinical criteria. The former category of suggestive features is no longer used. RBD is now included as a core clinical criterion, (see Table 32.2). Suggestive biomarkers have lower sensitivity and specificity as compared to the indicative biomarkers, and the suggestive biomarkers and supportive clinical criteria are not formally included in the diagnosis, but will when positive in the clinic support a clinical DLB diagnosis (McKeith et al., 2017).

Table 32.2 Diagnostic criteria for dementia with Lewy bodies (DLB)

Central feature Essential for a diagnosis of DLB is <i>dementia</i> , which is defined as progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function, or with usual daily activities.	Core clinical features (The first three typically occur early and may persist throughout the course) • Fluctuating cognition with pronounced variations in attention and alertness. • Recurrent visual hallucinations that are typically well formed and detailed.

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent and occur early.	• REM sleep behaviour disorder (RBD) which may precede cognitive decline. One or more spontaneous cardinal features of parkinsonism: • Bradykinesia (defined as slowness of movement and decrement in amplitude or speed) • Rest tremor • Rigidity.
Probable DLB can be diagnosed if: Two or more core clinical features of DLB are present, with or without the presence of indicative biomarkers, or; Only one core clinical feature, but with one or more indicative biomarkers. Probable DLB should not be diagnosed on the basis of biomarkers alone. Possible DLB can be diagnosed if: Only one core clinical feature is present, with no indicative biomarker evidence, or; One or more indicative biomarkers are present but there are no core clinical features.	Indicative biomarkers: • Reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET. • Abnormal (low uptake) of ¹²³iodine-MIBG myocardial scintigraphy. • Polysomnographic confirmation of REM sleep without atonia. Supportive biomarkers: • Relative preservation of medial temporal lobe structures on CT/ MRI images. • Generalized low uptake on SPECT/PET perfusion/ metabolism scan with reduced occipital activity ± the cingulate island sign on FDG-PET images. • Prominent posterior slow-wave activity on EEG with periodic fluctuations in the pre-alpha/ theta range. Supportive clinical features: • Severe sensitivity to antipsychotic agents • Postural instability • Repeated falls

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

	• Syncope or other transient episodes of unresponsiveness • Severe autonomic dysfunction, e.g. constipation, orthostatic hypotension, urinary incontinence • Hypersomnia • Hyposmia • Hallucinations in other modalities • Systematized delusions • Apathy • Anxiety • Depression
DLB is less likely	In the presence of any other physical illness or brain disorder, including cerebrovascular disease, sufficient to count in part or in total for the clinical picture, although these do not exclude a DLB diagnosis, and may serve to indicate mixed or multiple pathologies contributing to the clinical picture, or; If parkinsonian features are the only core clinical feature and appear for the first time at a stage of severe dementia.
Adapted with permission from McKeith, I. G., et al. Diagnosis and management of dementia with Lewy bodies: Fourth consensus report of the DLB Consortium. <i>Neurology</i>, 89(1): 88-100. Copyright © 2017, American Academy of Neurology. DOI: https://doi.org/10.1212/WNL.0000000000004058.	

Several preliminary reports suggested that the original consensus criteria had high specificity but low sensitivity (McKeith et al., 2000), but a systematically designed study with prospective validation against a pathological diagnosis found the criteria to have 83% sensitivity and 95% specificity. (McKeith et al., 2000). In another study from the Mayo Clinic, the criteria have been found to be more sensitive if RBD was included as a core feature (88%) or if probable DLB could be diagnosed with only RBD plus dementia (90%). The specificity in this study was 73% (Ferman et al., 2011). A study applying the 2005 clinical criteria found the

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

sensitivity, specificity, positive predictive value, and negative predictive values for probable DLB compared to pathology to be 73%, 93%, 79%, and 90%, respectively (Skogseth et al., 2017). Both the diagnostic criteria from before 1996 (sensitivity 60.2% and specificity 93.8%) and the original consensus clinical diagnostic criteria from 1996 had low sensitivity against pathology from 19.4% in early stages up to 72.3% in later stages, with specificity from 64.3% to 95.1%. One possible explanation being poor recognition of fluctuations in the early criteria and not including RBD. The revised clinical and pathological criteria from 2005 performed reasonably well in a validation study including prospectively diagnosed cases applying a battery of standardized clinical instruments in 76 patients with the clinical diagnosis of either DLB or AD (Fujishiro et al., 2008). A meta-analysis of the 2005 criteria showed a sensitivity of 87.2% and a specificity of 74.5%. Diagnostic accuracy was calculated to 79.9% for criteria defined before 1996, 75.5% for the 1996 criteria, and 81.5% for the 2005 criteria. A tendency towards underdiagnosing DLB in earlier phases of the disease and over-diagnosing DLB in later disease stages was noted (Halliday et al., 2011; Nelson et al., 2010).

DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism. The term Parkinson's disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson's disease. In practice, setting the term that is most appropriate to the clinical situation should be used and generic terms such as Lewy body disease or Lewy body dementia are often helpful. In research studies in which distinction needs to be made between DLB and PDD, the existing one-year rule between the onset of dementia and parkinsonism continues to be recommended (see McKeith et al., 2017).

Clinical diagnostic criteria for Parkinson's disease dementia

A Movement Disorders Society Task Force defined clinical criteria for probable and possible PDD (Emre et al., 2007) and later operationalization of these criteria for practical administration in the clinic with practical cognitive tests and suggested cut-off values has been published (Dubois et al., 2007; Goetz et al., 2008). The criteria define core and associated clinical features: The two core features are i) a diagnosis of PD according to Queen Square Brain Bank Criteria (Hughes et al., 1993), and ii) a dementia syndrome with insidious onset and slow progression with cognitive impairment in more than one domain representing a decline from previous level and impairment in activities of daily living (ADLs) independent of motor or autonomic symptoms. Associated clinical symptoms are i) cognitive features; impaired attention, executive functions, visuospatial functions, memory or language, and ii) behavioural features; apathy, changes in personality or mood like depression or anxiety, hallucinations, delusions, and excessive daytime sleepiness (EDS). Practical procedures for cognitive testing at different levels of diagnostic accuracy are defined; a score below 26 on the Mini-Mental State Examination (MMSE) as a global cognitive measure,

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

reversed months test for attention, lexical fluency and clock drawing for executive function, MMSE pentagons for visuospatial functions, and three word recall from the MMSE as a test for memory. The authors suggest the Neuropsychiatric Inventory (NPI) to detect behavioural features and the clinical interview with a caregiver to diagnose EDS and explore ADL abilities (Dubois et al., 2007).

The MMSE is sub-optimal for DLB and PDD due to little focus on executive functions, and scales such as Montreal Cognitive Assessment (MoCA) and PD-Cognitive Rating Scale have been validated and recommended (Kulisevsky and Pagonabarraga, 2009). MoCA tests executive and visuospatial domains more thoroughly, scores can be compared to MMSE, and MoCA performs at the same level as MMSE regarding detecting deterioration of cognitive impairment over time in DLB (Biundo et al., 2016).

Mild cognitive impairment (MCI) and subjective cognitive decline (SCD)

In recent years, similar to AD, there has been increased focus on subjective cognitive decline (SCD) and MCI in PD and the early stages of DLB, i.e. subjective or objectively verified cognitive impairment without significant functional consequences. The exact time when dementia should be diagnosed can be difficult to determine in PD due to the fact that ADL difficulties can be caused by motor, sleep, and autonomic problems in addition to the cognitive failure. Little is known so far about SCD in PD, and there are as yet no established criteria and no described reliable method of capturing SCD in PD, possibly owing partly to the confounding effects of motor symptoms and non-motor symptoms. However, SCD has been reported in people diagnosed with PD, and can be a harbinger of cognitive decline among PD patients (Erro et al., 2014). 25–43% of non-demented PD patients have mild cognitive impairment (PD-MCI) (Aarsland et al., 2010), and 10–20% even at the time of diagnosis in *de novo* PD (Aarsland et al., 2009b; Elgh et al., 2009). In the ICICLE study the frequency of PD-MCI was as high as 42.5% using level 2 criteria at 1.5 standard deviations (SDs) below normative values, and in this study memory impairment was the most common cognitive domain affected, with 15.1% impaired in this domain at 1.5 SDs (Yarnall et al., 2014).

MCI is associated with shorter time to develop dementia in PD. However, there is a large variability between patients with PD-MCI as some of these will remain stable in terms of their cognition with some even reverting to normal cognition during follow-up. In one study, one in five PD patients with MCI had normal cognition on follow-up, but among those with persistent MCI the conversion rate back to normal cognition was much lower (Pedersen et al., 2013).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Clinical diagnostic criteria for MCI in PD have been developed (Litvan et al., 2012). Typically, attentional and executive deficits occur early, but visuospatial and memory impairment are also common, and there is inter-individual heterogeneity in the cognitive profile (Barone et al., 2011; Litvan et al., 2011). There is some evidence that patients with different cognitive profiles differ in dementia risk; those with attention and executive deficits, usually due to fronto-subcortical dopaminergic lesions, may have a lower dementia risk than those with visual-constructive and semantic memory impairment, which is more associated with posterior and possibly non-dopaminergic lesions (Williams-Gray et al., 2007).

Three different subtypes of MCI have been described in DLB; i) cognitive, ii) behavioural and psychiatric, and iii) physical symptoms, and for the cognitive subtype both amnestic and non-amnestic MCI have been reported to precede DLB, with non-amnestic MCI most often converting to DLB (McKeith et al., 2016). Between 5–25% of MCI cases have been reported to convert to DLB in different studies (Donaghy and McKeith, 2014). DLB-MCI was found to be characterized by drooling, misjudging objects, and symptoms related to parkinsonism, fluctuating cognition, and RBD (Donaghy et al., 2017). Ferman and colleagues (2013) reported that among persons diagnosed with non-amnestic MCI, the progression rate to probable DLB was 20 events per 100 person-years among those with non-amnestic MCI.

Other pre-dementia DLB syndromes include idiopathic RBD (Claassen et al., 2010), primary autonomic failure (Larner et al., 2000), and somatoform disorder (Onofrj et al., 2010). Non-amnestic MCI patients with RBD had selective deficits in executive function and verbal memory, as well as a higher level of depressive symptoms in one study from Australia (Szeto et al., 2017). To conclude we have seen an increased focus on the MCI and MCI stages of both PD and DLB, and in this context formal research consensus diagnostic criteria for MCI in DLB have been recently published and include suggested biomarkers such as reduced dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET, polysomnographic confirmation of REM sleep without atonia and reduced MIBG uptake on myocardial scintigraphy (McKeith et al., 2020).

Epidemiology

Dementia with Lewy bodies (DLB)

The prevalence and incidence of DLB are not known in detail, and DLB is often diagnosed as AD and dementia in PD is often not diagnosed. The proportion with DLB among those with late life dementia is around 10–22% (Aarsland et al., 2008b; Rongve et al., 2006; Zaccari et al., 2005). A study from 40 Swedish nursing homes with a mean study population age 86.0 ± 7.5 years reported the prevalence of DLB to be 16–20% in this population, depending on the degree of parkinsonism required for the diagnosis (Zahirovic et al., 2016). Studies from routine clinical settings typically report low frequencies of DLB, and in one recent report from the

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

UK only 4.6% of the dementia cases were diagnosed as DLB in secondary care within the NHS (Kane et al., 2018). This has been a driver in the UK for the National Institute for Health Research DIAMOND Lewy Programme (improving the diagnosis and management of neurodegenerative dementia of Lewy body type), which focuses on improving the detection and management of DLB and PDD in clinical settings (Thomas et al., 2018).

Reports from research settings focusing on DLB typically report higher frequencies; a community-based survey from Japan, the Hisayama Study, found DLB in 10.6% of neuropathologically confirmed cases and pure DLB neuropathologically (i.e. Lewy body pathology alone with no co-pathologies) in 4.4% (Matsui et al., 2009). The Islington Community Study of Dementia from North London UK found 9.7% with a clinical diagnosis of probable DLB and 30.5% with possible or probable DLB combined (Stevens et al., 2002). A health survey of people 75 years and older in the Kupio area in Finland found the proportion of dementia cases diagnosed with DLB to be 21.9% (Rahkonen et al., 2003).

These three studies provide the best estimates of the prevalence of DLB in the general population and suggest that DLB accounts for 10–22% of the dementias in the 65+ age group, indicating that about 1% of the population over 65 years suffer from DLB. In a study from Western Norway applying the revised consensus criteria from 2005 on a referral cohort to old age psychiatry and geriatric medicine clinics in 2005–2007, 15.8% of persons with mild dementia were diagnosed with probable DLB (Aarsland et al., 2008b). In a systematic review of published population and clinical studies, 4.2% of all diagnosed persons living with dementia in the community fulfilled diagnostic criteria for DLB; in secondary care, this increased to 7.5%. The incidence of DLB was 3.8% of new dementia cases (Jones and O'Brien, 2014). These estimates are probably too low because many studies did not specifically focus on diagnosing DLB and did not use specific instruments to detect the core symptoms.

Parkinson's disease dementia (PDD)

Although originally considered to be relatively rare (Brown and Marsden, 1984), several more-recent studies reported that dementia is common in PD. A systematic review found that, in cross-sectional studies, more than 30% of PD patients have dementia (Aarsland et al., 2005b). Subsequent longitudinal studies reported a three- to six-times higher incidence of dementia in PD compared to non-PD subjects (Aarsland et al., 2003), and in two long-term studies it was shown that up to 80% of PD patients will eventually develop dementia (Buter et al., 2008; Hely et al., 2008), although lower dementia prevalence in a PD population of only 5% after four years has been reported elsewhere (Santangelo et al., 2015). In a cohort of persons diagnosed with PD and with normal cognition, 50% developed cognitive decline after six years of follow up (Pigott et al., 2015). In the CamPaIGN study, based on an incidence PD cohort, the incidence of dementia was somewhat lower, with less than 50% of the

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

cohort having developed dementia eight years after diagnosis. The mean time to dementia in this study was 6.2 years, with old age, postural and gait disturbance motor type, and early cognitive impairment predicting shorter time to dementia (Evans et al., 2011). Different subtypes of PD have been identified based on the clinical course and neuropathology. The different subtypes have different risk of dementia during the different stages of the disease; older onset patients (>70 years old) were found to reach dementia earlier, with much shorter disease duration and have more α -synuclein in Lewy bodies in the brain, and possible age-related plaque pathology in the cortex. Persons diagnosed with DLB have the shortest disease duration, with substantive amounts of Lewy bodies and Alzheimer-type pathologies in the whole brain. According to the authors, these data suggest that two age-related factors influence pathological progression in Parkinson's disease: the age at symptom onset, and the degree and type of age-related Alzheimer-type co-pathology (Halliday and McCann 2010).

Molecular pathology

The combination of both Lewy pathology (Lewy bodies and Lewy neurites) and AD pathology (fibrillary β -amyloid and intraneuronal tangles consisting of hyper-phosphorylated tau) predicts dementia better than the severity of any single pathology alone, and those with the combination of amyloid and Lewy pathology have a faster cognitive decline and shorter survival and thus a more aggressive disease. α -synuclein can induce hyper-phosphorylation of tau and β -amyloid can also increase phosphorylation of α -synuclein, thus explaining the additive and synergistic effect of the two types of pathology. Hyper-phosphorylated proteins will more easily aggregate. The neuronal damage might stem from shorter fibrils of α -synuclein like the case in AD with β -amyloid. The Lewy bodies are found in specific brain areas associated with wide neuromodulatory functions (e.g. substantia nigra, locus coeruleus, and pedunculopontine nucleus) and peripheral nervous systems, and researchers now believe that these cells are particularly vulnerable for this type of pathology because of long and highly branched axons with high numbers of synapses (Weil et al., 2017).

A proposed theory combining these effects and converging on lysosomal processes establishes lysosomal function and lipid processing as crucial mechanisms in disease development in both PD and DLB. Different genetic risk factors (see Genetics) including overexpression of α -synuclein lead to oxidation of dopamine causing glucocerebrosidase (GBA) dysfunction and slowing of lysosomal digestion, and consequently, the accumulation of more α -synuclein. In this way the Lewy body diseases share aggregation of α -synuclein and formation of Lewy bodies and Lewy neurites as their common hallmarks of pathology. The normal structure and function of α -synuclein is not yet well known, but it is believed to be involved in synaptic plasticity. Increased expression of α -synuclein will inhibit synaptic reclustering after neurotransmitter release and thus

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

inhibit neurotransmitter release in the synaptic cleft (Nemani et al., 2010).

Neuropathology

Different pathological staging-systems have been proposed for DLB, PDD, and PD. Kosaka and colleagues (1984) proposed to differentiate three subtypes of DLB pathologically on the basis of where the pathology is predominant: brainstem, transitional, and cortical. The revised pathological consensus criteria now implement severity and distribution of both Alzheimer and Lewy body pathology in the CNS in these three locations and defines the likelihood that the pathological findings are correlated with a clinical DLB syndrome as low, intermediate, or high (McKeith et al., 2017).

Braak and colleagues (2003) proposed criteria for staging the Lewy body pathology in PD and others have proposed models for DLB (Leverenz et al., 2008; Muller et al., 2005). Three distinctive groups have been described neuropathologically in dopa-responsive PD patients recruited and followed until death (Halliday et al., 2008); one group has younger onset PD and longer duration of disease with neuropathology distribution corresponding to the Braak stages (see Table 32.3). A second group is characterized by an early malignant dementia dominant syndrome and severe neocortical disease and thus is analogous to DLB. The third group consisted of persons who had older onset of PD, shorter survival, and a more complex disease with additional pathologies and higher Lewy body loads in the brain.

Table 32.3 Staging of Lewy body pathology in the human brain.

Reference	Year	Comment
(Kosaka et al. 1984)	1984	Group A: Diffuse type of LBD; cerebral cortex, basal ganglia, diencephalon, and brainstem affected by Lewy body pathology Group B: Transitional type between A and C Group C: Brainstem and diencephalon affected like in PD
(Braak et al. 2003)	2003	Stages 1-2: Presymptomatic; pathology confined to medulla oblongata and olfactory bulb Stages 3-4: Symptomatic phase; affection of the substantia nigra, midbrain, and basal forebrain. Stages 5-6: Cognitive failure and dementia, cortex affected.

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

(G. Halliday et al. 2008)	2008	Group 1: Younger patients with distribution of pathology according to the Braak staging. Group 2: Early malignant dementia dominant syndrome Group 3: Older onset, shorter survival, and more pronounced Lewy related pathology.
(Beach et al. 2009)	2009	I Olfactory bulb IIa Brainstem predominant IIb Limbic predominant III Brainstem and limbic IV Neocortical

Genetics

In PD, the proportion of phenotypic variance that can be explained from known genetic risk loci has increased as more of the genetic variants underlying the disease have been discovered, with recent estimates exceeding 40% (Hamza and Payami, 2010). Forty-one different genetic loci are related to the common type of PD, with ten of these loci possibly including more than one related gene (Chang et al., 2017). These genetic loci and genes provide evidence of disease mechanisms in PD like accumulation of α -synuclein, tau-pathology, disturbances in lysosomal functioning including *GBA* (the gene encoding the lysosomal enzyme glucocerebrosidase), and the immune system. *SNCA*, *MAPT*, *LRRK2*, *GBA*, and *HLA* have been found to be among the most important risk genes for PD (Hardy, 2010; Nalls et al., 2011). On the other hand, the genetic underpinnings of dementia in PD have been much less studied. Increased dementia risk in family members of people with PD has been reported (Kurz et al., 2006); associations between dementia and mutations in *MAPT* (Seto-Salvia et al., 2011) and *PSEN2* (Meeus et al., 2011) have also been reported, and Williams-Gray and colleagues (2009) found conflicting results regarding *APOE*. *GBA* is related to a 2.4-fold increase in the risk of cognitive impairment and dementia in PD (Creese et al., 2017). Previously known mutations in AD and PD have been found in both PDD and DLB and suggest a genetic overlap in these conditions (Guerreiro et al., 2016; Meeus et al., 2011).

In some families, DLB has been found to occur as an autosomal dominant heritable disease due to *SNCA* duplication or triplication, i.e. the gene coding for α -synuclein (Johnson et al., 2004). Traditional genetic studies have identified multiplications (Chartier-Harlin et al., 2004; Singleton et al., 2003) and mutations in the gene encoding α -synuclein (*SNCA*) (Brown, 1997; Yamaguchi et al., 2005; Zarranz et al., 2004) and β -synuclein (*SNCB*) (Ohtake et al., 2004).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

DLB is, however, typically late onset (i.e. after 65 years of age) and sporadic, and the heritability was, until recently, estimated at 36% with substantial genetic overlap with both AD and PD (Guerreiro et al., 2016; Guerreiro et al., 2018b). New and better methods and improved power due to a higher number of included cases have increased the heritability of DLB to 60%, i.e. in the same scale as in AD (Guerreiro et al., 2018). Indeed, genetic studies have suggested associations of *APOE*, *GBA*, *SCARB2*, *CNTN1*, and *SNCA* with DLB in both clinically and neuropathologically diagnosed cases (Bras et al., 2014; Guerreiro et al., 2018b; Rongve et al., 2019). *GBA* mutations have been reported in 7.8% of persons diagnosed with DLB with an odds ratio (OR) of 8 for DLB in those carrying these mutations (more than in PD, where the OR is 6.5; see Nalls et al., 2013). Even higher frequencies of *GBA* mutations (up to 31%) reported in Ashkenazi Jews diagnosed with DLB suggest that *GBA* is a stronger risk factor for DLB than for PDD. Like in AD but with a weaker effect, the *APOE* $\epsilon 4$ allele increases and the *APOE* $\epsilon 2$ allele decreases the risk of developing DLB (Berge et al., 2014). Involved in the brain's cholinergic activity, the k-variant of the butyrylcholinesterase gene is associated with the risk of developing both AD and DLB and with an increased rate of cognitive decline in DLB (Vijayaraghavan et al., 2015). Moreover, whole exome sequencing studies have identified rare and pathogenic variants in *GBA*, *PSEN1*, or *APP* in 4.4%–25% of participants with pathologically or clinically diagnosed DLB (Geiger et al., 2016; Keogh et al., 2016). However, regarding the common variants, none of the AD associated risk genes identified in large genome wide association studies (GWAS) have been associated to DLB except for *APOE* $\epsilon 4$. In DLB it is still challenging to collect big cohorts for GWAS; nevertheless, such efforts are ongoing, and will most likely lead to many more genes being associated with the disease in the future.

Biomarkers

A variety of imaging, electrophysiological, blood, and cerebrospinal fluid (CSF) biomarkers have been studied as potential diagnostic markers between DLB and AD (Aarsland et al., 2008a). ^{123}I -N-3-fluoropropyl-2beta-carbomethoxy-3beta-4-iodophenyl tropane (^{123}I -FP-CIT SPECT) or DaTSCAN, the visualization of the striatal dopamine transporter, a measure of the dopaminergic pre-synaptic nigro-striatal system, is the first established biomarker in the Lewy body dementias (McKeith et al., 2007). A meta-analysis found a sensitivity of 86.5% and specificity of 93.6% (Papathanasiou et al., 2011). An abnormal scan could identify those patients with possible DLB who progressed to probable DLB after 12 months (O'Brien et al., 2009), and FP-CIT SPECT has also been validated against neuropathology (Fig. 32.1; see also Thomas et al., 2017).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Fig. 32.1

FP-CIT SPECT images in autopsy confirmed AD and DLB.

Image on the right side from a person living with dementia with Lewy bodies (DLB) showing reduced uptake on both sides of the basal ganglia and most pronounced on the right side of the brain with no uptake in the putamen area and with normal uptake on both sides in the caudate nucleus and putamen areas in the person diagnosed with Alzheimer's disease (AD) on the image on the left side.

^{123}I -metaiodobenzylguanidine (MIBG) myocardial scintigraphy has been shown to reliably identify DLB even in mild cases (Suzuki et al., 2005), and is included as a supportive feature in the 2005 diagnostic criteria for DLB and as an indicative biomarker in the updated 2017 criteria. Both FP-CIT SPECT and myocardial scintigraphy can reliably differentiate PD from some other movement disorders (Hauser and Grosset, 2011; King et al., 2011).

Earlier studies found reduced perfusion in occipital cortical areas in DLB as compared to AD on perfusion SPECT-images. In a recent study relative preservation of cingulate glucose metabolism on PET imaging in the posterior cingulate gyri versus that in the precuneus had a 84.6% sensitivity and 84.6% specificity in discriminating DLB from AD (Imabayashi et al., 2017); see Fig. 32.2. Studies using glucose PET have found reduced metabolic activity in neocortex associated with cognitive impairment even early in PD (Pappata et al., 2011).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Structural imaging using MRI usually shows preservation of the medial temporal lobes in DLB as compared to AD, and this feature is now included in the revised diagnostic criteria as a supportive biomarker (Fig. **32.3**). Most studies of DLB and AD have reported low accuracy of this biomarker, but Burton and colleagues (2009) showed high accuracy, with sensitivity of 91% and specificity of 94%, in a prospective study with pathological verification of the clinical diagnosis. Watson and colleagues (2015) found alterations in cortical thickness in DLB, revealing relatively little grey matter thinning, with any changes predominantly affecting the posterior parietal areas in contrast to the temporoparietal pattern observed in AD. Subcortical volume changes on a group level have been noted in DLB with changes in left caudate, bilateral putamen, left thalamus, brainstem, and total subcortical grey volume, and these are more pronounced in DLB as compared to healthy subjects (Watson and Colloby, 2016; Watson et al., 2016). MRI has also demonstrated cortical atrophy in PDD (Beyer and Aarsland, 2008; Burton et al., 2005) and PD-MCI compared to cognitively normal PD patients. Atrophy of hippocampus and parietal-temporal cortex notably can also predict future cognitive decline in PD (Weintraub et al., 2011).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Fig. 32.3

Structural magnetic resonance image (MRI) of person with Dementia with Lewy bodies (DLB) (left side) with relative preservation of hippocampal volume and cortical structures compared to person with Alzheimer's disease (AD) (right side). Both patients were 78 years old males.

Promising findings have been reported also using quantitative EEG, with relatively more slowing of oscillatory brain activity in DLB and PDD compared to AD (Bonanni et al., 2008). Quantitative electroencephalogram (QEEG) methods are able to differentiate early DLB from AD, and QEEG may represent a powerful tool to predict the progression from MCI to DLB with a sensitivity and specificity close to 100% (Bonanni et al., 2015).

In AD, the concentration pattern of CSF proteins like beta-amyloid species such as amyloid beta 42 ($A\beta_{42}$), total tau, and p-tau have been found to distinguish between AD and normal controls (Mattsson et al., 2009). However, a change in the same direction has been shown in DLB, and thus the specificity against DLB is not high and CSF AD markers cannot presently be used to distinguish between AD and DLB (Mollenhauer et al., 2006; van Steenoven et al., 2016).

The concentration of α -synuclein, the key protein in DLB and PD, can be measured in CSF and plasma. Although lower concentrations have been reported in CSF in Lewy-body disorders, this cannot convincingly differentiate DLB from AD or normal controls as yet (Mollenhauer et al., 2011; Noguchi-Shinohara et al., 2009; Spies et al., 2009).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Alves and colleagues (2010) found that low CSF concentrations of $\text{a}\beta_{42}$ in PD correlate with poor cognition in cross-sectional studies, particularly regarding memory. Siderowf and colleagues (2010) confirmed these findings in a longitudinal study showing that low CSF levels of $\text{a}\beta_{42}$ predicted significant cognitive decline during the next two years, and Abdelnour and colleagues (2016) reported similar findings in DLB. In contrast, amyloid imaging usually finds low amyloid load in PDD when compared to AD and DLB (Jokinen et al., 2010).

Clinical features of dementia with Lewy bodies and Parkinson's disease dementia

These include cognitive, neuropsychiatric, behavioural, sleep, motor, and autonomic symptoms (Table 32.4).

Table 32.4 Clinical symptoms in dementia with Lewy bodies (DLB) and Parkinson's disease dementia (PDD).

Cognitive profile

Persons diagnosed with DLB and PDD have prominent visuospatial and executive cognitive dysfunction in contrast to those living with AD. DLB patients are equally impaired in semantic/category and phonemic/letter fluency tests, whereas AD patients perform significantly better on the phonemic/letter fluency tests (Goldman et al., 2014). No specific cognitive test battery has been developed to screen for or diagnose DLB, but as noted previously, the MoCA screening test includes more tests for executive and visuospatial cognitive functions as compared to the MMSE and its use has been recommended in DLB and PDD (Nasreddine et al., 2005). A composite risk score including cognition has been developed for detecting DLB and discriminating DLB from AD and DLB-MCI from AD-MCI. In a consecutive series of 256 persons the mean Lewy Body composite risk scores (LBCRS) were significantly different between DLB and AD (6.1 ± 2.0 vs. 2.4 ± 1.3 , $P < .001$) and between MCI-DLB versus MCI-AD (3.2 ± 0.9 vs. 1.0 ± 0.8 , $P < .001$). The LBCRS was able to discriminate DLB from other causes of dementia. Using a cut-off score of 3, areas under receiver operating characteristic (ROC) curve for DLB versus AD = 0.93 (0.89–0.98) and for MCI-DLB versus MCI-AD = 0.96 (0.91–1.0). The score is composed of ten questions for the patient and caregiver. Questions 1–4 are taken from the Unified Parkinson's Disease Rating Scale, question 5 from the Epworth Sleepiness Scale, questions 6–7 from the Mayo Fluctuation Questionnaire, question 8 from the Neuropsychiatric Inventory, question 9 from the Mayo Sleep Questionnaire, and question 10 from physical findings and complaints of the patient. (Galvin, 2015). Although caregivers reported memory problems to be the most frequent initial symptom in DLB (Auning et al., 2011), most studies objectively report an initial impairment in visuospatial and executive cognitive domains. In a cluster analysis to group all types of mild dementia subtypes according to the level of parkinsonism, hallucinations, fluctuations, and RBD, a group of patients was identified with high scores for both parkinsonism, hallucinations, and

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

fluctuations and consisted of exclusively patients diagnosed as having clinically DLB or PDD. This group scored significantly lower on tests for visuospatial cognitive skills as compared to the other three groups identified (Rongve et al., 2010b). From the same cohort, impaired verbal fluency was reported in those diagnosed with DLB, and tests where persons diagnosed with DLB performed worse than those with AD were highly correlated with degree of parkinsonism, but not with cognitive fluctuations or visual hallucinations (Brønnick et al. 2016). Hamilton and colleagues (2012) found that early visuospatial cognitive impairment predicts visual hallucinations in DLB. In longitudinal studies, Rongve and colleagues (2016) found a faster progression of cognitive decline in DLB as compared to in AD. In a review and meta-analysis three studies reported a faster cognitive decline on MMSE in patients with mixed DLB and AD compared to pure forms, whereas two studies reported a faster decline on delayed recall and recognition in AD and one in DLB on verbal fluency. Six studies were included in a meta-analysis that showed no significant difference in annual decline on MMSE between DLB (mean 3.4) and AD (mean 3.3) (Breitve et al., 2014). In DLB the progression of overall cognitive impairment is occurring at the same speed as in AD, and no cognitive domains have clearly been shown to worsen more rapidly in DLB in meta-analyses. However, clinical disease progression until nursing home placement is faster in DLB, and survival has been found to be shorter in DLB as compared to AD and other types of dementia (Strand et al., 2018).

In *de novo* diagnosed PD followed up after 36 months in the ICICLE-study, 8% of patients had developed a dementia all of which were previously PD-MCI. Applying level I criteria with MoCA scores of 26 or lower, 70% were cognitively stable, 19% cognitively declined, and 11% improved over 36 months. Applying level II criteria (at 1, 1.5, and 2 SD on cognitive tests), 25% were cognitively stable, 41% cognitively declined, 15% improved, and 19% fluctuated over 36 months. Eighteen per cent of participants reverted to normal cognition from PD-MCI (Lawson et al., 2017). In PD and PDD different types of cognitive profiles and dementia have been described; in MCI a subcortical profile with attentional and executive dysfunction, and cortical cognitive impairment in memory and language as well as a mixed group are described (Janvin et al., 2003; Janvin et al., 2006). However, in PDD most cognitive domains are impaired, typically attention, executive functions, and visuospatial functions, but Goetz and colleagues (2008) found memory or language impairment in some patients.

Cognitive fluctuations

Fluctuations in DLB commonly occur in cognition, attention and level of arousal and can mimic delirium, with some patients changing rapidly from normal alertness and cognition through to sleepiness and confusion. Cognitive fluctuation is one of the core features of DLB and occurs in 25–50% of cases (Farina et al., 2009; Savica et al., 2013), depending of method of detection and disease stage. However, inter-rater reliability is

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

low for clinical judgment of fluctuations, and standardized instruments should be applied (Ferman et al., 2004; Walker et al., 2000). The Mayo Fluctuations Composite Scale consists of four questions posed by the clinician to a caregiver regarding daytime drowsiness and lethargy, daytime sleep of two or more hours, staring into space for long periods, and episodes of disorganized speech. The scale has been validated in cognitively normal elderly, AD, and DLB, and fluctuations are present if three or four of the answers are 'yes'. Informed consent and decision-making from persons diagnosed with DLB should, ideally, therefore, be made in the most attentive phase (Spotorno et al., 2017).

Neuropsychiatric symptom profile

In addition to the visual hallucinations, delusions, and misidentification syndromes, apathy, depression, anxiety, and auditory hallucinations are common in DLB (Ricci et al., 2009). In PD, impulse control disorders like pathological gambling, hyper-sexuality, and compulsive buying have been described and found to be associated with dopamine-agonist treatment (Weintraub et al., 2010), but these symptoms have rarely been explored in DLB. Somatoform disorder, defined as medically unexplained symptoms, was found to occur in 7% of patients with PD and 12% of DLB patients preceding the DLB diagnosis for six months to ten years in all cases (Onofrj et al., 2010). Personality traits like diminished emotional responsiveness may distinguish DLB from AD (Galvin et al., 2007). Neuropsychiatric and behavioural symptoms are also very common in PDD, and were found in 89% in one study; symptoms most frequently reported were depression (58%), apathy (54%), anxiety (49%), and hallucinations (44%) (Aarsland et al., 2007).

Sleep disturbances in dementia with Lewy bodies and Parkinson's disease dementia

In DLB, as noted previously, RBD has been included as a core clinical feature in the clinical diagnostic criteria and hypersomnia or ED is included as a supportive clinical feature (McKeith et al., 2017). Up to 80% of patients with mild DLB or PDD have sleep disturbances, as compared to 56% of age-matched, cognitively normal controls and 64% of patients diagnosed with mild AD. The most common symptoms are insomnia (47%), sleep-related leg cramps (42%), EDS (41%), RBD (39%), restless legs syndrome (31%), obstructive sleep apnoea (26%), and periodic leg movements during sleep (21%) (Chwyszczuk et al., 2016; Rongve et al., 2010a). The Mayo sleep questionnaire has been validated to detect RBD in a dementia population (Boeve et al., 2013).

In PD, a wide range of different sleep disturbances have been described including insomnia, EDS, sleep attacks or unintended sleep episodes, RBD, restless legs syndrome, sleep-related leg cramps, periodic leg movements during sleep, obstructive sleep apnoea, and somnambulism (Jauregui-Barrutia et al., 2010; Mondragon-Rezola et al., 2010).

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

Sleep disturbances in dementia have been thought to relate to pathology in specific brain areas such as the suprachiasmatic nucleus, the hypothalamus and brainstem, and pons area. Neurochemical changes affecting melatonin and acetylcholine have been reported with the profile of change contingent upon the specific brain pathology (Claassen et al., 2010).

Motor symptoms in dementia with Lewy bodies

The classical Parkinson symptoms such as resting tremor, bradykinesia, rigidity, and postural changes also occur in DLB, but symptoms are usually bilateral and postural instability, gait disorder, and rigidity usually dominate (Burn et al., 2006). In the 2017 diagnostic criteria, one or more symptoms of motor parkinsonism; bradykinesia (defined as slowness of movement and decrement in amplitude or speed), rest tremor, or rigidity is sufficient for the core criterion to be fulfilled. Neuroleptic medication can cause or severely worsen parkinsonism and other motor disability in dementia, particularly in DLB and PDD (Aarsland et al., 2005a). Of note, in elderly people musculoskeletal problems are common and can lead to motor problems as well; the presence of these can compound the impact of any parkinsonism that is present. Repeated falls are one of the supportive clinical features for diagnosing DLB.

Autonomic failure in dementia with Lewy bodies and Parkinson's disease dementia

Autonomic failure can be an early and prominent feature of DLB and PDD as a consequence of involvement of the sympathetic ganglia and peripheral nervous system. Symptoms of autonomic failure are more common in DLB than in AD and include orthostatic hypotension, cardiac arrhythmias, syncope, constipation, impotence, urinary retention, and excessive sweating (Allan et al., 2007; Sonnesyn et al., 2009).

Clinical differential diagnosis

DLB and AD can be difficult to reliably differentiate clinically. The clinical diagnosis of dementia is based on an interview with both the person with dementia and the caregiver, and an active approach to the core and suggestive clinical features is important to detect DLB. In addition to a clinical examination, which includes physical and neurological examination and cognitive testing, other supplemental tests include blood work-up and magnetic resonance imaging (MRI), and CSF analysis to exclude other intracranial pathology is indicated. Although MRI and CSF can support a diagnosis of AD, these techniques cannot reliably distinguish between AD and DLB. Of note, both ^{123}I -FP-CIT SPECT and MIBG myocardial scintigraphy have been shown to have high sensitivity and specificity to differentiate between probable DLB and non-DLB dementia (see Biomarkers) and thus should be considered particularly where the diagnosis is less clear. A cognitive profile with executive and

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

visuospatial impairment and preserved memory and language may raise the suspicion of DLB.

As per the consensus criteria, DLB is differentiated from PDD based on the one-year rule, i.e. in DLB parkinsonian motor symptoms can start up to one year before the dementia syndrome. If motor parkinsonian symptoms start more than one year before dementia the condition is diagnosed as PDD. Whether this is a biologically valid distinction, or whether PDD and DLB are merely syndromes on a continuum of Lewy body disease, is not known. Currently, unlike the distinction between DLB and AD, there are no major prognostic or therapeutic consequences related to the distinction between PDD and DLB.

Vascular dementia and frontotemporal dementia (FTD) can, in most cases, be differentiated from DLB based on the clinical interview and examination and supplemental tests like MRI and perfusion SPECT. However, progressive supranuclear palsy (PSP), multisystem atrophy, corticobasal degeneration, and FTD can be difficult to differentiate from DLB and PDD on the basis of ^{123}I - FP- CIT SPECT alone as these conditions can present with parkinsonism, reduced uptake on ^{123}I - FP- CIT SPECT and cognitive impairment (McKeith et al., 2017). MRI can assist in identifying vascular parkinsonism. PSP is a tauopathy and characterized by axial parkinsonism, early tendency to fall backwards, and impaired vertical eye movements. PSP can be complicated by subcortical dementia and must be differentiated from other tauopathies like the FTDs. Corticobasal degeneration has tau pathology and is characterized by more severe motor impairment with apraxia, agnosia, parkinsonism, aphasia, and alien hand syndrome with poor response to L-dopa and. Multiple system atrophy (MSA), an α -synucleinopathy, is characterized clinically by the early development of ataxia, autonomic failure, and symmetrical parkinsonism with rigidity and bradykinesia without tremor. Patients have poor response to L-dopa treatment and poor prognosis. MRI can in many cases inform the clinical diagnosis. In frail, elderly people symptoms like parkinsonism and impaired cognition can be caused by neuroleptic medication and thus a drug history must be taken during the diagnostic process. A ^{123}I - FP- CIT SPECT can be used to differentiate brain-stem parkinsonism from other motor impairments, e.g. drug-induced parkinsonism, essential tremor, and vascular parkinsonism (Contrafatto et al., 2011; Vlaar et al., 2008).

Another potential differential is posterior cortical atrophy (PCA) is increasingly recognized as a new clinical subtype of dementia and can include visual symptoms that might resemble DLB.

Pharmacological treatment for Parkinson's disease dementia and dementia with Lewy bodies

The pharmacological treatment for DLB is challenging due to high sensitivity to side effects and the risk of improving one symptom and simultaneously worsen other symptoms. Treatment is still symptomatic as

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

no disease-modifying therapy is yet available. Identifying and prioritizing target symptoms and applying evidence-based measures with careful dosing and monitoring schedules is important for the comprehensive management of the disease (Aarsland et al., 2017; Velayudhan et al., 2017). Three meta-analyses, including 17 randomized and controlled studies, have found both rivastigmine and donepezil to be superior to placebo in improving cognition, behavioural disturbances, global functioning, and ADL-function with no worsening in motor functioning (Matsunaga et al., 2016; Stinton et al., 2015; Wang et al., 2014). Donepezil has been proven effective for up to 52 weeks regarding cognition and neuropsychiatric symptoms in DLB (Ikeda et al., 2013). Studies have suggested that memantine is a safe and potentially effective treatment for DLB and PDD, although findings have been inconsistent with significant improvement on a global measure and in neuropsychiatric symptoms in DLB only (Emre et al., 2010), although in a smaller study Aarsland and colleagues (2009a) indicated improvement also in PDD. Sleep (Aarsland et al., 2009a) and quality of life (Larsson et al., 2011) were shown to improve with memantine in another clinical trial, and in a meta-analysis Stubendorff and colleagues (2014) found memantine to improve DLB globally.

L-dopa is the main treatment of motor symptoms in PD and has been shown to improve parkinsonian symptoms in DLB in open-label studies, but side effects such as hallucinations and orthostatic hypotension can occur (Molloy et al., 2005). L-dopa has a complex and state-dependent effect on cognition in PD, and can improve some cognitive symptoms in some patients (MacDonald et al., 2011).

Treating psychotic symptoms in DLB is complicated and these patients often should be treated for psychosis in specialist settings. Nonpharmacological interventions like improving eye sight, exposure to light, and general activation (e.g. with social engagement) is recommended alongside reducing dopaminergic medications if possible. As a next step starting cholinesterase inhibitors (ChEIs) is recommended to reduce psychotic symptoms. Pimavanserin, a selective serotonin 5-HT_{2A} inverse agonist, is effective at doses of 40mg per day at reducing psychotic symptoms in PD (Cummings et al., 2014), but has not been studied in DLB and is only licensed for use in PD psychosis in a limited number of countries. In a sub-study of the effect of Pimavanserin in PD, a particular pronounced antipsychotic effect was noted in those with the most impaired cognition (Ffytche et al., 2017). Clozapine has been found to have a convincing effect on psychotic symptoms in PD, and this benefit may extend to include patients with cognitive impairment (Rongve et al., 2012). Although some open-label reports suggest that atypical antipsychotics such as quetiapine and clozapine may be useful for psychosis in PD or DLB (Poewe, 2005), the two randomized controlled trials in DLB reported either no effect of quetiapine on agitation and psychosis (Kurlan et al., 2007) or worsening of psychiatric symptoms from risperidone and citalopram (Culo et al., 2010). Antipsychotic medications

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

have been found to significantly increase the risk of cerebral haemorrhages and infarctions, pneumonia, and death in elderly people with dementia (Ballard et al., 2009) and in both DLB and PDD neuroleptic hypersensitivity is much more common than in AD (Aarsland et al., 2005a). We therefore advise to administer antipsychotic medication for this group of patients only if psychotic symptoms are severe and persistent, and preferably in a specialist setting with close monitoring of the patient.

In PD antidepressants such as nortriptyline, paroxetine, and venlafaxine and also the dopamine agonist pramipexole have demonstrated antidepressant effect compared to placebo, but unfortunately no randomized controlled trials for treating depression have been carried out in DLB or PDD (Seppi et al., 2011).

Autonomic failure can be treated symptomatically, i.e. orthostatic hypotension can be improved by reducing or omitting drugs with orthostatic hypotension as a known side effect, anti-hypertensive drugs, and ensuring an adequate intake of fluids. Standard laxatives can be used to treat constipation; anticholinergic agents are used to treat bladder dysfunction but should be used with caution, particularly in elderly patients who have cognitive decline and dementia, and in particular DLB or PDD. Phosphodiesterase inhibitors can be used to treat sexual dysfunction (Zesiewicz et al., 2010).

RBD can be treated using clonazepam, melatonin, ChEI, or pramipexole (Aurora et al., 2010). Hypersomnia has been shown to improve with armodafinil in a pilot study (Lapid et al., 2017).

Disease-modifying approaches are aimed at preventing, slowing, or ameliorating the production, aggregation, and deposition of pathological proteins, including immunotherapy targeting α -synuclein and, at time of writing, an ongoing trial using amroxol, which increases glucocerebrosidase activity to lower the levels of the protein α -synuclein. Nilotinib, a protein tyrosine kinase inhibitor, was found safe for treating motor and cognitive symptoms in advanced PD and DLB in a phase one study (Pagan et al., 2016), and phase two studies are ongoing at the time of writing. Other disease-modifying clinical trials are using agents to augment insulin signalling, stem cell therapy, reducing amyloid pathology, and gene therapy (Velayudhan et al., 2017).

Nonpharmacological treatment of dementia with Lewy bodies and Parkinson's disease dementia

Two systematic reviews on different types of nonpharmacological interventions in PDD and DLB have been published recently, and while the studies included mostly report the intervention to be effective, direct comparisons and meta-analyses are difficult due to the many small and methodologically different studies (Connors et al., 2018; Morrin et al., 2018). General principles regarding nonpharmacological interventions in dementia apply also in DLB and PDD. In PD, some improvement in

The Lewy body dementias: Dementia with Lewy bodies and Parkinson's disease dementia

cognitive tests has been reported after cognitive training in randomized trials (Paris et al., 2011; Peña et al., 2014) and improvements have been found in PD when combining cognitive training with gait training and in a study which used an integrative cognitive rehabilitation program (Díez-Cirarda et al., 2017; Strouwen et al., 2017). Transcranial direct cortical stimulation (tDCS) has been studied in DLB and PDD and found to be tolerated and potentially beneficial to increase attention and mood and improve motor symptoms in a small open and controlled study (Elder et al., 2016), but no effect was found with larger controlled study on cognition (Elder et al., 2017). Similar it has no effect on visual hallucinations (Elder et al., 2019) or mood in a larger controlled study in PD (Brys et al., 2016). It is important to inform patients and caregivers regarding the characteristic features of DLB including the potentially harmful effects of RBD and neuroleptics. Most authors recommend identifying one or only a few target symptoms to deal with first. Online support groups for carers and information for carers, patients, and professionals are available at <http://lbda.org/> or <http://www.lewybody.org/>, <http://www.parkinsons.org.uk/>, and at the DIAMOND-Lewy research programme: <https://research.ncl.ac.uk/diamondlewy/>

Frontotemporal dementia

Chapter: Frontotemporal dementia

Author(s): Martina Bocchetta and Jonathan D Rohrer

DOI: 10.1093/med/9780198807292.003.0033

Development and evolution of frontotemporal dementia concepts

The term ‘frontotemporal dementia’ (FTD) has evolved significantly since 1892, when Arnold Pick first described a 71-year-old male patient with a progressive speech disorder, reported as ‘transcortical sensory aphasia’ (Pick, 1892). Post-mortem examination confirmed focal cerebral atrophy, mainly in the left superior temporal gyrus. The histopathological presence of argyrophilic globular neuronal cytoplasmic inclusions (later termed Pick bodies) was subsequently described by Alois Alzheimer (1911). As a result, the concept of Pick’s disease (PiD) as a clinicopathological entity was introduced in the early 1920s (Gans, 1925; Onari and Spatz, 1926).

In the following decades, the clinical and neuropathological heterogeneity of cases with atrophy in the frontal and/or temporal lobe became apparent, with evidence that Pick’s pathology was present in only around 20% of clinical FTD cases (Escourolle, 1958). Multiple other pathologies

Frontotemporal dementia

were subsequently associated with this focal dementia presentation (Brun, 1987; Mann et al., 1993), culminating in the Lund and Manchester (1994) groups description of a set of clinical and neuropathological criteria for FTD in 1994. These were updated in 1998 with the 'Neary criteria', when the term 'frontotemporal lobar degeneration' (FTLD) was introduced to describe the group of neurodegenerative diseases characterized by selective frontal and/or temporal lobe atrophy and non-Alzheimer's disease neuropathology (Neary et al., 1998).

Clinically, it was recognized that patients with frontotemporal atrophy developed personality change and/or language impairment. The majority of early studies had focused on those with changes in behaviour and personality, and the term Pick's disease became synonymous with this condition. Few studies investigated progressive language disorders until the last quarter of the twentieth century when two parallel streams of research started to describe such cases: Warrington (1975) described a group of patients with selective impairment of semantic memory, subsequently called 'semantic dementia' (SD) (Hodges et al., 1992), and Mesulam (1982, 1987) described people who had developed a 'primary progressive aphasia' (PPA).

The 'Neary criteria' (1998) provided diagnostic descriptions for both the behavioural and language variants, with the language impairment group divided into two separate syndromes: progressive non-fluent aphasia (PNFA) and SD. Although Mesulam (1987) and McKhann and colleagues (2001) independently described other criteria around the same time, the 'Neary criteria' provided the main research and clinical descriptions of these conditions until the last few years.

An international consortium of FTD researchers came together at the end of the first decade of the twenty-first century to revise the criteria for both the behavioural and language variants. The 'Rascovsky criteria' (Rascovsky et al., 2011) introduced the term behavioural variant (bvFTD), and the 'Gorno-Tempini criteria' (Gorno-Tempini et al., 2011) brought together work from various studies showing that there were more than two forms of PPA—these criteria describe three: a non-fluent or agrammatic variant (nfvPPA), a semantic variant (svPPA), and a logopenic variant (lvPPA), also called logopenic aphasia (LPA). While there is general consensus over the naming of bvFTD, there remains some disagreement over the nosology of PPA; PNFA/nfvPPA, SD/svPPA, and LPA/lvPPA are often used interchangeably, with the recognition that there are a sizeable minority of cases that do not fit criteria for any of the three subtypes (Harris et al., 2013).

Neither the Rascovsky nor the Gorno-Tempini diagnostic criteria describe the overlap of FTD with motor disorders. Around 15% of patients with FTD develop motor neurone disease (MND; Jackson et al., 1996) or amyotrophic lateral sclerosis (ALS), and a separate set of criteria have been developed by Strong (Strong et al., 2009, 2017) to describe any form of cognitive or behavioural change that occurs in MND/ALS. Individual

Frontotemporal dementia

diagnostic criteria also exist for the atypical parkinsonian disorders, corticobasal syndrome (CBS), and progressive supranuclear palsy (PSP)—the most recent criteria mention the possibility of the development of behavioural and language problems in these conditions (Armstrong et al., 2013; Hoglinger et al., 2017).

Epidemiology and life expectancy survival

Typical onset of FTD is between 45 and 65 years of age but there is a wide range from the early twenties through to the nineties (Rascovsky et al., 2011; Coyle-Gilchrist et al., 2016). There have been very few epidemiological studies of FTD (Onyike and Diehl-Schmid, 2013) but in the 45–65 age group, the estimated prevalence has been calculated as 15–22/100,000, with an incidence of 2.7–4.1/100,000, and an equal gender distribution. However, a recent study that incorporated all of the FTD spectrum disorders (including CBS and PSP) suggested an overall all age prevalence of 10.8/100,000 and incidence of 1.6/100,000, and an estimated lifetime risk of 1 in 742 (Coyle-Gilchrist et al., 2016).

Currently, the only confirmed risk factors for FTD are mutations in specific genes (see Genetics). Clear non-genetic risk factors are yet to be identified: a Dutch retrospective study found that head trauma was associated with a 3.3-fold higher risk for FTD, and thyroid disease with a 2.5-fold higher risk (Rosso et al., 2003a,b), but these have not been replicated yet in other studies, although more recently, one group has found a higher incidence of autoimmune diseases in a subgroup of patients with FTD (Miller et al., 2016).

Survival varies widely, ranging from 1–20+ years, and is dependent on the underlying clinical, genetic, and pathological cause (Onyike and Diehl-Schmid, 2013): clinically, svPPA has the longest median survival (12 years), nfvPPA and bvFTD show comparable survival (9 years) (Nunnemann et al., 2011; Roberson et al., 2005), while FTD-MND has the poorest prognosis with average time to death from symptom onset being between two and three years (Hodges et al., 2003). However, there is variability within each group, and a slowly progressive form has been described with survival >20 years, in some cases in association with an expansion in the *C9orf72* gene.

Genetics

A family history of dementia is found in about a third to a half of cases of FTD (Gräsbeck et al., 2005), but a true autosomal-dominant disorder is only found in 20–30% (Goldman et al., 2005; Rohrer and Warren, 2011; Rohrer et al., 2009b). Mutations in three genes account for more than 80% of genetic FTD: microtubule-associated protein tau (*MAPT*) (Hutton et al., 1998), progranulin (*GRN*) (Baker et al., 2006; Cruts et al., 2006), and chromosome 9 open reading frame 72 (*C9orf72*), (DeJesus-Hernandez et al., 2011; Renton et al., 2011). Many other rare genetic causes for FTD have been described in a small number of families worldwide (Table 33.1).

Frontotemporal dementia

Table 33.1 Genetic causes of FTD.			
Gene		Year of discovery	Reference
<i>MAPT</i>	Microtubule-associated protein tau	1998	Hutton et al., 1998; Spillantini et al., 1998; Poorkaj et al., 1998

<i>TIA1</i>	T cell-restricted intracellular antigen-1	2017	Mackenzie et al., 2017

Few genetic modifiers of FTD have been described, although two GWAS studies have been performed in FTD (van Deerlin et al., 2010; Ferrari et al., 2014). The first study focused only on those with TDP-43 pathology (see Neuropathology) and found that variants in the transmembrane protein 106B (*TMEM106B*) gene were a risk factor for FTD in that cohort, particularly in those with *GRN* mutations (Lattante et al., 2014; van Deerlin et al., 2010). The second GWAS study was in an unselected FTD cohort and therefore heterogeneous containing patients with multiple different pathologies. Nonetheless, two novel associations were found, with an *HLA* locus and with a locus at 11q14, encompassing *RAB38/CTSC*.

Among the clinical syndromes, bvFTD is most frequently associated with a genetic cause, followed by FTD-MND, nfvPPA, CBS, PSP, and lastly svPPA, which is usually sporadic (Rohrer et al., 2009a). *MAPT* gene mutations are typically associated with bvFTD and they account for virtually all hereditary tau-positive FTD. *GRN* mutations are most commonly associated with bvFTD, but nfvPPA can also be seen as can CBS. *C9orf72* expansions are found in patients with bvFTD, FTD-MND (or pure MND), and less commonly nfvPPA.

Neuropathology

The term FTLT is now most commonly used to describe the pathological forms of FTD, with its subclassification based on the type of protein inclusions found (Fig. 33.1; Lashley et al., 2015). The main distinction is between FTLT-tau, accounting for about 45% cases and the tau-negative cases. FTLT-tau can be subdivided on the basis of the predominant tau species (characterized by the presence of three or four repeat sequences in the isoform) present in the inclusions: while the amount of 3R-tau and 4R-tau is equal in the normal brain, 3R-tau is the predominant form in Pick's disease (Delacourte et al., 1996) and in some forms of FTDP-17, i.e. in those with *MAPT* mutations (Ghetti et al., 2015) while 4R-tau is seen in corticobasal degeneration (CBD), PSP, argyrophilic grain disease (AGD), globular glial tauopathy (GGT), and in some FTDP-17 variants (Ghetti et al., 2015; Flament et al., 1991; Ksiezak-Reding et al., 1994; Tolnay et al., 2002). Some FTDP-17 *MAPT* variants show both 3R-tau and 4R-tau in the inclusions (Ghetti et al., 2015). Of the tau-negative FTD cases, the vast

Frontotemporal dementia

majority have inclusions of the nuclear protein TDP-43 (accounting for ~50% of all FTLD): based on the predominant lesion type and the distribution of the pathological inclusions, FTLD-TDP can be subdivided into four different subtypes: A, B, C, and D (Mackenzie et al., 2011).

Fig. 33.1

A schematic illustration of the pathological classification of frontotemporal lobar degeneration. Current classification is based on the molecular features of the disease-associated, inclusion-forming proteins, morphological phenotypes and genetic data (for description of the different disease groups and individual diseases see text).

3R-tau, three-repeat tau; 4R-tau, four-repeat tau; aFTLD-U, atypical frontotemporal lobar degeneration with ubiquitin immunoreactive neuronal inclusions; AGD, argyrophilic grain disease; BIBD, basophilic inclusion body disease; CBD, corticobasal degeneration; DLDH, dementia lacking distinctive histology; FTLD, frontotemporal lobar degeneration; FTDP-17, frontotemporal dementia and parkinsonism linked to chromosome 17; GGT, globular glial tauopathy, NFT-dementia, neurofibrillary tangle dementia; NIFID, neuronal intermediate filament inclusion disease.

Reproduced with permission from Lashley T., et al. Review: an update on clinical, genetic and pathological aspects of frontotemporal lobar degenerations. *Neuropathol Appl Neurobiol.*, 41(7): 858–81. Copyright © 2015 British Neuropathological Society. <https://doi.org/10.1111/nan.12250>.

Other pathologies are rare. Inclusions positive for the FUS protein (FTLD-FUS) account for ~5% of all FTLD (Mackenzie et al., 2010; Neumann et al., 2009a,b), and this group includes diseases such as neurofilament inclusion body disease (NIFID), atypical FTLD-U (aFTLD-U), and basophilic inclusions body disease (BIBD) (Neumann et al., 2009a,b; Urwin et al., 2010; Munoz et al., 2009). Patients with *CHMP2B* mutations are extremely rare (occurring mainly only in a single large Danish family)—these patients have ubiquitin-positive inclusions (FTLD-UPS) that are

Frontotemporal dementia

negative for tau, TDP-43, and FUS (MacKenzie et al., 2006; Seelaar et al., 2010).

bvFTD is the most heterogeneous of the clinical syndromes and it can be caused by any of the pathologies. svPPA is usually caused by FTLD-TDP type C, while nvPPA is associated with CBD, PSP, or Pick's disease (i.e. FTLD-tau) more commonly than FTLD-TDP (types A or B). A PSP clinical syndrome is predominantly associated with PSP pathology but CBS is only associated with CBD pathology in about 50% of cases, with other causes being PSP, Pick's disease, and FTLD-TDP type A. FTD-MND is generally associated with FTLD-TDP type B.

Genetic mutations in *MAPT* are associated with the FTDP-17 pathology, while the majority of the other genetic forms of FTD are associated with FTLD-TDP: *GRN* (type A), *C9orf72* (type A or B), *TBK1* (type A or B), *VCP* (type D). *C9orf72*, in addition to TDP-43 pathology, is characterized by neuronal inclusions composed of dipeptide repeat proteins (DPRs) in the cerebellar granule cell layer, hippocampal pyramidal neurons, and other neuroanatomical sites (Ash et al., 2013; Mori et al., 2013).

Clinical features

Behavioural variant FTD

bvFTD presents with an insidious onset of change in personality and behavioural symptoms. In the early stages these can be subtle and may be misdiagnosed as depression or a primary psychiatric illness. In the diagnostic criteria, symptoms fall into five main groups: disinhibition, apathy, changes in eating habits (gluttony, food fads, sweet food preference), obsessive-compulsive behaviour, and loss of empathy (Table 33.2). However, other changes of behaviour can be seen that do not form part of the criteria, including loss of insight, changes in pain and temperature sensitivity (Fletcher et al., 2015), and in a smaller number of patients delusions and/or hallucinations (commonly visual) (Woollacott and Rohrer, 2016).

Table 33.2 Summary of behavioural and cognitive symptoms within the current diagnostic criteria for behavioural variant frontotemporal dementia (bvFTD) and other commonly seen features.

Behavioural/cognitive symptoms - diagnosis of possible bvFTD requires at least three of the following symptoms to be fulfilled:	Examples of specific symptoms
Early behavioural disinhibition ≥ 1 of:	

Frontotemporal dementia

Socially inappropriate behaviour	Staring, inappropriate physical contact with strangers, inappropriate sexual behaviour, verbal or physical aggression
Loss of manners or decorum	Lack of social etiquette, insensitive or rude comments, preference for crass jokes and slapstick humour, inappropriate choices of clothing or gifts
Impulsive, rash or careless actions	New gambling behaviour, driving or investing recklessly, overspending, gullibility to phishing/Internet scams
Early apathy or inertia ≥ 1 of:	
Apathy	Reduced drive, stops previous hobbies, stops going out, reduced bathing or personal care
Inertia	Lack of persistence or completion of an activity, does not initiate activities or conversations
Early loss of sympathy or empathy ≥ 1 of:	
Diminished response to other people's needs and feelings	Selfish or hurtful comments or actions, inability to perceive when someone is upset, embarrassed, or in pain, reduced appreciation of sarcasm or sophisticated humor
Diminished social interest, interrelatedness, or personal warmth	Emotionally cold or detached, lack of rapport in conversation, loss of interest or affection in relationships with friends or family members, reduced interest in sex
Early perseverative, stereotyped or compulsive or ritualistic behaviour ≥ 1 of:	
Simple repetitive movements	Repetitive rocking, tapping, clapping, or rubbing

Frontotemporal dementia

Complex compulsive or ritualistic behaviours	Hoarding, strict grooming or walking routines, timekeeping and counting, checking or sorting items, cleaning or tidying, new obsessions or interests (usually spiritual, religious, artistic, or musical)
Stereotypy of speech	Habitual repetition of particular words, sentences, or topics
Hyperorality and dietary changes ≥ 1 of:	
Altered food preferences	Sweet tooth (sweets, biscuits, ice cream), carbohydrates, or obsessive food fads
Binge eating, increased consumption of alcohol or cigarettes	Cramming food into mouth, overeating or messy eating, new addictions to alcohol or smoking
Oral exploration or consumption of inedible objects	Pica
Neuropsychological profile - all 3 of:	
Deficits in executive tasks	Vary as per neuropsychological assessment used
Relative sparing of episodic memory	
Relative sparing of visuospatial skills	
Other features of bvFTD (not in diagnostic criteria)	
Loss of insight	Lack of awareness of own condition or symptoms
Impaired social cognition	Poor response to social or emotional clues; impaired performance on tests of theory of mind or emotion recognition

Frontotemporal dementia

Altered sensitivity to pain	Heightened perception of a non-painful stimulus or reduced response to painful stimulus; hypochondriasis or overly focusing on mild physical complaints
Altered tolerance of temperature	Inappropriate clothing for the ambient temperature, such as wearing multiple coats or blankets
Psychotic features	Delusions (usually somatic or paranoid) and hallucinations (usually visual or tactile)

Table content is adapted from Rascovsky et al. (2011) and Warren et al. (2013). To qualify for a diagnosis of possible bvFTD, patients need to have a progressive deterioration of behaviour and/or cognition as per observation or history from an informant, and must possess persistent evidence of least three of the six main groups of behavioural/cognitive symptoms as listed above. The term 'early' refers to within three years of initial symptom onset as per Rascovsky et al. (2011). Reproduced with permission from Woollacott, I.O., and Rohrer, J.D. The clinical spectrum of sporadic and familial forms of frontotemporal dementia. *J Neurochem.*, 138(S1):6–31. Copyright © 2016, International Society for Neurochemistry. <https://doi.org/10.1111/jnc.13654>.

Early cognitive impairment is usually in the domain of executive function, e.g. difficulties with decision-making, planning, and problem solving, and this also forms part of the diagnostic criteria. However, impairment of social cognition also commonly occurs in the early stages (Kumfor and Piguet, 2012), with many people arguing that the absence of this from the criteria is a major weakness. As the disease progresses other cognitive domains become involved, although there are a subset of patients that develop early episodic memory or parietal dysfunction.

Primary progressive aphasia

PPA is characterized by progressive and insidious language decline, affecting at least one of the following functions: speech production, object naming, syntax, and word comprehension (Gorno-Tempini et al., 2011). For the diagnosis of PPA, the deficits should not be caused by other non-degenerative disorders (e.g. tumour or stroke), initial symptoms should not include prominent behavioural or cognitive difficulties, and the symptoms should not be better accounted for by a psychiatric diagnosis. As noted earlier, within PPA, three main PPA variants are recognized: svPPA, nfvPPA, or lvPPA (Table 33.3; Gorno-Tempini et al., 2011), but a subgroup of patients who have PPA do not fit neatly into one of these three diagnoses, and have been called various names over the years,

Frontotemporal dementia

including a 'mixed aphasia', 'PPA-unclassified', or 'PPA-not otherwise specified' (Harris et al., 2013).

Table 33.3 Summary of clinical features across the syndromes of primary progressive aphasia.

Clinical features	svPPA	nvPPA	lvPPA
<i>Spontaneous speech (fluency, errors, grammar, prosody)</i>	Fluent, garrulous, and circumlocutory; semantic errors; intact grammar and prosody	Slow and hesitant, effortful +/- apraxic; phonetic errors; may be agrammatic; aprosodic	Hesitant; not effortful or apraxic; frequent word-finding pauses and loss of train of sentence; intact grammar; intact prosody
<i>Naming</i>	Severe anomia with semantic paraphasias	Moderate anomia with phonetic errors and phonemic paraphasias	Mild to moderate anomia with occasional phonemic paraphasias
<i>Single word comprehension</i>	Poor	Intact early on, but affected later on	Intact early on, but affected later on
<i>Sentence comprehension</i>	Initially preserved, later on becomes impaired as word comprehension is impaired	Impaired if grammatically complex	Impaired, especially if long
<i>Single word repetition</i>	Relatively intact	Mild to moderately impaired if polysyllabic,	Relatively intact (compared with

Frontotemporal dementia

		otherwise intact	sentence repetition)
<i>Sentence repetition</i>	Relatively intact	Can be effortful; impaired if grammatically complex	Impaired, with length effect
<i>Reading</i>	Surface dyslexia	Phonological dyslexia +/- phonetic errors on reading aloud	Phonological dyslexia
<i>Writing</i>	Surface dysgraphia	Phonological dysgraphia	Phonological dysgraphia

Clinical features are adapted from tables in Rohrer et al. (2008); Rohrer et al., 2010a; Seelaar et al. (2011); and Gorno-Tempini et al. (2011). Reproduced with permission from Woollacott, I.O., and Rohrer, J.D. The clinical spectrum of sporadic and familial forms of frontotemporal dementia. *J Neurochem.*, 138(S1):6–31. Copyright © 2016, International Society for Neurochemistry. <https://doi.org/10.1111/jnc.13654>.

Patients with svPPA present with anomia and impaired single word comprehension, and then later nonverbal semantic impairment as well. Speech is fluent, with frequent circumlocutions and semantic paraphasias. Speech articulation, prosody, and repetition of spoken words are usually preserved, and grammar is intact (Gorno-Tempini et al., 2011).

In comparison, patients with nfvPPA develop agrammatism and/or apraxia of speech, with phonemic and phonetic errors. Speech is non-fluent and the prosody of speech is disrupted, while single word comprehension, object knowledge, and repetition of single words are preserved (Gorno-Tempini et al., 2011). There is ongoing controversy over whether nfvPPA consists of more than one syndrome. For example, there is a parallel literature on patients who have a pure progressive apraxia of speech (PAOS) (Botha et al., 2015), i.e. have impaired planning of articulation but no language deficits per se. PAOS is then distinguished from those with progressive agrammatic aphasia who have syntax problems but no articulatory deficits. While nfvPPA remains undoubtedly heterogeneous, many patients have both apraxia of speech and agrammatism, making the distinction into two separate diseases difficult practically.

Frontotemporal dementia

lvPPA is characterized by word-finding pauses, anomia, phonemic errors, impaired sentence repetition, and impaired working memory. Single word comprehension and object knowledge are preserved, but there is impaired comprehension of longer sentences without agrammatism or apraxia of speech (Gorno-Tempini et al., 2011; Woollacott and Rohrer, 2016).

Motor disorders

Around 15% of people with FTD (usually bvFTD, or rarely nvfPPA) develop MND/ALS, although behavioural and/or cognitive impairment not meeting criteria for FTD is seen in around 50% of people with MND/ALS. Early features commonly include fasciculations and brisk reflexes.

Parkinsonian syndromes are seen most commonly in people with bvFTD or nvfPPA (and almost never in people with svPPA or lvPPA). While the majority of patients meet criteria for one of the atypical parkinsonian syndromes, PSP or CBS, there are a subgroup of people with (usually asymmetrical) parkinsonism who do not meet criteria for any of the defined parkinsonian disorders.

Summary of genetics, neuropathology, and clinical features

Fig. 33.2 summarizes the clinical syndromes, pathology and genetics of the FTD disorders, and shows (as discussed earlier) there are no one-to-one correlations between clinical syndrome and pathology, although a PSP syndrome (with PSP pathology), svPPA (with FTLD-TDP type C), and FTD-MND/ALS (with FTLD-TDP type B) have the strongest associations.

Fig. 33.2

Association between clinical syndromes, pathology, and genetics of the FTD spectrum disorders. Thicker lines linking clinical syndromes to pathology represent stronger associations. PSPS refers to a clinical syndrome of classical PSP, sometimes called Richardson's syndrome.

Frontotemporal dementia

Neuroimaging

FTD has been always described as a disease with a frontal and temporal lobe atrophic pattern (hence its name), which is clearly visible as volume loss on T1-weighted magnetic resonance imaging (MRI), and as areas of hypometabolism on ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET). However, it is clear that cortical atrophy is also present in the insula and anterior cingulate (in particular) as well as, on occasion, more posterior cortical structures. Furthermore, recent studies have shown that subcortical structures such as the hippocampus, amygdala, striatum, thalamus, and cerebellum can be affected even in the earliest stages of the disorder (Rohrer and Rosen, 2013; Whitwell et al., 2012; Seeley et al., 2008; Schroeter et al., 2007; Halabi et al., 2013).

In bvFTD, the atrophy pattern is often asymmetrical, affecting the right hemisphere more than the left (Rohrer and Rosen, 2013). However, this is not the case for all individuals, and at least four anatomical subtypes of bvFTD have been postulated: focal frontal- and temporal-dominant subtypes, as well as combined frontal/temporal and more widespread temporo-frontal-parietal subtypes (Whitwell et al., 2009).

svPPA is associated with a characteristic pattern of asymmetrical (usually left greater than right) atrophy of the temporal lobes, particularly the inferior temporal and fusiform gyri, the temporal pole, the parahippocampal and the entorhinal cortex, the anterior hippocampus, and the amygdala (Rohrer and Rosen, 2013; Gordon et al., 2016; Rohrer et al., 2009b; Schroeter et al., 2007). Less frequently, patients present with predominant right temporal lobe atrophy at onset, a condition often called right temporal lobe atrophy (RTLA) (Chan et al., 2009).

nvPPA patients typically show atrophy of the inferior frontal gyrus (particularly the pars opercularis), dorsolateral prefrontal cortex, superior temporal gyrus, and insula (Rohrer et al., 2009b), with involvement of the caudate and putamen (Gorno-Tempini et al., 2004). In contrast, lvPPA shows left temporoparietal atrophy, encompassing the posterior superior temporal lobe and inferior parietal lobe, as well as the precuneus, posterior cingulate, and medial temporal lobe (Gorno-Tempini et al., 2004; Rohrer, Caso et al., 2013).

The genetic forms of FTD appear to have a differential involvement of the cortical and subcortical areas (Fig. 33.3): patients with *MAPT* mutations present with focal symmetric anterior temporal and orbitofrontal lobe atrophy, with hippocampus and amygdala atrophy. Patients with *GRN* mutations usually present with asymmetric atrophy of the temporal, inferior frontal, and inferior parietal lobes and of the striatum, whereas patients with *C9orf72* expansions show a more distributed symmetric pattern of atrophy, predominantly involving dorsolateral and medial frontal and orbitofrontal lobes, with additional loss in the anterior temporal, parietal, and occipital lobes, as well as in the thalamus and

Frontotemporal dementia

cerebellum (Rohrer et al., 2010b, 2015; Whitwell et al., 2012; Sha et al., 2012).

Fig. 33.3

Coronal T1 volumetric MR images displaying characteristic patterns and distribution of regional volume loss for each of the main genetic and pathological subtypes of FTD.

Reproduced with permission from Gordon E., et al. Advances in neuroimaging in frontotemporal dementia. *J Neurochem.*, 138 (S1): 193-210. Copyright © 2016 International Society for Neurochemistry. <https://doi.org/10.1111/jnc.13656>.

Some studies have started to show specific imaging features in pathological subtypes of FTLTD (Fig. 33.3), e.g. PiD can be associated with asymmetric atrophy in the frontal, anterior temporal, and insula cortex, FTLTD-TDP type A with asymmetric fronto-temporo-parietal atrophy with anterior cingulate and caudate involvement, FTLTD-TDP type B with symmetrical frontal, insular, and anteromedial temporal lobe atrophy, FTLTD-TDP type C with asymmetrical loss in the antero-inferior temporal lobe, and FUS pathology with caudate, orbitofrontal, anteromedial temporal, anterior cingulate, and insula atrophy (Gordon et al., 2016; Seelar et al., 2010; Josephs et al., 2010).

Hypometabolism measured with FDG-PET and SPECT is commonly found in FTD, with similar patterns of neuroanatomical involvement to those seen with T1 MRI imaging (Diehl-Schmid et al., 2007). However, there have been fewer studies of these imaging modalities compared with MRI, in particular within genetic or pathological subtypes of FTD. Newer imaging techniques, e.g. arterial spin labelling (ASL), offer the opportunity of potentially measuring similar abnormalities as part of an MRI protocol (e.g. hypoperfusion in ASL; Hu et al., 2010) while not requiring injection of a radioactive ligand.

Initial studies using diffusion tensor imaging (DTI) and resting state functional magnetic resonance imaging (rs-fMRI) have started to highlight the involvement of structural and functional networks in FTD. Structurally, multiple white matter tracts have been identified as abnormal in FTD, e.g. the superior longitudinal, inferior longitudinal, and

Frontotemporal dementia

uncinate fasciculi (Mahoney et al., 2014; Lee et al., 2016; Dopper et al., 2013), while functionally, the key networks involved have been shown to be the salience and executive control networks in bvFTD and the language and semantic networks (predominantly in the left hemisphere) in PPA (Seeley et al., 2009; Lee et al., 2014; Pievani et al., 2014).

Amyloid-PET imaging (using tracers such as PIB or florbetapir) has demonstrated utility in FTD and PPA clinical syndromes in differentiating those people with underlying AD pathology (commonly lvPPA, and only rarely the other syndromes) from those with FTLD pathology (Rabinovici et al., 2008). Several PET ligands selective for tau pathology (e.g. AV1451, PBB3) have been developed but none have so far been shown to selectively identify non-AD tauopathies, or differentiate them from the TDP-43 proteinopathies (Villemagne et al., 2015).

Fluid biomarkers

Multiple studies have been performed in order to identify biomarkers in cerebrospinal fluid (CSF) or blood that might improve differential diagnosis of FTD or track disease progression (Oeckl et al., 2015; Oeckl et al., 2016). Similar to amyloid PET imaging, core AD CSF biomarkers (levels of total-tau, phospho-tau, and $A\beta_{42}$) show diagnostic power in differentiating those people with underlying AD pathology from those with FTLD (Bian et al., 2008; Paraskevas et al., 2017). However, also similarly to PET, no markers have been found that can differentiate those with FTLD-tau from those with FTLD-TDP; while the ratio of phospho-tau/total-tau is lower in FTLD-TDP than in FTLD-tau, the sensitivity and specificity is poor.

A promising biomarker of disease progression is the level of neurofilament light chain (NfL), which can be measured in CSF and blood. NfL levels are 2.5–11-fold higher in patients with all FTD subtypes than in controls, and they are correlated with survival and rate of brain atrophy (Landqvist Waldö et al., 2013; Meeter et al., 2016a; Rohrer et al., 2016).

Serum and CSF levels of progranulin are reduced by 25–40% in carriers of *GRN* mutations with high sensitivity (96–100%) and specificity (93–100%), and are therefore considered diagnostic biomarkers of pathogenic *GRN* mutations (Ghidoni et al., 2012; Meeter et al., 2016b).

C9orf72 expansion carriers show elevated levels of glycine-proline-repeating protein, one of the DPR proteins, in the CSF (Gendron et al., 2017).

Recent studies have focused on other potential fluid biomarkers for FTD, such as CSF levels of pTDP-43 (Kuiperij et al., 2017), neurogranin (Janelidze et al., 2016), or inflammation-related proteins (Oeckl et al., 2015; Oeckl et al., 2016).

Frontotemporal dementia

Management and treatment

There are currently no therapies that can delay the onset or prevent the progression of FTD. There have also been few clinical trials of potential disease modifying therapies so far, although that is likely to change in forthcoming years.

There are also few pharmacological therapies with any proven symptomatic benefit in FTD (Tsai and Boxer, 2016). Trials of symptomatic AD therapies (cholinesterase inhibitors and memantine) in FTD have been negative, and there is in fact some evidence that these therapies may aggravate behavioural disturbance in bvFTD (Mendez et al., 2007). There is some evidence from small studies (not double-blind randomized control trials) that selective serotonin reuptake inhibitors may improve behaviour in bvFTD and a trial of such a medication is commonly attempted clinically. There is also no strong evidence base for the use of neuroleptic drugs in FTD, despite relatively common use for agitation and other behavioural symptoms, and the risk/benefit ratio remains unclear.

Patients with PPA can benefit from a review from a speech and language therapist with an interest in PPA. Augmentative and alternative communication strategies and devices can be of benefit in PPA, particularly in the early stages of the disease.

In the absence of adequate therapies for FTD, management is directed at building a support network through community mental health, psychological, and social services as well as both local and national support groups (e.g. the national FTD, PPA, and familial FTD support groups run by www.raredementiasupport.org in the UK). Day centres and respite care are important to relieve the burden on carers and families. Provision of accurate information is required (e.g. from websites such as www.ftdtalk.org) to allow patients, family members, and carers to understand a disease which is commonly poorly understood in the community due to its rarity.

For those with familial FTD, access to genetic services is important. This may include genetic counselling, pre-symptomatic genetic testing, and preimplantation genetic diagnosis for family members.

Future management of FTD will hopefully include quicker and more accurate diagnosis and improved prediction of the rate of progression. For familial FTD, the ability to identify the time at which people will develop symptoms will be hugely important for pre-symptomatic mutation carriers (Woollacott and Rohrer, 2016). Lastly, while there is hope that future trials of disease modifying therapies are successful, until that time, it is important that patients and family members are able to access and participate in research studies as easily as possible.

Neurological dementias

Chapter: Neurological dementias

Author(s): Andrew Graham

DOI: 10.1093/med/9780198807292.003.0034

Dementia with onset in old age is usually due to neurodegenerative disease. Alzheimer pathology is the commonest cause, followed by Lewy body changes and, more rarely, the range of pathologies associated with frontotemporal dementia (FTD). These neurodegenerative conditions, in which dementia is the dominant feature, are often referred to as the *primary* dementias and are covered separately in Chapter 30, Chapter 32, and Chapter 33. Unfortunately, despite decades of research, the primary dementias are currently incurable.

Less commonly, dementia can arise as a complication of general medical conditions: in such *secondary* dementias, cognitive impairment is typically accompanied by symptoms and signs in other organ systems. Most commonly the underlying pathology is vascular disease; vascular risk factors such as smoking, alcohol use, obesity, diabetes, hypertension, and hypercholesterolaemia are also all risk factors for dementia, and vascular cognitive impairment and vascular dementia are covered separately in Chapter 31. General medical conditions such as hypothyroidism and

Neurological dementias

vitamin B₁₂ deficiency are often listed as causes of a secondary dementia and are included in screening because they are treatable. However, dementia due solely to such conditions is rare and they are probably better regarded as treatable comorbidities rather than 'causes' as such.

Alternatively, dementia may develop as just one facet of a more extensive neurological disorder. Such *neurological* dementias are much less common than primary or vascular dementia but important to recognize because their management and outcomes may be very different. Accurate diagnosis and appropriate treatment often require referral outside of old age psychiatry services, and this chapter focuses on a selection of neurological dementias where a neurological consultation is likely to be of value: idiopathic normal pressure hydrocephalus, Huntington's disease, multiple sclerosis, antibody-mediated encephalitis, and prion disease.

Idiopathic normal pressure hydrocephalus (INPH)

Overview

INPH is a disorder in which abnormal accumulation of cerebrospinal fluid (CSF) results in gait disturbance, urinary incontinence, and dementia. Clinicians are anxious not to miss the diagnosis as it is potentially treatable, and the possibility of INPH is not infrequently raised in neuroimaging reports. However, the disorder in its full form is uncommon, diagnosis is challenging, and treatment can be associated with significant complications.

Hydrocephalus is an umbrella term for the abnormal accumulation of CSF within the cranium, whether due to defective CSF production, flow, or absorption. The two main types are *obstructive hydrocephalus*, where there is a structural barrier to CSF flow through the ventricular system, and *communicating hydrocephalus*, where the defect is inadequate CSF absorption by the arachnoid granulations. Hydrocephalus secondary to overproduction of CSF is rare. Communicating hydrocephalus may in turn be classified as either *primary* or *secondary*. In secondary communicating hydrocephalus, the defect in CSF absorption is due to a well-established cause of damage to the arachnoid granulations, e.g. meningitis, subarachnoid haemorrhage, or significant head injury. In primary communicating hydrocephalus, no such cause is apparent.

In 1965, Adams and colleagues (1965) published a description of three patients with ventriculomegaly, gait disturbance, urinary incontinence, and dementia in whom symptoms were improved by the insertion of a ventricular shunt. All three patients had CSF opening pressures within the normal range, and in two of the three cases no secondary underlying cause for the hydrocephalus could be found. Subsequently, this scenario was termed 'idiopathic normal pressure hydrocephalus' (INPH), but the label may be misleading—intracranial pressure (ICP) in INPH is in fact on average slightly higher than normal, with slow pulses (0.33 to 3 cycles/min) of slightly increased pressure known as B waves, probably related to

Neurological dementias

rhythmic changes in cerebral blood volume. For this reason, some authors prefer the alternative label 'idiopathic adult hydrocephalus syndrome'.

The pathophysiology of INPH is incompletely understood. CSF dynamics are disturbed, with a high resistance to CSF outflow, slightly raised intracranial pressure, increased B-waves, an increased aqueductal stroke volume, and ventriculomegaly. However, the underlying cause for this disturbance is unknown, as is the mechanism by which these CSF pressure abnormalities affect the brain and result in clinical symptoms. A leading theory is that the symptoms of INPH are due to a complex interaction between a disturbance of CSF dynamics and cerebrovascular small vessel disease, resulting in low-grade cerebral ischaemia of periventricular white matter (Momjian, Owler et al., 2004) and basal ganglia (Townley et al., 2018). Microdialysis studies show that CSF removal is associated with improvement in this periventricular ischaemia (Agren-Wilsson et al., 2005).

Epidemiology

There are no definitive figures for the incidence and prevalence of INPH. In a door-to-door community survey of two Bavarian villages, the population prevalence of INPH in people older than 65 years was 0.4% (Trenkwalder et al., 1995), while in three Japanese studies the prevalence varied from 0.5% to 2.9% depending on the definition used (Hiraoka et al., 2008; Tanaka et al., 2009; Iseki et al., 2009). A more recent Swedish community-based study of 1,238 individuals who underwent both CT scanning and clinical examination suggests that in older adults INPH could be more common than previously thought, with a prevalence of 0.2% in individuals aged 70–79 years but 5.9% in individuals aged 80 and above (Jaraj et al., 2014). However, only a minority of patients proceed to surgical treatment. In a survey of six Swedish neurosurgical centres, the number of shunt insertions performed for INPH was only 1–2/100,000 per year (Tisell et al., 2005), while in a retrospective survey of Mayo Clinic records the number was 1.2/100,000 per year (Klassen and Ahlskog, 2011). In summary, INPH is not a common cause of dementia in later life but may be more common than previously thought.

Clinical features

The diagnosis of INPH rests first on clinical suspicion. The cardinal feature is disturbance of balance and gait, which almost always precedes the development of other symptoms and worsens insidiously over months and years. Patients walk with a mildly broad-based, small-stepped gait, and locomotion is impaired to a degree out of all proportion to the examination findings on the couch: this is often termed a gait apraxia. Although minor extrapyramidal features may be found on examination, the presentation is quite distinct from that of idiopathic Parkinson's disease (PD). Cognitive impairment is present in most patients with INPH by the time of diagnosis, generally with a 'subcortical' pattern, including pronounced slowness of thought, difficulty in sustaining, dividing, and

Neurological dementias

switching attention, and difficulties in planning. However, simple bedside screening tests are generally unable to discriminate between the profiles of cognitive impairment associated with INPH and AD. Finally, urinary urgency, frequency, and incontinence are common but non-specific features (Malm and Eklund, 2006).

Investigations

A CT or MRI brain scan should be performed in any patient with clinical features suggestive of INPH. The first aim of neuroimaging is to exclude any structural lesion causing obstructive hydrocephalus, and the second is to look for supporting evidence of INPH. Enlargement of the ventricles is the cardinal feature of INPH and is traditionally assessed by calculation of Evan's ratio (the ratio of the greatest width of the frontal horns of the lateral ventricles to the maximum internal width of the skull). An Evan's ratio greater than 0.3 suggests significant ventriculomegaly, but not all ventriculomegaly is due to INPH: in the Swedish study mentioned above, 20.7% of the population had an Evan's ratio > 0.3 (Jaraj et al., 2014). Thus, other features are also important: e.g. disproportionate widening of the temporal horns of the lateral ventricles or flattening of the cortical sulci superiorly. In patients where significant ventriculomegaly is accompanied by marked cortical atrophy or signs of extensive cerebrovascular disease, ventriculomegaly may simply represent loss of brain tissue rather than INPH.

If there is supporting evidence for INPH on neuroimaging, the next step is typically specialist referral to either neurology or neurosurgical services. Before proceeding to more invasive tests and a decision about surgery, it is important to exclude degenerative disorders such as PD, significant vascular disease, and common neurological disorders of old age, e.g. cervical spondylotic myelopathy, lumbar canal stenosis, and a polyneuropathy (Malm et al., 2013). Exclusion of these possibilities rests largely on clinical assessment, but occasionally spinal imaging or neurophysiology studies may be necessary. Any MRI of the brain should also be carefully examined to rule out subtle secondary causes of hydrocephalus such as aqueduct stenosis. Based on the combination of clinical features and imaging abnormalities, consensus clinical diagnostic criteria for possible and probable INPH have been proposed (Relkin et al., 2005; Mori et al., 2012).

If specialist assessment confirms probable INPH, and there is no contraindication to proceeding, the next step is to decide if surgery (the placement of a ventricular shunt) will be of benefit. This usually involves further invasive investigations, either to measure aspects of CSF dynamics directly or to simulate the result of a shunt by removing a volume of CSF. The most widely used investigation is probably the CSF tap test, where 40–50 ml of CSF is withdrawn by lumbar puncture, with assessment of gait and cognition before and afterwards. Unfortunately, while this test has a reasonable specificity and positive predictive value (i.e. a positive result is a good predictor of a response to shunting), it has

Neurological dementias

a low sensitivity and negative predictive value (i.e. a negative result does not exclude a response to shunting). For this reason, some neurosurgical centres advocate a prolonged trial of CSF removal, usually involving the placement of a lumbar catheter and the steady drainage of approximately 10 ml of CSF per hour for up to 72 hours. There is certainly some evidence that external lumbar CSF drainage is more sensitive in predicting response to shunting than a simple tap test, but drainage has the drawback of requiring an inpatient stay and carries a risk of catheter-related complications, including infection.

Alternatively, CSF dynamics may be measured directly. Twenty-four-hour intracranial pressure monitoring often reveals abnormalities that indicate poor cerebral compliance, such as the presence of low-amplitude B waves (as mentioned in Overview). However, studies suggest that the presence or absence of B waves has a poor correlation with response to shunting. A more comprehensive assessment of CSF dynamics can be obtained by CSF infusion testing, in which saline is infused into the sub-arachnoid space through a lumbar puncture needle, while CSF pressure is continuously recorded via a second lumbar puncture needle placed at a different level. In most patients, the pressure rises constantly and then reaches a plateau. From the baseline pressure, plateau pressure, and infusion rate, the resistance to CSF absorption can be calculated. At present, CSF infusion measurements suffer from the same problem as drainage studies when it comes to predicting a response to shunting, namely a good specificity but poorer sensitivity. However, sophisticated analysis of the infusion data and refinements of the technique may improve its sensitivity in the future. Table 34.1 summarizes clinical factors and investigation results that may help predict the response to shunting.

Table 34.1 Factors associated with response or lack of response to shunting in INPH	
Factors associated with response to shunting	Factors associated with a lack of response to shunting
• Gait disturbance preceding cognitive impairment • Mild cognitive impairment, present for a short duration	• Cognitive impairment preceding gait disturbance • Moderate or severe cognitive impairment, present for two or more years
• Clinical improvement (usually in gait) following lumbar puncture or	MRI shows significant cerebral atrophy or white matter abnormalities

Neurological dementias

continuous lumbar CSF drainage • Resistance to CSF outflow of 18 mmHg/ml per min or greater during continuous lumbar CSF infusion test • Presence of B waves more than 50% of the time during continuous lumbar CSF monitoring	

Treatment and outcome

The surgical treatment for INPH is placement of a ventriculoperitoneal (VP) shunt, consisting of a proximal shunt catheter inserted in one of the lateral ventricles, a valve to regulate CSF drainage, and a distal catheter discharging into the peritoneal cavity. Fig. **34.1** shows typical preoperative and postoperative CT scan appearances in INPH. Most shunt valves are differential pressure-regulated, with an opening pressure above which the valve opens to permit CSF drainage and below which it closes again. The dilemma is that while adequate drainage is needed to see any clinical benefit, overdrainage may lead to low pressure symptoms and the accumulation of subdural hygromas or haematomas: in an early Dutch trial, low opening pressure valves were associated with better clinical outcomes than medium-pressure valves but also a threefold higher relative risk of chronic subdural effusions (Boon et al., 1998). The development of adjustable pressure-regulated shunt valves has allowed a more nuanced approach (e.g. rather than setting a fixed, low opening pressure, the opening pressure can be set high initially and then adjusted downwards at intervals to either a predetermined level or until clinical benefit is seen), but there is no consensus as to the optimum approach. One Dutch study found an adjustable strategy was as effective as a fixed low-pressure strategy, with significantly fewer subdural effusions (Delwel et al., 2013), and one Norwegian study found an adjustable strategy was more effective but with the same rate of complications (Saehle et al., 2014), but a randomized double-blind trial found no difference in effectiveness or complication rates between the two approaches (Farahmand et al., 2016).

Fig. 34.1

Preoperative (left) and postoperative (right) axial CT brain scans in INPH. Preoperatively, the ventricles are widened (upper left) and the cortical sulci in the top slices are partially effaced (lower left). Evan's ratio, calculated as the ratio of the greatest width of the frontal horns of the lateral ventricles (A) to the maximal internal diameter of the skull (B), is approximately 0.4; a ratio more than 0.3 is significant. Postoperatively, observe the tip of the shunt catheter in the lateral ventricle (upper right) and traversing the brain parenchyma (lower right), with a reduction in ventricular size and widening of cortical sulci.

Reproduced with permission from Malm, J. and Eklund, A. Idiopathic normal pressure hydrocephalus. *Practical Neurology*, 6(1): 14-27. Copyright © 2006, *British Medical Journal*. <http://dx.doi.org/10.1136/jnnp.2006.088351>.

One reason for this variation in outcome with differential pressure-regulated shunt systems may be that the pressure differential changes with changes in posture. If the valve is programmed to provide adequate drainage with the patient supine, it may result in overdrainage when upright, leading to subdural collections. However, if the drainage is set with the patient standing, it may result in underdrainage when supine, reducing the effectiveness of shunt surgery. To overcome this effect, gravitational ball-in-cone units have been developed that switch between a low-pressure mode when supine and a high-pressure mode when upright: one open-label study suggested that this reduced the rate of shunt-related complications (Lemcke et al., 2013), but the different shunt systems have not been trialled against one another head to head. Flow-regulated (as opposed to pressure-regulated) valves are also available.

Neurological dementias

The nature, magnitude, and duration of the benefit obtained by shunting is controversial. In non-placebo-controlled studies, up to two-thirds of patients demonstrate significant initial improvement after shunting (Malm et al., 2000; Hebb and Cusimano, 2001), although only up to one-third show sustained benefit at three years (Malm et al., 2000; Klassen and Ahlskog, 2011). Unfortunately, out of the key triad of impairments in INPH, dementia is the feature least likely to respond to shunting (Savolainen et al., 2002; Poca et al., 2004; Klassen and Ahlskog, 2011), particularly when cognitive impairment is severe or of long duration. One reason for this lack of response may be additional AD pathology, which of course is very common with older age even in the 'normal' population. However, benefits to gait appear to be independent of the presence or absence of AD pathology, and so, provided that patients and carers appreciate the limitations of surgical treatment, shunting for gait improvement alone may still be perfectly appropriate. Improvement also appears to be independent of age (Marmarou et al., 2005).

Key Points: INPH

- INPH is an uncommon, but potentially reversible, cause of dementia in old age.
- INPH should be excluded in patients with the classical triad of gait impairment, dementia, and urinary incontinence.
- All patients with INPH should have enlarged ventricles, but not all elderly patients with enlarged ventricles have INPH.
- After CT or MRI brain imaging, CSF removal and/or dynamic CSF testing are usually required before deciding on suitability for shunt insertion.
- Gait impairment is the feature most likely to improve after shunting.
- Dementia is less likely to be reversible where cognitive impairment is severe or of long duration, perhaps because of additional AD pathology; however, provided the risks are understood, shunting may still be considered for the benefits to gait alone.

Huntington's disease (HD)

Overview

HD is an inherited, autosomal dominant, neurodegenerative disorder resulting from an unstable expansion of a CAG trinucleotide repeat in the gene coding for the protein *huntingtin* on chromosome 4. The normal repeat number is between 6 and 35, and expansions of 40–44 repeats or greater lead to HD with 100% penetrance. The clinical features of HD usually emerge in early adulthood, but both juvenile and late-onset presentations are well recognized. HD is commonly associated with

Neurological dementias

prominent psychiatric symptoms, and when it presents in old age the clinical syndrome may be atypical. The family history may also be obscured by factors such as death from other causes in an affected parent or sibling before clinical features of HD are manifest; missing or 'hidden' relatives with unrecognized HD, particularly relatives who committed suicide; and nonpaternity. Up to 10% of cases of HD may represent new mutations. For old age psychiatrists, an appreciation of the wide range of clinical features in HD is therefore important to avoid a missed or delayed diagnosis. The only assessment that definitively excludes HD is genetic testing.

Epidemiology

HD is one of the commonest inherited neurodegenerative illnesses, with a prevalence in most western European countries of 4-8/100,000 (Harper, 1986). Lower prevalences are seen in certain other countries (e.g. Finland) and ethnic groups (e.g. Afro-Caribbean populations), but essentially HD is found worldwide. The peak age of onset is between 35 and 44 years, but HD can present at any age. Both sexes are affected equally.

Clinical features

HD classically presents with the combination of a movement disorder and a frontal dementia. Typically, the initial movement disorder is hyperkinetic, with chorea or dystonia, later progressing to an akinetic-rigid state. However, some patients with late-onset HD may present with an akinetic-rigid syndrome from the outset, causing diagnostic confusion (Reuter et al., 2000). Other physical clues to the diagnosis include oculomotor abnormalities (e.g. slowed voluntary saccades and impersistence of gaze).

HD is also associated with a wide range of psychiatric and cognitive symptoms. The commonest psychiatric disturbance is depression, affecting 40-50% of patients with HD during the course of their illness. The suicide rate in HD is reported to be four to six times higher than in the general population, and in one early cohort of HD patients, suicide accounted for over 2% of deaths (Schoenfeld et al., 1984). Anxiety and obsessive-compulsive symptoms are also frequently reported. Psychosis is less common, but up to 10% of patients show psychotic symptoms at some stage in their illness, usually poorly systematized paranoia with behavioural changes such as aggression and irritability. An early age of onset may be associated with an increased risk of psychosis, and psychiatric disturbance can occasionally be the presenting feature of HD in younger patients (Lovestone et al., 1996). Frank auditory hallucinations of the type seen in schizophrenia are rare.

Cognitively, patients with HD show prominent deficits on tests of attention, semantic verbal fluency, processing speed, and executive function. Performance on tests of memory can be poor, but the profile of problems (with recall affected more than recognition) suggests difficulties

Neurological dementias

with retrieval rather than encoding. Cognitive impairment can also be detected prior to diagnosis in gene-positive individuals at risk for the development of HD (Lawrence et al., 1998a,b).

Investigations

MRI in patients with HD may show generalized cortical atrophy or specific caudate atrophy (see Fig. 34.2). However, the only definitive investigation is genetic testing for the CAG expansion. This is a routine procedure, but because of the significant implications of a positive test for patients and their families, referral to clinical genetics services for counselling prior to testing is generally recommended.

Fig. 34.2

Coronal FLAIR MRI in HD, showing bilateral caudate atrophy (arrows).

Treatment and outcome

There is currently no cure for HD. Neuropsychiatric symptoms may all be treated with conventional medications, but many HD patients have an increased sensitivity to side effects. Longitudinal studies show a steady decline in cognitive function, with progressive functional disability and eventual death after an interval ranging from 10–30 years. Recently, there has been excitement about the prospect of genetic treatment in HD using anti-sense oligonucleotides (ASOs) injected by lumbar puncture to reduce the expression of the mutant huntingtin protein (mHTT) and modify the disease course. Initial studies show this approach is well tolerated, with a significant, dose-dependent reduction of mHTT in CSF of a magnitude

Neurological dementias

that exceeds effective levels in animal models. However, it is too early to say whether this treatment will be of clinical benefit in humans.

Key Points: Huntington's Disease

- HD is an inherited, autosomal dominant, neurodegenerative condition that most usually presents with the combination of a frontal dementia and hyperkinetic movement disorder.
- Late-onset HD is well described and may present atypically, e.g. as an akinetic-rigid syndrome. Sometimes the family history is obscured or lacking.
- HD can only be completely excluded by genetic testing. Because of the implications of a positive test, it is usually wise to involve clinical genetics services prior to making a diagnosis.
- There is currently no cure for HD, although survival may be prolonged in some patients. Gene therapy trials hoping to modify the disease course are in progress.

Multiple sclerosis (MS)

Overview

MS is a chronic, relapsing, and remitting or progressive disease of the central nervous system (CNS) that involves both inflammatory/demyelinating and neurodegenerative processes. Symptoms are typically motor or sensory and intermittent and unpredictable to start with, later becoming progressive and disabling, but the disease course in MS is extremely variable. Most commonly, the initial pattern is of attacks affecting different sites in the CNS at different times, but with good recovery between attacks (relapsing-remitting MS). However, after a period of years, recovery after attacks tends to be less complete, leading to a gradual accumulation of fixed disability, followed later by steady deterioration irrespective of the frequency or severity of acute attacks (secondarily progressive MS). Occasionally, patients follow a steadily progressive course from disease onset (primary progressive MS). It is tempting to assume that reducing the frequency or severity of acute attacks would retard the progression of disability in MS, but unfortunately this is not necessarily the case. Increasingly, evidence suggests that neurodegeneration is taking place alongside inflammatory/demyelinating changes from an early stage (Chard et al., 2002). A primary progressive course, particularly with motor symptoms, may be more common in late-onset disease.

Epidemiology

The prevalence of MS varies widely according to geography and ethnic group, with the highest rates in populations of northern European descent. In a longitudinal study over 15 years in Olmstead County,

Neurological dementias

Minnesota, the prevalence of MS was 177 per 100,000 of the adult population (Mayr et al., 2003); in a similar longitudinal study in Cambridge, UK, the prevalence was 152 per 100,000 (Robertson et al., 1996). MS is the commonest neurological disorder of young adults in the UK, with disease onset typically between the ages of 15 and 50 years. Later onset MS (age more than 50 years) is well recognized, although there is no consensus as to whether this refers to age at first symptoms or at diagnosis, and onset (however defined) is still usually before the age of 65 years. In a retrospective Israeli study of 640 patients cared for at a specialist MS centre, 30 (4.6%) had their first symptoms after the age of 50 (mean 53.5 years, SD 3.1, range 50–62) (Polliack et al., 2001), while a similar single-centre German study identified 52 patients over a ten-year period aged over 50 years at diagnosis (mean 57 years, SD 7, range 50–82) (Kis et al., 2008).

However, while MS presenting *de novo* to old age psychiatry with predominantly cognitive symptoms and onset after the age of 65 years is uncommon, two other scenarios are possible. First, patients with established MS may develop dementia in later life, either due entirely to their MS, additional degenerative disease, or a combination of both. In any of these situations, accurate diagnosis and management is likely to be more challenging. Second, the possibility of demyelinating disease may be raised on imaging investigations of dementia, especially with the sensitivity of MRI for white matter abnormalities. Over the age of 50 years, white matter changes are much more likely to be due to vascular disease than demyelination, but once the possibility of MS has been raised, careful clinical evaluation may be needed to exclude it.

Clinical features

Acute inflammatory/demyelinating attacks in MS may affect any site within the CNS, giving rise to an enormous breadth of possible clinical manifestations. The commonest symptoms involve motor, sensory, cerebellar, and visual/oculomotor systems, but neuropsychiatric and cognitive disturbance are also well described. The commonest neuropsychiatric disturbance is mood disorder (euphoria, mania, or depression); psychosis is rare, but recognized. Cognitively, impairment is generally most marked on tests of attention, processing speed, and executive function, followed by impairment on tests of verbal memory (recall more so than recognition). Language functions are generally better preserved, and frank aphasia secondary to MS is rare. In keeping with the presumed frontal/subcortical basis of this profile of deficits, a good predictor of cognitive impairment in MS is the degree of frontal lobe atrophy (Benedict et al., 2002). Cognitive impairment may occasionally be the presenting or only manifestation of MS (Zarei et al., 2003).

Investigations

The key investigation in suspected MS is an MRI scan, typically showing multiple high signal white matter lesions (Trip and Miller, 2005).

Neurological dementias

However, as mentioned, high signal white matter lesions are a common finding in old age and may be entirely non-specific or reflect vascular disease. Radiological features that might specifically suggest demyelination include an ovoid shape to the lesions; involvement of the corpus callosum, brainstem, and cerebellum; and enhancement after contrast when lesions are acute (see Fig. 34.3); diagnostic criteria specify the profile of expected MRI abnormalities in MS very closely (McDonald et al., 2001; Thompson et al., 2017). Other supportive investigation results include unilateral or bilateral delay on visual evoked potentials (VEPs) and positive oligoclonal bands in CSF (but not serum) at lumbar puncture. Assessment of suspected MS and access to these secondary investigations will usually require referral to local neurology services.

Fig. 34.3

MRI findings in MS. (Left) Axial FLAIR sequence showing multiple high signal periventricular white matter lesions, some transversely oriented; (Right) axial T1-weighted sequence showing that some of these lesions enhance after gadolinium, indicating active disease.

Reproduced with permission from Trip, S. A. and Miller, D. H. Imaging in multiple sclerosis. *J Neurol Neurosurg Psychiatry*, 76 (S3): iii11-18. Copyright © 2005, *British Medical Journal*. <http://dx.doi.org/10.1136/jnnp.2005.073213>.

Treatment and outcome

There is no curative treatment for MS. For acute relapses, a short course of corticosteroids may speed recovery but has no impact on the development of later disability. For patients with frequent disabling relapses, disease-modifying treatments are now available. The beta-interferons and glatiramer acetate reduce relapse rates by approximately a third; agents in development such as alemtuzumab may reduce relapse rates by up to two-thirds. However, once again, the impact of these treatments on the development of eventual disability remains to be shown, and all may be associated with significant side effects. Given the frontal/subcortical profile of deficits in dementia associated with MS, it

Neurological dementias

might be expected that cognitive rehabilitation would be of benefit, but systematic studies in this area are lacking.

Key Points: Multiple Sclerosis

- MS may be associated with a variety of cognitive and psychiatric disturbances including dementia.
- MS is an uncommon cause of dementia in old age, but might be suspected in a patient with a clinically isolated syndrome or established MS in middle life who later goes on to develop a frontal-subcortical pattern of cognitive impairment.
- The key test in suspected MS is an MRI scan, but distinguishing between demyelination and vascular disease in old age can be difficult, and specialist assessment and/or secondary investigations (evoked potentials and CSF examination) are likely to be required for a definite diagnosis.

Antibody-mediated encephalitis

Overview

Antibody-mediated encephalitis is an umbrella term for a rapidly expanding group of inflammatory central nervous system disorders, commonly involving subacute cognitive impairment, behavioural disturbance, seizures, and movement disorder in association with autoantibodies against neuronal cell surface proteins, ion channels, or synaptic antigens. The spectrum is broad—some types of antibody-mediated encephalitis may present with a rapidly progressive dementia with neurological signs, while other types may present with purely psychiatric symptoms, at least in the early stages. Another key characteristic is that if recognized early, many of these disorders are potentially treatable.

The background to the discovery of the antibody-mediated encephalitides was the recognition over 50 years ago of the syndrome of limbic encephalitis (LE), with behavioural disturbance, memory impairment, and seizures related to inflammation of the limbic system. In the 1960s Brierley and colleagues (1960) reported three patients with non-specific prodromal symptoms, progressive cognitive impairment, coma, and death 3–14 months after onset; one patient additionally had focal seizures of temporal lobe origin. At post-mortem all showed evidence of a subacute encephalitis, mainly affecting the limbic system; one patient had malignant infiltration of mediastinal lymph nodes suggesting bronchial carcinoma. Corsellis and colleagues (1968) later reported three similar patients with prominent severe memory impairment and death up to 24 months after onset; two had focal and secondarily generalized seizures. All patients had encephalitis at post-mortem and underlying bronchial carcinoma. Investigators speculated at the time that the neurological

Neurological dementias

syndrome might be an immunological reaction to the underlying cancer and subsequently a range of anti-neuronal antibodies were described in patients with LE and a tumour, principally anti-Hu in patients with small cell lung cancer (Dalmau et al., 1992); anti-Ma2 in patients with testicular tumours (Voltz et al., 1999); and anti-CV2/CRMP5 in patients with thymoma (Antoine et al., 1995). The discovery of these antibodies gave hope that patients with LE could be treated, but the response to immune therapy was generally disappointing and indeed it was uncertain as to whether the antibodies in these paraneoplastic conditions were truly pathogenic (Dalmau et al., 1992).

However, it was then recognized that some patients with LE showed antibodies of a quite different type, directed not against intracellular antigens but against cell surface ion channels such as the voltage gated potassium channel (VGKC). Furthermore, these antibodies were much less likely to be associated with cancer and the response to immune treatment could be very good (Thieben et al., 2004; Vincent et al., 2004). Subsequent work has identified that in fact anti-VGKC antibodies are directed against a range of VGKC-associated proteins rather than against the channel itself: key targets include LGI-1 (leucine-rich, glioma-inactivated protein 1), CASPR2 (contactin-associated protein 2) (Irani et al., 2010; Lai et al., 2010) and, less commonly, DPPX (dipeptidyl-peptidase-like protein) (Boronat et al., 2013). Finally, in the past decade the field of antibody-mediated encephalitis has exploded with the discovery of a whole range of novel antibodies directed against synaptic targets, e.g. the NMDA receptor (Dalmau et al., 2007; Dalmau et al., 2008), AMPA receptor (Lai et al., 2009) and the GABA-B (Lancaster et al., 2010; Hoftberger et al., 2013) and GABA-A receptors (Petit-Pedrol et al., 2014; Spatola et al., 2017). Some of these newer syndromes are less likely to present to psychiatrists (e.g., anti-GABA-B and anti-GABA-A encephalitis generally present with prominent seizures or new onset status epilepticus), but anti-NMDA receptor encephalitis is notable because it is quite distinct from typical LE and often has a psychiatric prodrome. For an up-to-date review, see Dalmau and Graus (2018)—key differences between the major antibodies discussed are summarized in Table 34.2 (not an exhaustive list).

Table 34.2 Antibodies associated with antibody-mediated encephalitis

Antibody	Commonly associated neurological syndrome(s)	Association with underlying cancer	Response to treatment (immune therapy or cancer removal)
Antibodies against ion channels			

Neurological dementias

LGI-1	Typical LE Facio-brachial dystonic seizures	5-10% Thymoma	Excellent if immunotherapy instituted early
CASPR2	Typical LE	20-50% Thymoma	Variable
DPPX	Encephalitis with an exaggerated startle response	<10% Lymphoma	Requires prolonged therapy, may relapse
Other antibodies against cell-surface antigens			
Anti-NMDA receptor	Psychosis, cognitive and behavioural change, distinct from typical LE	Ovarian teratomas (younger women)	Improvement in up to 60%, but recovery typically prolonged
Anti-AMPA	LE	60-70% Thymoma, SCLC	Requires prolonged therapy, may relapse
Anti-mGluR5	Encephalitis	70% Hodgkin's lymphoma	Requires prolonged therapy, may relapse
Against intracellular antigens			
Anti-Hu	LE Cerebellar ataxia Subacute sensory neuropathy	SCLC (>90%)	Poor
Anti-Ma2	LE Brainstem encephalitis	Testicular germ-cell tumours (younger men) Non-SCLC, breast	Good in up to 30% (typically younger men with testicular germ- cell tumours)

Neurological dementias

Anti-CV2/ CRMP5	LE Cerebellar ataxia Subacute sensory neuropathy	SCLC (>70%) Thymoma	Poor

LE, limbic encephalitis; VGKC, voltage gated potassium channel; LGI-1, leucine-rich, glioma-inactivated protein 1; CASPR2, contactin-associated protein 2; DPPX, dipeptidyl-peptidase-like protein; NMDA, N-methyl-D-aspartate; SCLC, small cell lung cancer.

Epidemiology

The incidence of antibody-mediated encephalitis is unknown. A prospective study of encephalitis in 24 hospitals in England between 2005 and 2008 gave an incidence for all forms of encephalitis (infectious and autoimmune) of between 2.73 and 8.66 cases/100,000/year depending on the modelling assumptions, with a best estimate of 5.23 cases/100,000/year (Granerod et al., 2010). Of 203 patients with encephalitis, 86 patients (42%) had infectious causes, including 38 (19%) with herpes simplex virus (HSV); while 42 patients (21%) had an immune mediated cause, including 16 (8%) with either anti-VGKC or anti-NMDA receptor antibodies (Granerod et al., 2010). These figures suggest that antibody-mediated encephalitis is less common than HSV encephalitis, but in a US study of 761 individuals with encephalitis referred to the California Encephalitis Project from 2007 to 2011, anti-NMDA receptor encephalitis was four times as common as HSV (Gable et al., 2012). After NMDA, anti-LGI1 encephalitis is probably the next most common individual antibody detected (van Sonderen et al., 2017). It is also notable that 75 patients (37%) in the UK prospective study had an unknown cause for their encephalitis. Given the range of new antibodies described in the last decade it is plausible that at least some of these patients had an undiagnosed antibody-mediated encephalitis.

Antibody-mediated encephalitis affects patients of all ages, although some forms such as anti-NMDA receptor encephalitis predominantly affect a younger age group. In a large, retrospective US study of encephalitis-related hospitalizations between 1998 and 2010 the estimated mortality rate for all causes of encephalitis was 5.8% (95% CI 5.6–6.0%), with a higher mortality of 17.1% (95% CI 14.6–20.0%) for patients with HIV infection, or a history of organ transplant (Vora et al., 2014). There is no single figure for mortality related specifically to antibody-mediated encephalitis, reflecting the heterogeneity of the condition and the rapidly expanding range of treatments available.

Neurological dementias

Clinical features

Recognizing antibody-mediated encephalitis can be difficult. Sometimes it presents with a well-specified clinical syndrome such as classical limbic encephalitis, with subacute onset of behavioural disturbance, memory impairment, and seizures. When all features are present, LE is unlikely to be mistaken for a primary degenerative dementia. However, when features are present in isolation the diagnosis is more challenging. Anti-LGI1 limbic encephalitis may present with rather subtle memory disturbance and brief, lateralised spasms of the face and upper limb known as facio-brachial dystonic seizures. Anti-NMDA receptor encephalitis presents differently to classical LE, with more prominent psychiatric disturbance, followed by a variety of hyperkinetic movement disorders, and eventually coma.

Investigations

A common clinical problem is that even when an antibody-mediated encephalitis is suspected, it can be weeks before confirmatory autoantibody test results are available. Therefore, if suspicion is high enough, and key investigations such as MRI, CSF examination, and EEG are supportive, clinicians may choose to start treatment presumptively while waiting for the confirmatory tests.

Patients with anti-VGKC complex antibodies and classical LE tend to show abnormal high signal in the medial temporal lobes on MRI. However, imaging in patients with early disease or isolated clinical features, e.g. facio-brachial dystonic seizures, may be normal. In anti-NMDA receptor encephalitis imaging may be normal or show predominantly extratemporal abnormalities. The findings in paraneoplastic LE are variable. Typical MRI findings in patients with paraneoplastic and anti-VGKC complex antibody-associated LE are illustrated in Fig. **34.4**.

Neurological dementias

Fig. 34.4

MRI findings in LE. (A) Axial FLAIR sequence in paraneoplastic LE showing bilateral mesial temporal high signal change; (B) coronal FLAIR sequence in anti-voltage gated potassium channel LE showing high signal change in the hippocampi bilaterally (arrows).

B: Reproduced with permission from Schott, J. M. Limbic encephalitis: a clinician's guide. *Practical Neurology*, 6(3): 143–153. Copyright © 2006 *Journal of Neurology Neurosurgery and Psychiatry*. DOI: <http://dx.doi.org/10.1136/jnnp.2006.091827>.

CSF examination may show a variety of abnormalities in all forms of antibody-mediated encephalitis, including a lymphocytosis or pleocytosis, raised protein, and (occasionally) unmatched CSF oligoclonal bands.

EEG may confirm focal cerebral dysfunction or epileptiform activity but is rarely specific for antibody-mediated encephalitis, except in the case of anti-NMDA receptor encephalitis where it may show a characteristic 'extreme delta brush' abnormality.

Combining clinical information with MRI, CSF, and EEG results, typical LE can be diagnosed and treatment started before confirmatory autoantibody test results are available. When typical features are missing, a confirmatory autoantibody test result is required. Probable anti-NMDA receptor encephalitis can be diagnosed from the combination of clinical information, CSF, and EEG results, but a definite diagnosis always requires a positive anti-NMDA antibody test (see Table 34.3).

Table 34.3 Clinical presentation, typical investigation findings, and suggested diagnostic criteria for limbic encephalitis and anti-NMDA receptor encephalitis

	Limbic encephalitis	Anti-NMDA receptor encephalitis

Neurological dementias

Clinical presentation	Subacute onset¹ of symptoms suggesting involvement of the limbic system: • memory deficits • seizures • psychiatric symptoms	Subacute onset¹ of symptoms from the following six major groups of symptoms: • Abnormal (psychiatric) behaviour or cognitive dysfunction • Speech dysfunction (pressured speech, verbal reduction, mutism) • Seizures • Movement disorder, including dyskinesias or rigidity/abnormal postures • Decreased level of consciousness • Autonomic dysfunction or central hypoventilation
MRI	Bilateral brain abnormalities on T2-weighted fluid-attenuated inversion recovery MRI highly restricted to the medial temporal lobes ²	May be normal, or show extra-temporal abnormalities
CSF	CSF pleocytosis ³	CSF pleocytosis ³ or oligoclonal bands
EEG	Abnormal EEG with epileptic or slow-wave activity involving the temporal lobes	Abnormal EEG (focal or diffuse slow or disorganised activity, epileptic activity, or extreme delta brush)

Neurological dementias

Diagnosis	Definite limbic encephalitis: Requires all four of 1. Typical clinical presentation as above 2. Bilateral temporal lobe abnormalities on MRI (or ¹⁸F-FDG PET) 3. Either CSF or EEG changes as above, or both 4. Reasonable exclusion of alternative causes If one of the first three criteria is not met, then a diagnosis of definite limbic encephalitis can only be made with the detection of antibodies against cell-surface, synaptic, or onconeural proteins	Probable anti-NMDA encephalitis: Requires all three of 1. Typical clinical presentation as above 2. Either CSF or EEG changes as above, or both 3. Reasonable exclusion of alternative causes Or: Systemic teratoma plus one or more symptom groups Definite anti-NMDA encephalitis can be diagnosed with one or more of the six major groups of symptoms above plus positive IgG anti-NMDA receptor antibodies,⁴ after reasonable exclusion of alternative causes

¹ Less than three months

² ¹⁸Fluorodeoxyglucose (¹⁸F-FDG) PET can be used to fulfil this criterion, by showing an increase in FDG uptake in normal-appearing medial temporal lobes

³ CSF white blood cell count of more than five cells per mm³

⁴ Antibody testing should include testing of CSF. If only serum is available, confirmatory tests should be included (eg, live neurons or tissue immunohistochemistry, in addition to cell-based assay). Source: data from Graus, F. et al. (2016) A clinical approach to diagnosis of autoimmune encephalitis *Lancet Neurol* 15(4):391-404. doi: 10.1016/S1474-4422(15)00401-9.

When should psychiatrists suspect antibody-mediated encephalitis?

Psychiatric disorder is common in antibody-mediated encephalitis (Schott, 2006). In a German study of 100 patients diagnosed with autoimmune encephalitis at a specialist centre, psychiatric symptoms were the

Neurological dementias

commonest individual clinical feature; psychiatric symptoms were the first feature in 60% of patients; and one third of patients were initially hospitalized on a psychiatric ward (Herken and Pruss, 2017). However, discriminating early antibody-mediated encephalitis from a primary psychiatric disorder is challenging. The authors of the study above suggest several 'yellow flags' that may point to an autoimmune cause in new onset psychosis, including rapid progression despite therapy, headache, autonomic instability, focal neurological symptoms, hyperkinetic movement disorders, catatonia, reduced consciousness, hyponatraemia, and a past medical history of other autoimmune disease. In such cases antibody-mediated encephalitis should at least enter the differential. Facio-brachial dystonic seizures, generalized seizures, and suspected malignant neuroleptic syndrome are clear red flags and should prompt assessment with MRI, EEG, CSF examination, and antibody testing. With increased awareness of these conditions, and wider availability of antibody testing, diagnoses are being made more rapidly—in Herken and Pruss's study, for patients presenting between 2007 and 2012, the mean time from first symptoms to diagnosis was 483 days, compared to 74 days for patients presenting between 2013 and 2016. The as-yet unanswered question is whether antibody-mediated encephalitis is a significant cause of wholly psychiatric presentations with no atypical features such as first episode psychosis. In a prospective study of 228 patients with first episode psychosis and 105 healthy controls, 20 patients (9%) had positive antibodies compared to four controls (4%). Overall, this difference was not significant, but seven of the 20 patients had anti-NMDA receptor antibodies compared to none of the controls, raising the possibility that at least some patients with first episode psychosis have an autoimmune cause (Lennox et al., 2017).

Treatment and outcome

As indicated in Table 34.2, response to treatment in antibody-mediated LE very much depends on the associated antibody and whether the disorder is paraneoplastic. Patients with anti-LGI-1 antibodies and no underlying cancer respond the best to immunotherapy, which might include steroids, intravenous immunoglobulin, plasma exchange, and rituximab. However, if treatment is delayed, hippocampal atrophy may develop and clinical deficits become permanent. Seizures in LE tend to be rather resistant to conventional anti-epileptic drug treatment.

Key Points: Antibody-Mediated Encephalitis

- LE is a condition in which relatively selective inflammation or dysfunction of the limbic system leads to behavioural disturbance, subacute memory impairment, and seizures, classically associated with medial temporal lobe abnormalities on MRI.
- Anti-VGKC antibody-associated LE due to anti-LGI-1 antibodies tends to present with a full spectrum of clinical features,

Neurological dementias

together with abnormalities on imaging, sometimes abnormalities on EEG and CSF examination, and often abnormalities of serum sodium; it may respond favourably to immune treatment if instituted early enough. Anti-CASPR-2 VGKC disease is more likely to be paraneoplastic and resistant to immunotherapy.

- Anti-NMDA receptor encephalitis presents rather differently to typical LE, with more psychiatric disturbance initially, sometimes relatively normal investigations, and a very variable course.
- Paraneoplastic LE is associated with a variety of antibodies to intracellular antigens, may be accompanied by other neurological syndromes such as sensory neuropathy and cerebellar ataxia, and tends to be resistant to treatment.

Prion diseases

Overview

The prion diseases are a heterogeneous group of disorders, neuropathologically characterised by the abnormal folding and accumulation of prion protein with accompanying spongiform degeneration. Prion diseases are rare but can present in a wide variety of ways, including with purely psychiatric symptoms.

Prion diseases develop by three mechanisms: spontaneously (sporadic); through exposure to affected tissue from the same or another species (acquired); and because of genetic mutations in the prion protein gene (familial). The majority of prion disease (~85%) is sporadic, involving the spontaneous conversion of normal cellular prion protein (PrP^C) into an abnormally folded and protease-resistant isoform (PrP^{Sc}). Abnormally folded PrP^{Sc} then acts as a template for the conversion of further PrP^C, and the process continues exponentially. As PrP^{Sc} accumulates there is accompanying neurodegeneration, and inexorable clinical progression; the commonest presentation of sporadic prion disease is a rapidly progressive dementia with ataxia and myoclonus (classical sporadic Creutzfeldt-Jakob disease, or sCJD). In acquired prion disease the conversion process is triggered by inadvertent exposure to abnormally folded PrP^{Sc}: either human-derived (causing iatrogenic CJD and the historical condition of *kuru* in the Fore people of Papua New Guinea), or bovine-derived (causing the completely distinct condition of variant CJD, or vCJD).

Phenotypic variability in sporadic and acquired prion diseases is influenced by multiple factors, particularly the pattern of polymorphisms in the prion protein gene (PRNP) and the physico-chemical properties of the accumulating PrP^{Sc}. For example, a common PRNP polymorphism at codon 129, while not being specifically disease-causing, strongly

Neurological dementias

determines susceptibility to sCJD (Worrall et al., 1999): individuals who are homozygous for methionine (MM; 42% of the UK population) or valine (VV; 11%) are significantly more susceptible than individuals who are heterozygous (MV; 47%). At a molecular level, following limited protease digestion, at least two (Parchi et al., 1999), or four (Hill et al., 2003) different PrP^{Sc} isoforms can be identified, each linked to a distinct group of prion diseases. Combined with the pattern of PRNP codon 129 polymorphisms and the findings on histopathological examination, researchers have suggested various classificatory systems for the resulting prion *strains* (Gambetti et al., 2011; Wadsworth and Collinge, 2011; Parchi et al., 2011), but thus far none have been universally accepted (see Brandner, 2011; Cali et al., 2006 for a comparison). None of these systems can currently account for the finding of different prion strains in different brain areas in the same individual, nor accommodate familial prion diseases where the patho-biochemical properties of the accumulating prion protein are quite different to sporadic and acquired prion disease.

Iatrogenic CJD arises because although PrP^{Sc} is not a conventional infectious agent, exposure to human tissues or fluids containing PrP^{Sc} can initiate the process of PrP^C-to-PrP^{Sc} conversion in the recipient. The vast majority of cases of iatrogenic CJD to date have been reported either in patients exposed to PrP^{Sc}-contaminated human-derived growth hormone (prior to 1985), or patients receiving PrP^{Sc}-contaminated cadaveric dura mater grafts in neurosurgical procedures (prior to 1992). Transmission has also been reported with PrP^{Sc}-contaminated corneal grafts and neurosurgical instruments such as EEG depth electrodes.

vCJD arises because in certain circumstances transmission may even take place across species, leading to one of the most worrying UK public health disasters of recent decades. Scrapie, an endemic prion disease of sheep and goats in the UK, was never previously thought to be directly transmissible to humans. However, when nervous tissue from scrapie-affected sheep found its way into cattle feed, it sparked an epidemic of a novel prion disease of cattle in the UK in the 1980s and 1990s, termed bovine spongiform encephalopathy (BSE). Eventually, the total number of cattle definitely diagnosed with BSE in the UK was nearly 200,000, but the true number is likely to have been much higher; in total, four million asymptomatic cattle were slaughtered to halt the epidemic. During this time, over 600,000 cattle affected with BSE likely entered the human food chain (Anderson et al., 1996).

It was not long before patients with a novel type of CJD were recognized, often with purely psychiatric symptoms in the initial stages (Bateman et al., 1995; Britton et al., 1995). One of the key differences between classical sporadic CJD and vCJD is that tissues outside the nervous system can be affected. The BSE prion protein is hypothesized to enter the body through the gut, and PrP^{Sc} deposition can be seen in lymphoid tissue at a variety of sites, including the appendix (Hilton et al., 1998) and the tonsils. This also means that vCJD can potentially be transmitted between

Neurological dementias

humans by exposure to affected non-nervous tissue, including via blood transfusion (Llewelyn et al., 2004).

Finally, approximately 10–15% of prion disease is familial, secondary to a variety of genetic abnormalities in the PRNP: including point mutations in the C-terminal domain, premature stop codon mutations, and the insertion of octapeptide repeats in the N-terminal domain. Different mutations can be associated with very different clinical phenotypes.

Epidemiology

Classical sCJD, the commonest form of human prion disease, has an approximate annual incidence of 1–2 per million population. There is little or no variation in incidence across geographical boundaries or ethnic groups. The mean age at onset is approximately 65 years (range 42–91), with a mean duration to death of four months (range 1–18) (Parchi et al., 1999).

Approximately 226 cases of iatrogenic CJD related to human-derived growth hormone and 228 cases related to dura mater grafts have been reported worldwide. The incidence has fallen steadily since the transmission risks were recognized in the 1980s/1990s, but iatrogenic CJD related to cadaver-derived growth hormone exposure can have an extremely long incubation period (range 5–42 years; mean 17 years); therefore, even though this treatment was stopped in 1985, cases still occur occasionally. Since 2013, four patients have died in the UK with definite or probable iatrogenic CJD (<http://www.cjd.ed.ac.uk/sites/default/files/figs.pdf>, accessed 12 March 2018). The incubation time may also be influenced by genetic factors. In a UK cohort of patients with growth hormone derived iatrogenic CJD, individuals with a PRNP codon 129 VV genotype tended to have a much shorter incubation period than those with MV or MM genotypes; this perhaps suggests that the contaminated tissue came from a patient with a VV subtype of sporadic CJD (Rudge et al., 2015). Survival in iatrogenic CJD related to cadaver-derived growth hormone exposure tends to be longer than sporadic CJD with death after 5–42 months (mean 14 months). Most of the contaminated dura mater grafts were implanted outside of the UK (two-thirds in Japan).

The mean age of onset in vCJD has so far been much earlier than for classical sCJD (median 27 years), but old age psychiatrists should not be complacent—of the first 100 patients with vCJD, the oldest was aged 74 years (Spencer et al., 2002). To date (March 2018), 178 cases of definite or probable vCJD have been reported in the UK, all of whom have died (with pathological confirmation of the diagnosis in 123 patients; <http://www.cjd.ed.ac.uk/sites/default/files/figs.pdf>, accessed 12 March 2018). From a peak of 28 deaths from definite or probable vCJD in 2000 the incidence rate has been steadily falling, with only two deaths in the past five years and no new diagnoses since 2014. On the face of it, a major epidemic of vCJD now looks unlikely, but we cannot be entirely complacent. First, a UK-wide anonymized study of appendix samples from

Neurological dementias

operations in England between 2000 and 2012 found 16 samples positive for PrP^{Sc} out of 32,441 specimens; a prevalence of one in 2,000 (Gill et al., 2013). By extrapolation, there are tens of thousands of people in the UK who have been exposed to BSE prion protein but have not so far developed neurological disease. Second, all 177 patients diagnosed with definite or probable vCJD in the UK up until 2014 were homozygous for methionine (MM) at codon 129 of the PRNP gene. However, the 178th patient in the UK was heterozygous for methionine and valine (MV) (Mok et al., 2017). This raises the possibility that there may be a second wave of the vCJD epidemic still to come, affecting patients with an MV (or VV) genotype who have a longer incubation period. Finally, there is the potential risk of vCJD through blood transfusion. In the UK, 67 individuals are known to have received non-leukodepleted packed red cell transfusions from 18 patients who later developed definite or probable vCJD. To date, three of these recipients are believed to have contracted vCJD as a consequence: one with clinical disease diagnosed after death (Llewelyn et al., 2004), one with clinical disease diagnosed in life (Wroe et al., 2006), and a third patient with clinical disease notified in 2007. One further individual known to have been exposed to contaminated packed red cells died from non-neurological causes and was found to have abnormal PrP^{Sc} in his spleen and a lymph node at post-mortem (Peden et al., 2004). Finally, one individual with haemophilia who had received pooled factor VIII concentrate known to include donations from a patient with vCJD also showed abnormal PrP^{Sc} in his spleen at post-mortem (Peden et al., 2010). There have been no further clinical cases since 2007, and together with the measures put in place by UK blood transfusion services since the 1990s it is hoped that there will be no further transfusion-related transmissions. However, given the likelihood of a large pool of asymptomatic infected individuals and potentially long incubation times, further cases cannot be ruled out (Urwin et al., 2016).

Clinical features

Sporadic CJD classically presents with a rapidly progressive dementia with ataxia and myoclonus (>50% of cases), but alternative presentations are well recognized. Sometimes patients present with a pure cognitive syndrome (~15%), pure ataxia (~1%), visual disturbance (~5%), or psychiatric disorder (~5%) (Mead and Rudge, 2017). Iatrogenic CJD related to growth hormone exposure often presents with ataxia rather than a rapidly progressive dementia.

The typical clinical phenotype of vCJD is quite distinct from classical sCJD. In a retrospective case notes analysis of the first 100 patients diagnosed with vCJD in the UK, psychiatric symptoms were the first feature in 63 patients; neurological symptoms were the first feature in 15; and in the remaining 22 both psychiatric and neurological features were present from onset (Spencer et al., 2002). Common, early (<4 months from onset) psychiatric symptoms included dysphoria, withdrawal, anxiety, irritability, insomnia, and loss of interest. Agitation and aggression were common later symptoms. There was a wide range of

Neurological dementias

rarer later psychiatric symptoms, including hallucinations, paranoid delusions, confabulation, and bizarre behaviours. Early neurological symptoms were uncommon and non-specific; for example, persistent, unpleasant pain without sensory disturbance affecting the limbs, face, or trunk. However, all patients subsequently developed neurological features; most commonly ataxia and dysarthria, with cognitive impairment later (median 4–7.5 months from onset).

The clinical features of inherited prion disease depend on the specific PRNP mutation. The E200K point mutation (the commonest mutation worldwide) results in a phenotype that is indistinguishable from classical sCJD. About a dozen different point mutations result in the phenotype of Gerstmann-Sträussler-Scheinker syndrome (GSS); a slowly progressive ataxia or parkinsonian syndrome with later dementia, often with prolonged survival. The D178N point mutation, combined with an M polymorphism at codon 129 of the affected gene, causes the rare syndrome of fatal familial insomnia (FFI), in which patients develop severe progressive insomnia followed by autonomic disturbance, with cognitive disturbance much later. Premature STOP codon mutations can present as progressive dementia with prolonged survival, mimicking Alzheimer's disease or frontotemporal dementia. Finally, octapeptide repeat insertion mutations may present with a classical sporadic CJD phenotype or GSS phenotype, depending on the repeat length.

Investigations

Box 34.1 shows the current European MRI-CJD Consortium criteria for the diagnosis of sporadic CJD (Zerr et al., 2009), which combines clinical criteria with the results of MRI, EEG, and CSF examination for the 14-3-3 protein.

Box 34.1 European MRI-CJD Consortium criteria for the diagnosis of sporadic CJD

Rapidly progressive dementia (obligatory) plus

I. Clinical signs

- 1 Myoclonus
- 2 Cerebellar or visual
- 3 Pyramidal or extrapyramidal
- 4 Akinetic mutism

II. Tests

- 1 PSWCs in EEG
- 2 14-3-3 detection in CSF

Neurological dementias

3 High signal abnormalities in caudate nucleus and striatum or at least two cortical regions (temporal-parietal-occipital) either in DWI or FLAIR

Probable CJD

Rapidly progressive dementia and two out of I and at least one out of II

Possible CJD

Rapidly progressive dementia and two out of I and duration less than two years

PSWCs, positive sharp wave complexes; DWI, diffusion-weighted imaging; FLAIR, fluid-attenuated inversion recovery

Reproduced with permission from Zerr, I., and Kallenberg, K. Updated clinical diagnostic criteria for sporadic Creutzfeldt-Jakob disease. *Brain*, 132(10): 2659–68. Copyright© The Author(s) 2009. Published by Oxford University Press on behalf of Brain. DOI: <https://doi.org/10.1093/brain/awp191>.

Typically, in classical sCJD, DWI sequences show high signal change in the caudate and putamen, or multiple areas of the cortical ribbon (see Fig. **34.5**); the EEG is abnormal, classically with periodic sharp wave complexes (PSWCs); and at lumbar puncture, basic CSF constituents are normal, with negative oligoclonal bands, but raised CSF 14-3-3 protein levels. However, none of these tests are 100% sensitive and specific for sCJD; in particular, the 14-3-3 protein is just a marker for severe neuronal injury.

Neurological dementias

Fig. 34.5

MRI findings in sporadic and variant CJD. (A) Coronal FLAIR sequence in sporadic CJD, showing bilateral hyperintensity of caudate and putamen (arrows), but no signal change within the thalami; (B) coronal FLAIR sequence in variant CJD, showing the opposite pattern with bilateral hyperintensity of the thalami (arrows), but no signal change within caudate and putamen; (C) coronal FLAIR sequence in sporadic CJD, showing no deep nuclear changes but patchy bilateral hyperintensity of the cortical ribbon.

However, in the last few years a more specific test for the presence of misfolded prion protein has been developed: the real-time quaking-induced conversion test, or RT-QuIC. This test detects PrP^{Sc} by its ability to initiate the conversion of normal cellular PrP^C to misfolded PrP^{Sc} in vitro. Early studies showed that this method was similar in sensitivity but had superior specificity compared to 14-3-3 analysis (McGuire et al., 2012); second-generation RT-QuIC testing is up to 96% sensitive and 100% sensitive from CSF samples, can even be applied to nasal brushings (Zanusso et al., 2016), and is likely to replace 14-3-3 CSF analysis in future consensus criteria. The gold standard in sCJD is neuropathological examination with direct demonstration of abnormal PrP^{Sc} in brain tissue.

Investigation results in patients with vCJD are different to patients with sCJD. The EEG doesn't usually show the typical changes of sCJD, CSF 14-3-3 (and RT-QuIC) testing may be negative, and the pattern of MRI changes is different with high signal in the pulvinar nucleus of the thalamus (Mihara et al., 2005; see Fig. 34.5). As in sCJD, the gold

Neurological dementias

standard is neuropathological confirmation of abnormal PrP^{Sc} in brain tissue, but as vCJD also affects lymphoid tissue outside of the CNS tonsillar biopsy in life may also be helpful in supporting a diagnosis (see Box 34.2).

Box 34.2 World Health Organization criteria for the diagnosis of variant Creutzfeldt-Jakob disease

I	A	Progressive neuropsychiatric disorder
	B	Duration of illness >6 months
	C	Routine investigations do not suggest an alternative diagnosis
	D	No history of potential iatrogenic exposure
	E	No evidence of a familial form of TSE
II	A	Early psychiatric features ^a
	B	Persistent painful sensory symptoms ^b
	C	Ataxia
	D	Myoclonus or chorea or dystonia
	E	Dementia
III	A	EEG does not show the typical appearance of sCJD in the early stages of illness ^c
	B	Bilateral pulvinar high signal on MRI scan
IV	A	Positive tonsil biopsy ^d

Definite: IA and neuropathological confirmation of vCJD^e

Probable: I and 4/5 of II and IIIA and IIIB; or I and IVA.

Possible: I and 4/5 of II and IIIA.

^a Depression, anxiety, apathy, withdrawal, delusions.

Neurological dementias

^b This includes frank pain and/or dysesthesia.

^c The typical appearance of the EEG in sCJD consists of generalized triphasic periodic complexes at approximately one per second. These may occasionally be seen in the late stages of vCJD.

^d Tonsil biopsy is not recommended routinely, nor in cases with EEG appearances typical of sCJD, but may be useful in suspect cases in which the clinical features are compatible with vCJD and MRI does not show bilateral pulvinar high signal.

^e Spongiform change and extensive prion protein deposition with florid plaques throughout the cerebrum and cerebellum.

vCJD—variant Creutzfeldt-Jakob disease; TSE—transmissible spongiform encephalopathy; EEG—electroencephalography; MRI—magnetic resonance imaging.

(World Health Organization, 1998)

A blood test for vCJD would be invaluable—either as a non-invasive test for patients with suspected clinical disease or to screen for preclinical infection—but the low level of PrP^{Sc} in blood makes this technically challenging. Candidate assays developed so far are highly specific for vCJD in clinically affected individuals but are not sensitive enough to use as a screening test (Edgeworth et al., 2011; Jackson et al., 2014). The key test in familial prion disease is obviously sequencing of the PRNP gene. In the UK, advice on the investigation and management of patients with suspected prion disease can be obtained through regional neurology services or the National Prion Clinic.

Treatment and outcome

There is no curative treatment for prion disease and all forms are ultimately fatal. Life-expectancy in classical sCJD is usually measured in weeks to months, but survival in vCJD or familial prion disease may sometimes be prolonged. Symptoms such as myoclonus and sleep disturbance may be palliated with appropriate medication.

Key Points: Prion Disease

- Prion disease is an uncommon cause of dementia in old age.
- The form of prion disease most likely to present to old age psychiatrists is classical sCJD, with the combination of a rapidly progressive dementia, ataxia, and myoclonus; vCJD typically

presents with neuropsychiatric symptoms, and neurological signs later.

- Positive investigations in prion disease include abnormal signal change on MRI, PSWCs on EEG, and 14-3-3 protein in the CSF, but the yield of these tests depends on the age of onset, disease duration, and underlying molecular subtype (Collins et al., 2006). Next-generation CSF testing with the RT-QuIC assay will likely replace 14-3-3 analysis in future diagnostic criteria. Tonsillar biopsy is an option in suspected vCJD.
- Definitive diagnosis can only be achieved by neuropathological examination, or in familial cases, sequencing of the PRNP gene.
- The prognosis in late-onset classical sCJD is uniformly poor, with deterioration and death in months. There is currently no effective treatment.

Pharmacological treatment of dementia

Chapter: Pharmacological treatment of dementia

Author(s): Roy W Jones

DOI: 10.1093/med/9780198807292.003.0035

Introduction

This chapter considers specific pharmacological treatment of dementia and summarizes the available clinical evidence with an emphasis on practical considerations and realistic expectations of the currently available antidementia drugs. Other topics, such as the treatment of motor symptoms for people with Parkinson's disease dementia (PDD) or dementia with Lewy bodies (DLB), vascular dementia (VaD), or fronto-temporal dementia (FTD) are discussed more briefly given these are covered elsewhere (e.g. Chapters 31–33). The chapter also considers drug treatments for mild cognitive impairment (MCI), but not the general management of this condition nor more specifically MCI due to Alzheimer's disease (Albert et al., 2011), also known as prodromal Alzheimer's disease (Dubois et al., 2010) as these are covered elsewhere (see Chapter 29 and Chapter 30).

Pharmacological treatment of dementia

Finding treatments for dementia has concentrated on Alzheimer's disease (AD), partly because it is the commonest cause of dementia and partly because scientific progress has provided more potential therapeutic targets for AD than other dementias. Many neurochemical studies have been carried out in AD looking at specific neurotransmitters and a number of approaches have been investigated; the changes in acetylcholine are particularly consistent and significant. In this context the cholinergic hypothesis (Francis et al., 1999) suggests that AD results from a selective loss in cholinergic neurones, especially within the basal forebrain and neocortex resulting in decreased acetylcholine (ACh) levels: strategies to enhance these levels provide a logical treatment target. Acetylcholinesterase (AChE) is the principal enzyme that breaks down ACh and the first drugs licensed specifically for use in AD were AChE inhibitors (AChEIs).

By analogy with Parkinson's disease (PD), where there is dopaminergic deficiency, it would be expected that replacement therapies could potentially enhance residual synaptic activity. While replacement therapy may be important, it would only be expected to provide symptomatic benefit and not affect the underlying disease process.

In PD patients with cognitive impairment, there is cell loss in the cholinergic basal nucleus of Meynert and a cortical deficit in AChE that correlates with the severity of dementia and is independent of any coexisting AD (Bohnen and Albin, 2011). Patients with DLB also show a severe loss of choline acetyltransferase in the cerebral cortex that is even greater than that found in AD and this correlates with the severity of the dementia (Lippa et al., 1999). Such deficits therefore suggest a possible therapeutic role for cholinergic therapies in both PDD and DLB.

Glutamate, the principal fast excitatory neurotransmitter in the CNS, is the neurotransmitter of the neocortical pyramidal cells, neurones that are selectively lost in AD (Francis et al., 1993). Glutamate may be important in the pathogenesis of dementia for several reasons, including its activity at the N-methyl-D-aspartate (NMDA) receptor (Danysz et al., 2000), which is capable of long-term potentiation, a key element of memory formation, and therefore another potential therapeutic target. Memantine is the only other licensed treatment to date involving a neurotransmitter approach and it acts as an uncompetitive antagonist at the NMDA receptor (Danysz et al., 2000).

Treatment of Alzheimer's disease

Cholinesterase inhibition

Changes in the cholinergic system in AD have been known for many years. Several therapeutic approaches to stimulate the cholinergic system have been tried but AChEIs are the only compounds to have shown consistent efficacy in both clinical trials and clinical practice. In 1993, tacrine became the first agent specifically approved for treating the

Pharmacological treatment of dementia

cognitive symptoms of AD in countries such as the US and Sweden but not in the UK. While the efficacy of tacrine in mild to moderate AD was clear (Arrieta and Artalejo, 1998), there were problems with its dosing frequency and tolerability, especially with a reversible hepatotoxicity, and it has been supplanted by later AChEIs.

Three other AChEIs are licensed for use in AD in most countries: donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl), and all three drugs have now reached the end of their patent lives so that generic forms are also available. AChEIs block the hydrolysis of acetylcholine at the synapse, increasing its availability to muscarinic and nicotinic receptors. All three are active against AChE, the principal form of the enzyme. Rivastigmine is also active against butyrylcholinesterase while galantamine appears to be an allosteric modulator of nicotinic receptors in animal models. It has been suggested that these subsidiary actions may lead to different clinical effects, although this has never been convincingly demonstrated. They are licensed in the UK for use in mild to moderate dementia in AD. Donepezil is also licensed for severe AD in some countries, including the US, where high-dose rivastigmine skin patches (13.3mg/24h) are also approved for severe AD, but neither is licensed for severe disease in Europe. Rivastigmine is also approved in the UK for mild to moderate dementia in PD.

Donepezil

Licensed in the UK in 1997, donepezil is the most widely used AChEI and has been studied the most intensively. It is beneficial for people with mild, moderate, and severe AD (Birks and Harvey, 2018), and is associated with improvements in cognitive function and activities of daily living (ADLs). The effects on cognition remained measurable and statistically significant at 52 weeks in one placebo-controlled study (Winblad et al., 2001). A Cochrane review (Birks and Harvey, 2018) suggested that 10mg was marginally better than 5mg and that the lower dose may be preferable because of improved tolerability, but clinically most patients are titrated to 10mg if possible. It is the simplest to use with an effective initial dose, one dose titration, and no interaction with food. Dosing up to 20 mg has been used by clinicians and a 23mg dose has been developed and approved by the FDA in the US. The 23mg/d dose improved cognition compared with 10mg/d in a 24-week study but there was no significant between-treatment difference for global functioning and there were more adverse effects and withdrawals at the higher dose (Farlow et al., 2010). Approval of this higher dose formulation has been controversial: Cummings and colleagues (2013) advocated the availability of the 23mg formulation, but it should be noted that Eisai sponsored the meeting where that paper was developed. In contrast, Schwartz and Wolosin (2012) regarded it as unjustified on both efficacy and safety grounds and argued that the sole purpose was to provide additional patent protection for a dose that cannot be achieved with 5 or 10mg tablets. Birks and

Pharmacological treatment of dementia

Harvey (2018) also concluded that 23mg daily offered no benefits and was associated with more side effects.

Formerly, it was recommended to discontinue AChEI treatment when dementia became severe. However, this has changed since Howard and colleagues (2012) studied donepezil and memantine in moderate to severe AD (DOMINO), which found that continued treatment with donepezil was associated with cognitive and functional benefits over the course of 12 months in patients where the clinician was considering a change in drug treatment (i.e., stopping donepezil or introducing memantine). In addition, withdrawal of donepezil increased the risk of nursing home placement during the 12 months of treatment, but it should be noted that it made no difference during the following three years of follow-up (Howard et al., 2015). The authors suggest that decisions to stop or continue donepezil should be informed by potential risks of withdrawal even if perceived benefits of continued treatment are not clear. It is now recommended that AChEIs should not be stopped on the basis of disease severity alone (NICE, 2018).

Rivastigmine

Rivastigmine was licensed in the UK in 1998 for the treatment of mild to moderately severe AD. Capsules are given twice daily with food commencing at a non-effective dose of 1.5mg bd and increasing gradually and according to tolerability at a minimum of 2-weekly intervals to a maximum of 6mg bd. The efficacy of oral rivastigmine has been clearly demonstrated but adverse effects such as nausea and vomiting, especially at higher doses, are more frequent, for example, by comparison with donepezil. Since rivastigmine is a small molecule and both lipophilic and hydrophilic, it is well suited for transdermal delivery and once daily patches (4.6mg, 9.5mg, and 13.3mg/24 h) have now been widely licensed, including in the UK.

A Cochrane review by Birks and colleagues (2015) concluded that, based on seven clinical trials, rivastigmine 6–12mg/d orally and 9.5mg/24h transdermally appears to be beneficial for people with mild to moderate AD after six months treatment (it should be noted that they did not review the 13.3mg/24h patch). In comparison with placebo, better outcomes were seen for rate of decline of cognitive function and ADLs, although the effects were small and of uncertain clinical importance. There was also a benefit in the clinician's global assessment, but no difference for behavioural changes (three trials) or impact on carers (one trial). At doses up to 9.5 mg daily the transdermal patch had fewer side effects than capsules, but had comparable efficacy. The review assessed the quality of the data as moderate for all the outcomes reviewed because of a risk of bias due to dropouts for rivastigmine (Birks et al., 2015). One study comparing the 13.3mg patch with the 9.5mg version showed significantly reduced deterioration in instrumental ADLs with similar skin

Pharmacological treatment of dementia

tolerability but a higher incidence of cholinergic gastrointestinal adverse effects (Cummings et al., 2012).

The skin patch, certainly at lower doses, presents fewer tolerability problems, e.g. gastrointestinal adverse effects, than oral rivastigmine and offers an alternative dosing route that may be preferred by, and for, some patients, but is more expensive. Application site reactions may occur, although these are usually mild or moderate in intensity and not generally an indication of sensitization. However, use of rivastigmine skin patches may lead to allergic contact dermatitis, which in some cases may indicate sensitivity to rivastigmine exposure such that rivastigmine in any form cannot be taken (Electronic Medicines Compendium UK, 2018).

Galantamine

Galantamine was licensed in the UK in 2000 for the treatment of mild to moderately severe AD. The drug is usually prescribed in a modified-release form as capsules of 8mg, 16mg, and 24mg, to be administered once daily.

Galantamine improves global and cognitive symptoms at doses of 16mg/day or greater for at least six months in people with mild to moderate AD (Loy and Schneider, 2006). Although there are no long-term placebo-controlled trials, a more recent analysis suggested that patients demonstrating improvement, stability, or limited cognitive decline after two to five months at their maintenance dose were more likely to experience longer-term continued benefit with galantamine (Kavanagh et al., 2011). Its safety profile in AD is similar to other AChEIs with respect to cholinergically mediated gastrointestinal symptoms (Loy and Schneider, 2006). The prolonged-release once-daily formulation at 16–24mg/day was found to have similar efficacy and side-effect profiles as the equivalent twice-daily regime (Loy and Schneider, 2006). Galantamine can rarely cause serious skin reactions (including Stevens-Johnson syndrome and acute generalized exanthematous pustulosis) and the manufacturer advises discontinuation at the first appearance of skin rash (BNF, 2019).

Adverse effects of cholinesterase inhibitors

The principal difference between the three AChEIs is in the frequency and type of adverse events (O'Brien et al., 2017). The main side effects are gastrointestinal, particularly anorexia, nausea, vomiting, and diarrhoea, as would be expected given the cholinergic enhancement provided by the compounds. Weight loss is also seen with galantamine and rivastigmine. These side-effects are most likely soon after treatment is commenced or when the dose is increased, hence the reason the drugs are all titrated up over a number of weeks.

Compliance with therapy is always a potential issue, especially in older patients who are also likely to be taking several other medications. There are particular issues if rivastigmine capsules have been omitted for a few

Pharmacological treatment of dementia

days since re-titration up from 1.5mg twice daily must occur. This follows a reported case of severe vomiting and a ruptured oesophagus in someone restarted straightaway at a high dose (Babic et al., 2000). This re-titration also applies if rivastigmine skin patches have been omitted for a few days. The rivastigmine skin patch may be helpful for people who cannot tolerate an oral dose of an AChEI as gastrointestinal side-effects are reduced but skin sensitivity may occasionally be a problem instead (discussed earlier) and also overdose resulting from a failure to remove each day's patch, which has been associated with serious adverse reactions, hospitalization, and even death (Electronic Medicines Compendium, 2018). Donepezil may cause abnormal dreams and this can be reduced by giving the drug in the morning rather than at night—though conversely, night-time administration may mitigate any dizziness or hypotension associated with AChEIs. In addition, donepezil may cause muscle cramps and galantamine muscle spasms.

Adverse interactions with other drugs have not generally been an issue, although it is important that everyone is aware of the therapy they are receiving and to mention this when any other medical issue arises because of their role as cholinergic stimulants. Care should be exercised in patients with reversible airways disease or peptic ulcer disease and in those with cardiac conduction defects or significant bradycardia as the compounds increase vagal tone. Given the potential for AChEIs to slow the heart rate, some clinics routinely obtain ECGs before prescribing these drugs. However, the available evidence suggests that this is not necessary (Rowland et al., 2007; NHS Yorkshire and Humber Clinical Networks, 2016). What is recommended is checking the pulse, and then avoiding AChEIs if the heart rate is less than 50 beats/minute, and investigating patients who are symptomatic, but otherwise prescribing for patients who do not have cardiovascular symptoms.

Switching from one AChEI to another

The rationale for switching from one AChEI to another is that they are from different chemical classes and with slightly different pharmacological properties. The main reason for switching is because of poor tolerability, usually gastrointestinal, and the hope that an alternative compound will avoid this. There is no easy way of identifying subjects in advance who are likely to respond to an AChEI but differences, for example, in individual metabolism of a drug may lead to higher or lower drug levels, which could improve efficacy but possibly at the risk of side effects. One study has suggested that functional polymorphisms in the *CYP2D6* gene can influence the clinical efficacy of donepezil (Seripa et al., 2011). A significantly higher frequency of gene variants conferring decreased or absent enzyme activity were observed in responders in comparison with non-responders (73.7% versus 36.8%; $p = 0.005$); it might be predicted that 'non-responders' would be able to tolerate a higher dose of donepezil because of their enhanced metabolism of the

Pharmacological treatment of dementia

compound and that more patients would then show a positive response to the compound.

Few studies of switching have been carried out, and all switching has been from donepezil; no recent or double-blind studies are available. However, it does appear that a proportion (up to 50%) of patients may benefit from a switch (O'Brien et al., 2017) and a change of formulation (particularly from a standard oral form to either a transdermal patch, or oral solutions that are available for all three drugs, or the orodispersible form of donepezil) does offer additional opportunities to find a treatment that is tolerated satisfactorily, and particularly in subjects where swallowing tablets or capsules is a problem. NICE (2018) has recommended that memantine should be considered as an alternative to an AChEI in moderate AD if there are contraindications or tolerability issues.

N-methyl-D-aspartate receptor antagonism

Memantine

Memantine is a non-competitive moderate affinity antagonist at the NMDA receptor. It is believed to restore glutamatergic neuronal transmission to physiological levels while preventing the effects of tonic pathologically elevated synaptic glutamate levels that may lead to neuronal dysfunction and damage (Danysz et al., 2000). Memantine was licensed in the UK in 2002 for the treatment of moderately severe to severe AD but this licence was subsequently extended to cover moderate dementia in AD. Initially recommended for 10mg twice daily dosage, clinical trials later demonstrated that 20mg once daily dosing was identical (e.g. Jones et al., 2007); the dosage has now been modified to once daily dosing beginning with a non-effective dose of 5mg and increasing to 20mg over a four-week titration period. Either 10mg or 20mg is an effective dose and it is still possible to give 10mg twice a day if this is more convenient (e.g. if patients are also receiving rivastigmine or galantamine twice daily); a memantine oral solution is also available.

Memantine is currently recommended as an option in moderate AD for those for whom AChEIs are contraindicated or where tolerability is poor, or in severe AD (NICE, 2018). Indeed, it is the only drug licensed in the UK for severe AD. A recent consensus statement confirmed that there is type I evidence (from meta-analysis of randomized, controlled trials) that memantine is an effective treatment for moderate to severe AD (O'Brien et al., 2017). Memantine is well tolerated and slightly fewer patients with moderate to severe AD taking memantine develop agitation in comparison with placebo (McShane et al., 2006).

One of the striking features of clinical trials with memantine has been that adverse events are often similar to placebo (in contrast to AChEIs) and, in general, gastrointestinal side effects are uncommon (but include constipation in contrast to the diarrhoea which is a common side effect of

Pharmacological treatment of dementia

AChEIs). Memantine is thus generally extremely well tolerated (Jones, 2010) and therefore may be especially suitable for older and/or frailer patients, although hypertension has been reported as a common adverse event (in up to 10% of patients) so care should be shown in people with poorly controlled hypertension. Caution is recommended in patients with epilepsy or predisposing factors to epilepsy, and concomitant use of other NMDA antagonists (e.g. amantadine, ketamine, and dextromethorphan) should be avoided. The maximum daily dose should be 10mg in patients with severe renal impairment (with an estimated glomerular filtration rate (eGFR) of 5–29ml/min/1.73m²) and memantine should be avoided altogether if the eGFR is less than 5ml/min/1.73m².

Add-on or combination therapy of AChEIs with memantine

Simultaneous initiation of therapy with an AChEI and memantine has not been studied. This may partly be explained by their different licensed indications being mild to moderately severe AD for AChEIs and moderate to severe AD for memantine. Although it might be useful to know whether using lower doses of both types of drug would lead to similar or increased efficacy compared with full doses of either drug alone, in practice, prescribers are likely to start with a single drug in order to assess potential side effects. Adverse events, particularly gastrointestinal problems, might be reduced by combination therapy, especially if this enables treatment with lower doses, and this was seen in subjects receiving memantine and donepezil compared with placebo and donepezil in one memantine add-on study (Tariot et al., 2004). This may reflect either that memantine has some intrinsic cholinergic effects or that it offers protection to septal area cholinergic neurons (Colom et al., 2013), although these observations are from animal work so of uncertain clinical relevance.

There are no published studies investigating the addition of an AChEI to patients already established on memantine, which is probably because patients are usually commenced on an AChEI first, with memantine being considered as a later alternative or additional treatment; increasingly in countries like the US, adjunctive therapy with memantine is being commenced in patients who still have mild AD.

The evidence of the benefits of adding memantine to an AChEI is largely favourable, although the evidence is not strong, and whether any additional effects are clinically important remains questionable. A group from the European Federation of Neurological Societies reviewed four trials, comprising 1549 patients with moderate to severe AD, and found statistically significant improvements in global outcomes, cognition and behaviour (Schmidt et al., 2015). Despite grading the evidence as weak, the group recommended the use of combination therapy. The British Association for Psychopharmacology (O'Brien et al., 2017) also favoured combination treatment with a recommendation of grade B (range A to D). NICE (2018) recommended that, in patients with moderate AD, adding

Pharmacological treatment of dementia

memantine should be *considered*, and in severe AD, combination treatment with memantine should be *offered*.

The DOMINO study in the UK found that starting memantine at the time donepezil was discontinued was better than not adding memantine, but adding memantine while continuing with donepezil did not seem significantly better than donepezil alone (Howard et al., 2012). This study was criticized (Tariot, 2012) partly because of the marked placebo decline in subjects randomized to receive neither memantine nor donepezil. Also, that there was no evidence for the lack of adjunctive memantine therapy based on the small sample sizes at the study end and the differential dropout rates between the groups. Subject recruitment was significantly lower than planned with a marked dropout rate even in the group that continued with donepezil, where only half of the patients continued the treatment for the entire one-year study period (Schneider, 2012). Unfortunately, such a trial is unlikely to be repeated, yet more information is still required about long-term benefits, safe discontinuation of AChEIs, and the role of combination therapy with memantine (Schneider, 2012).

In summary, in many countries, combination therapy with an AChEI initially, followed by the later addition of memantine, is now accepted as the optimal treatment for patients with AD, especially as the dementia progresses.

Practical considerations and realistic expectations of treatment in AD

How early should treatment be initiated?

Although the AChEIs are only licensed for people with a diagnosis of AD, some clinicians do commence treatment for people with MCI, where many but not all subjects will go on to develop a dementia, usually AD, in the coming years. The evidence to support this is poor, with several negative trials with different AChEIs and, indeed, in two placebo-controlled MCI trials of galantamine there was an unexplained excess death rate in the drug-treated group (Loy and Schneider, 2006).

Clinical relevance of benefits

It is by now well established that AChEIs and memantine produce statistically significant differences when compared to placebo in clinical trials. However, an important question is how clinically relevant such benefits are, and also to what extent might effects seen in trials also operate in routine clinical practice, given that trial participants are often healthier and better motivated than other members of the population from which they are drawn. Howard and colleagues (2011) estimated that the minimum clinically important difference (MCID) on the standardized Mini Mental State Examination was 1.4 points. In an extensive review of AChEIs and memantine, Tricco and colleagues (2018) found that only donepezil achieved a MCID for cognitive outcomes. Galantamine led to a

Pharmacological treatment of dementia

clinically relevant global outcome, but there were no significant improvements in function from any individual drug or combination treatment with memantine. At an anecdotal level, clinical experience suggests that AChEIs sometimes lead to a noticeable improvement in attention and motivation, often for a period of several months, and this also seems like a worthwhile effect.

Less than expected decline

In a chronic progressive neurodegenerative disease like AD, improvements in symptoms are important. The evidence suggests that some 40–75% of patients experience a significant benefit from AChEIs, but it is difficult to predict in advance who will respond. There may be an initial, usually relatively short-term, improvement above baseline, but stabilization or less than expected decline are more realistic therapeutic targets. A patient treated early and persistently with medication would be expected to show less evidence of behavioural, functional, and cognitive deterioration over a period of time; there is substantial evidence that this is the case for the currently available drug treatments for AD (Geldmacher et al., 2006). For example, using a definition of marked clinical worsening for a patient showing cognitive decline (equivalent to the average natural decline in moderate to severe AD patients over six months) plus any decline in both ADLs and global function, 30% of patient on placebo showed clinical worsening at six months in comparison with only 14% on donepezil (Wilkinson et al., 2009). For memantine, 21% of patients showed a significantly greater degree of worsening on placebo in comparison with 11% on memantine (Wilkinson and Anderson, 2007). The DOMINO study also provided further support that patients who are declining while taking a drug for AD may still be benefiting by comparison with patients not on therapy (Howard et al., 2012).

However, it is difficult in clinical practice to decide whether or not treatment is beneficial for an individual patient. There is great variation between individuals and there are fluctuations in test performance that are of similar magnitude to the likely therapeutic effects. Thus, in practice, it is important to treat the patient and not be governed too much by scores on cognitive tests. If appropriate, therapy may be withdrawn for a short period or the dose reduced to see if there is a change in the patient's condition, but this is often very subjective and largely depends on the primary caregiver's opinion.

For an individual patient, slowing the rate of decline may have important consequences, e.g. reduced caregiver stress and delayed nursing home placement (Lopez et al., 2009). However, it is important that the patient, caregiver, and others—such as the primary care physician—have realistic expectations of the treatment. Since patients may improve very little, stabilize, or even decline, despite benefiting, people may become disillusioned if they have not been warned about this; this may affect compliance or lead to premature withdrawal of therapy.

Pharmacological treatment of dementia

Withdrawal of treatment

Given the discussion above, there is no justification in withdrawing treatment with either an AChEI or memantine merely because of the progression of the dementia. The decision to withdraw treatment, or try to withdraw treatment, should be made on an individual basis when it is considered that the treatment may potentially be causing adverse effects or at a time when the dementia has advanced to a point where withdrawal of other therapy is also being considered. It is advisable to reduce the dose gradually where possible, since deterioration may occur and the drug may need to be reinstated.

Treatment of non-Alzheimer dementia

Dementia with Lewy bodies (DLB) and Parkinson's disease dementia (PDD)

Patients with DLB or PDD have a severe deficit in cortical ACh levels so that AChEIs might be expected to help. Rivastigmine is licensed in the UK, US, and elsewhere for mild to moderately severe dementia in people with idiopathic PD. Donepezil now has a marketing authorization for DLB in Japan and the Philippines based on a 12-week double-blind phase III study with open-label extension (Mori et al., 2015), but all other prescribing for DLB remains off-label.

Nonetheless, there are current recommendations for prescribing AChEIs and memantine for patients with DLB. O'Brien and colleagues (2017) gave a grade A recommendation for the use of donepezil or rivastigmine in DLB and PDD, and a grade B recommendation for memantine. Following from this, the current NICE (2018) guidance is: offer donepezil or rivastigmine to people with mild to moderate DLB; only consider galantamine in mild to moderate DLB if donepezil and rivastigmine are not tolerated; consider donepezil or rivastigmine in severe DLB; and consider memantine for people with DLB if AChEIs are not tolerated or are contraindicated.

For PDD, NICE (2017) advises: offer a cholinesterase inhibitor for people with mild or moderate PDD; consider a cholinesterase inhibitor for people with severe PDD; and consider memantine for people with PDD only if cholinesterase inhibitors are not tolerated or are contraindicated.

Visual hallucinations and visuoperceptual deficits are common to both PDD and DLB, together with fluctuating attention. The combination of cognitive, neuropsychiatric, motor, and autonomic features in DLB causes considerable functional decline. Treating neuropsychiatric features such as hallucinations may exacerbate parkinsonism, while antiparkinsonian medications may exacerbate psychosis. There is variability both between individuals and as the disease progresses, so that getting the right combination of therapies is challenging. Patients with DLB generally do not respond well to antiparkinsonian medication. One small study (Goldman et al., 2008) suggested that around a third of subjects did

Pharmacological treatment of dementia

obtain a good motor response to L-dopa; however, a third of these also experienced a worsening of hallucinations or the development of psychosis. Side-effects must be monitored carefully and the dose increased slowly, avoiding high doses. Other antiparkinsonian medications should be used extremely cautiously because of the likelihood of inducing confusion and psychosis (Goldman et al., 2008).

There are still relatively few trials in DLB and PDD but there are several comprehensive reviews of the treatment of DLB and PDD and meta-analysis of trials (e.g. Stinton et al., 2015; Wang et al., 2015). AChEIs seem to benefit global and cognitive outcomes whereas memantine has only produced change in global ratings rather than cognition. The recent consensus statement (O'Brien et al., 2017) supported the use of donepezil and rivastigmine in DLB and PDD with the strongest recommendation (grade A), and for memantine with a grade B recommendation for producing global improvement in DLB and PDD but with the pattern of cognitive and neuropsychiatric responsiveness remaining uncertain. The current NICE guidance quoted earlier in this section reflects these findings.

Vascular dementia (VaD)

Managing vascular risk factors

No specific antidementia treatments are licensed for VaD, so it is important to focus on managing the underlying cardiovascular risk factors, including hypertension, diabetes, heart disease, and hypercholesterolaemia; these should be treated whenever possible, particularly in younger people. It can be hard to decide at what stage in life cardiovascular prevention is no longer worthwhile. Lipid-lowering therapy is probably inappropriate for a person with a life expectancy of fewer than two years or where there is an irreversibly poor quality of life; at this stage, end-of-life care becomes more important, but all such decisions should be made individually and not on the basis of age alone.

There is good evidence for the effectiveness of treating hypertension in older people but clinicians are often reluctant to do so. In extreme old age, lower blood pressure is associated with increased mortality, but there is at least one RCT (the SPRINT trial) of people aged over 75 in which treating hypertension was associated with better outcomes (Williamson et al., 2016). There may be concerns about compliance and also the risk of side effects, e.g. postural hypotension. Successful blood pressure control can enhance cognitive performance in patients with multi-infarct dementia (Meyer et al., 1986) and antihypertensive treatment is associated with a lower incidence of dementia in elderly people with isolated systolic hypertension (Forette et al., 1998). Aggressive treatment of hypertension may be unreasonable, especially in patients with severe dementia. A review by Harrison and colleagues (2016) concluded that, overall, there was no good evidence of benefit or harm from treatment for hypertension in people with dementia. Clinicians

Pharmacological treatment of dementia

should therefore consider patient preferences, possibly assess further using ambulatory monitoring, and consider deprescribing, especially if there are side-effects.

The elevated incidence of stroke in patients with atrial fibrillation (AF) explains the relationship between AF and the development of VaD (Alonso and Arenas de Larriva, 2016). AF is associated with at least a doubling of stroke risk and the effects of stroke on cognitive function are well established (Gerelick et al., 2011). AF also more than doubles the risk of silent cerebral infarction independent of stroke (Kalantarian et al., 2014) and the presence of silent cerebral infarcts is a risk factor for dementia (Vermeer et al., 2003).

Guidelines are clear in recommending anticoagulant and antiplatelet drugs that can reduce the risk of stroke for most individuals with AF. A recent analysis comparing the risk of dementia in people with AF using warfarin versus non-vitamin K oral anticoagulants (NOACs) reported a lower risk of dementia among NOAC users (Jacobs et al., 2016). The four NOACs licensed in the UK (apixaban, dabigatran etexilate, edoxaban, and rivaroxaban) are all recommended by NICE as an option for prevention of stroke and systemic embolism in people with non-valvular AF (NICE, 2016), although dabigatran is the only NOAC with a specific reversing agent (idarucizumab) for use in an emergency. Older people with AF have the lowest frequency of anticoagulant use and dementia appears to be a significant independent determinant of non-treatment with either aspirin or warfarin for the prevention of recurrent stroke (Moroney et al., 1999).

There may be reluctance to use warfarin where compliance may be a problem and NOACs may be a simpler and potentially safer option. It is important to take into account a patient's overall situation when deciding whether the benefits of anticoagulation outweigh any risks: age alone should not be the deciding factor. If necessary, it may be safer though less effective to select alternatives such as aspirin, 75–300mg/day, or another antiplatelet drug, e.g. clopidogrel.

Antidementia drug treatment for VaD

Several clinical trials in VaD have been conducted with the drugs currently licensed for AD. A meta-analysis by Kavirajan and Schneider (2007) reviewed all VaD placebo-controlled clinical trials of donepezil, rivastigmine, galantamine, and memantine. There were small benefits of uncertain significance in cognition but there was significant heterogeneity of the patients that made generalizations about efficacy difficult. The evidence indicates that neither AChEIs nor memantine should be prescribed for people with VaD, although those with mixed VaD and AD may benefit (O'Brien et al., 2017).

Pharmacological treatment of dementia

Other dementias

No specific antidementia treatments are licensed for use in other dementias such as frontotemporal dementia (FTD). Classification of FTD is becoming more complex and the different clinical syndromes may ultimately reveal a variety of underlying pathology, including AD. AD pathology may be seen in 25% of cases of non-fluent/agrammatic primary progressive aphasia (PPA), 25% of cases of semantic variant PPA, and 50% of the logopenic variant of PPA (Grossman, 2012). It would seem reasonable that the sub-set of FTD with underlying AD pathology might respond to AChEIs or memantine, although there are no formal trials confirming this and worsening of behavioural symptoms in FTD by AChEIs has been reported (Mendez et al., 2007). In the logopenic variant of PPA and another condition, posterior cortical atrophy, which are both thought to be atypical variants of AD (Gorno-Tempini et al., 2008; Mendez et al., 2002), it would potentially be worth trying AChEIs or memantine.

There is little evidence for the efficacy of AChEIs or memantine in other important causes of dementia, e.g. corticobasal degeneration, Huntington's disease, and prion disease; in progressive supranuclear palsy, clinical trial data does not support the use of either AChEIs or coenzyme Q (O'Brien et al., 2017).

There have been limited formal trials of drug treatment for people with Down syndrome and AD. There were no trials of rivastigmine or galantamine but one randomized controlled trial with donepezil, and reported as part of a Cochrane review (Mohan et al., 2009), showed a modest non-statistically significant trend in favour of those able to tolerate donepezil treatment. Memantine does not appear to be effective for people with dementia in Down's syndrome (Hanney et al., 2012).

Other putative antidementia therapies

Numerous agents with a variety of properties have been suggested as possible treatments for dementia. Where there have been trials, they have mainly been in AD. However, for no other treatments has adequate evidence emerged to date for them to be part of routine practice. Some examples are discussed in this section. Other treatments that have been considered include statins, anti-inflammatory drugs, and vitamin E.

Ginkgo biloba

There is still considerable controversy about the use and value of Ginkgo biloba extracts. The extracts contain many agents, including flavonoids, terpenoids (including several ginkgolides that are unique to the ginkgo tree), and organic acids. A Cochrane review (Birks and Grimley Evans, 2009) noted that ginkgo appears to be safe with no excess side effects compared with placebo, but many early trials used unsatisfactory methods with small numbers of subjects and publication bias could not be excluded. Overall, the evidence that it has predictable and clinically significant benefits for people with dementia or AD is inconsistent and

Pharmacological treatment of dementia

unreliable. Three other studies have now been reported, one examining people with dementia and two primary prevention studies (O'Brien et al., 2017). A study in subjects with dementia and neuropsychiatric features found no additional benefit from ginkgo added to donepezil. In the primary prevention studies, ginkgo did not prevent the development of dementia or AD but there appeared to be an increased risk of stroke and transient ischaemic attack in the ginkgo treated groups (O'Brien et al., 2017); concerns have been expressed previously about possible bleeding complications with ginkgo that are probably uncommon but possibly linked to antagonism of platelet-activating factor. People taking anticoagulants, antiplatelet agents, or with a bleeding diathesis should be especially cautious about taking ginkgo.

Folic acid and B vitamins

Folate is an essential dietary element and low plasma and red cell folate levels lead to increases in plasma total homocysteine, which is a risk factor for brain atrophy, cognitive impairment, and dementia. Plasma homocysteine can be lowered by dietary administration of B vitamins (folic acid and vitamin B₁₂). A Cochrane review (Malouf and Grimley Evans, 2008) concluded that there was no evidence that folic acid with or without vitamin B₁₂ improved cognitive function in unselected elderly people with or without dementia. Since this review, one 18-month study of high-dose folic acid, vitamin B₁₂, and vitamin B₆ involving 409 subjects with mild to moderate AD (MMSE 14-26) and normal plasma homocysteine levels has been reported (Aisen et al., 2008). No benefits on cognition were seen in the intervention group but there was an unexpected increase in depression. Another study (Smith et al., 2010) in subjects with MCI showed that plasma concentrations of homocysteine could be lowered by high-dose folic acid, vitamin B₆, and vitamin B₁₂ given over 24 months and found evidence that this slowed the progression of brain atrophy. Further research is needed to confirm this result and to see whether similar benefits could be seen in people with AD. On current evidence, neither vitamin B₁₂ nor folate, either singly or in combination, can be recommended as treatment for dementia (O'Brien et al., 2017).

Souvenaid

Souvenaid is a nutritional supplement or medical food, containing vitamins and trace elements such as selenium, marketed for the dietary management of early AD. Its components are intended to provide neuroprotection by targeting disease processes in early Alzheimer's disease. There is type II evidence from mainly small, non-replicated randomized controlled trials indicating possible benefits on cognition but the effects are variable between studies and no effect has been shown on global outcomes. A randomized controlled trial of Souvenaid involving over 300 participants with prodromal AD (MMSE > 24) showed no benefit compared with placebo (Soininen et al., 2017). At present, this

Pharmacological treatment of dementia

supplement is not recommended unless further evidence becomes available (O'Brien et al., 2017).

Management of non-cognitive symptoms

At some time in the course of their disease, almost all people with dementia will develop one or more non-cognitive symptoms in the form of BPSD (behavioural and psychological symptoms of dementia), which include affective syndromes (depression, anxiety, and irritability), apathy, agitation, aggression, psychosis (delusions and hallucinations), disorders of sleep, wandering, and a variety of inappropriate behaviours (Kales, et al., 2015). BPSD are a complex, heterogeneous group of phenomena that have both a basis in brain disease (Sultzer et al., 2003) and also often represent expressions of distress or attempts at communication by the person with dementia. BPSD cause distress to the individual with dementia, and add considerably to the stresses experienced by family and professional carers and can result in serious risks to the person and others. They are also associated with earlier institutionalization, higher costs, and mortality (Habermann et al., 2009; Herrmann et al., 2006).

Good practice recommendations such as the NICE dementia guideline (2018) recommend nonpharmacological interventions as the first line approach for BPSD and emphasise the importance of assessing pain and other medical conditions, which can often precipitate the development of these problems.

Despite the fact that many of these symptoms may improve or change over a period of a few weeks, pharmacological interventions have often been used as a first line treatment. In particular, there has been concern about the excessive use of antipsychotic drugs for the management of BPSD. This was highlighted by Banerjee (2009) in a report to the UK Department of Health that estimated that at least 180,000 people with dementia were being prescribed antipsychotics each year in the UK. Banerjee estimated that this led to an extra 1,800 deaths a year in the UK, together with an additional 1,620 cerebrovascular adverse events (about half of which are severe). Consequently, official guidelines and regulatory bodies have warned about the risks of these drugs in people with dementia; for example, NICE (2018) recommends that antipsychotics should only be offered to people who are at risk of harming themselves or experiencing agitation, hallucinations, and delusions that are causing them severe distress.

Use of cholinesterase inhibitors or memantine for BPSD

There have been more than 30 randomized controlled trials, with follow-up over 6–12 months, with AChEIs. However, few of these have specifically looked at people with BPSD, particularly clinically relevant agitation. Evidence from these trials suggests an overall effect on neuropsychiatric symptoms over six months, but the main benefits are probably for anxiety and apathy, rather than agitation and aggression

Pharmacological treatment of dementia

(Ballard et al., 2009). In the 12-week CALM-AD trial (Howard et al., 2007) donepezil was not more effective than placebo in treating agitation in patients with AD.

Memantine seemed to be a promising treatment for BPSD, based on the main clinical trials, which appeared to show a benefit in reduced irritability, lability, agitation, aggression, and psychosis (Ballard et al., 2009). Clinically, it does seem that memantine may damp down or reduce the appearance of agitation and it has been used by clinicians for this purpose. One trial of memantine in patients with clinically significant agitation from care homes or hospitals did not show improvement (Fox et al., 2012), but it was significantly better than placebo for cognition. The authors commented that it still remains to be determined whether memantine has a role in milder degrees of agitation in AD.

Agitation, aggression, and psychosis

It is important to look for causes of agitation and this has been confirmed in a study that demonstrated that effective management of pain significantly reduced agitation in residents of nursing homes with moderate to severe dementia (Husebo et al., 2011). Paracetamol 1g up to four times per day is a suitable and safe option.

One study (Porsteinsson et al., 2014) assessing the selective serotonin reuptake inhibitor (SSRI) citalopram in people with dementia and clinically significant agitation demonstrated significant improvement over placebo on several clinical measures, including clinical global impression of change and reduced carer distress, but citalopram must be used with caution in people over 65 years (see Depression).

Antipsychotics

Risperidone is the only antipsychotic specifically licensed for use in dementia in Europe and Canada, but not in the US, and only for short-term (up to six weeks) treatment of persistent aggression in moderate to severe AD unresponsive to nonpharmacological approaches and when there is risk of harm to the patient or others. The starting dose should be 0.25mg twice daily, increasing gradually to a maximum dose of 1mg twice daily. There are several alternative antipsychotic drugs, but the evidence for their efficacy is limited and the risks are great (Kales et al., 2015). It is worth emphasizing that patients with DLB may show severe sensitivity to neuroleptic drugs such as the atypical antipsychotics, and fatal reactions have occurred (McKeith et al., 1992).

Depression

Evidence about the potential benefits of antidepressants for treating depression in the context of pre-existing dementia has been provided by two large trials. The DIADS-2 study in the US compared sertraline 100mg (N=67) with placebo (N=64) in depression in AD and found no significant difference in symptom change or response or remission rates, but did find

Pharmacological treatment of dementia

an increase in adverse events on sertraline (Rosenberg et al., 2010), and that the evidence does not support the use of SSRIs in depression in AD. The SADD Study in the UK reported similar findings in a larger sample of 326 subjects. In this study a broader and more representative definition of dementia was used and subjects randomised to placebo (N=111), sertraline (N=107), or mirtazapine (N=108) (Banerjee et al., 2011). Sertraline was not better than placebo and was associated with more adverse events, and mirtazapine was no better than placebo on any outcomes. These two large studies and a recent Cochrane review (Dudas et al., 2018) demonstrate that, contrary to previous belief, monoamine-based antidepressants are not generally effective in depression in dementia. As is typical of clinical trials, the most severely ill patients were not assessed; for severe depression pharmacological treatment may be appropriate, for example, with an SSRI such as citalopram 10mg daily, increasing to a maximum of 20mg per day. Higher doses should not be used in patients older than 65 years because of an association of the drug with dose-dependent QT interval prolongation (MHRA, 2011).

Sleep disturbance

Non-drug sleep hygiene measures are always preferable but treatment with medicines is often used to try and improve sleep in people with dementia. There is a lack of evidence to guide such treatment. A recent Cochrane review (McCleery et al., 2016) noted no randomized clinical trials of benzodiazepine or non-benzodiazepine hypnotics and no evidence that sleep problems were helped either by melatonin (up to 10mg) in moderate to severe AD or ramelteon in mild to moderate AD. There was some limited evidence of benefit with low dose (50mg) trazodone.

Overview of pharmacological treatment for people with dementia

Box 35.1 provides a summary of the main aspects of pharmacological treatments for dementia discussed thus far in this chapter.

Box 35.1 Summary overview of pharmacological treatment for people with dementia

- Assess the patient with a possible dementing disorder carefully, including a formal screening instrument (e.g. MMSE, sMMSE, MoCA)
- Establish that the patient has dementia
- Establish the most likely type of dementia

If Alzheimer's disease:

- consider oral AChEIs (donepezil, galantamine, or rivastigmine) and explain goals of treatment (some early benefits potentially

Pharmacological treatment of dementia

but stabilization or less than expected decline more likely). Assess cognition (e.g. MMSE, MoCA). Titrate to maximum dose if possible according to side effects and benefits

- if problems with first AChEI, consider switching to another AChEI (consider transdermal rivastigmine) or memantine
- if AChEIs poorly tolerated or contraindicated, consider memantine
- as disease progresses, consider switching to memantine or adding memantine to the AChEI, particularly if the patient is developing agitation
- monitor the patient's progress regularly (approximately six-monthly)
- if stopping drug treatment, consider dose *reduction* rather than complete withdrawal, and be aware that the patient may deteriorate and medication may need to be restarted

If dementia with Lewy bodies:

- consider L-dopa for parkinsonian symptoms with careful monitoring for emergent psychosis
- consider AChEIs (and possibly memantine), especially for visual hallucinations
- do *not* use neuroleptics

If vascular dementia:

- consider sources of emboli (e.g. carotid disease, AF)
- if atrial fibrillation, consider anticoagulation
- give low-dose aspirin (if contraindicated, consider clopidogrel)
- ensure other relevant conditions (e.g. hypertension, diabetes) are being managed appropriately

AChEI—acetylcholinesterase inhibitor; MMSE—Mini-Mental State Examination; sMMSE—Standardized Mini-Mental State Examination; MoCA—Montreal Cognitive Assessment.

Prospects for future treatment

Unfortunately, no new drugs have been licensed for the treatment of dementia since memantine in 2002; the search for more effective and potentially disease-modifying drugs continues. There have been several new initiatives to try and increase the chances of success, including several international partnerships, such as the Global Alzheimer's Platform (GAP, mainly North America); the European Prevention of

Pharmacological treatment of dementia

Alzheimer's Disease Consortium (EPAD); and the Dementias Platform UK (DPUK). These are private-public collaborations, aimed at developing new treatments but also establishing cohorts of well-characterized potential participants.

Recently an international political agenda has developed with the ambition to identify 'a cure, or a disease-modifying therapy, for dementia by 2025' outlined at the G8 dementia summit in December 2013 (Department of Health and Social Care, 2014) and in the US National Plan to address Alzheimer's disease 'to prevent and effectively treat AD by 2025' (US Department of Health and Social Services, 2013). Given the 2025 target, under current conditions, only drugs already in phase II or later will have any chance of being approved by 2025 (Cummings et al., 2016). Cummings and colleagues (2016) also identified several factors that could reduce the time and risk of AD drug development, such as improved trial design; better trial infrastructure; disease registries of well-characterized participant cohorts; validated biomarkers for disease detection, assessing risk, monitoring disease progression, and prediction of disease response; more sensitive clinical assessment tools; and faster regulatory review.

Many compounds have been investigated for AD with numerous unsuccessful or failed trials leading to discussion about the reasons for this. Most approaches have focused on the amyloid hypothesis and compounds that in some way affect the production, deposition, or removal of the toxic 42-amino acid peptide amyloid-beta (A β). For example, there has been much interest in the possibility that monoclonal antibodies that bind to A β might be effective treatments for AD. However, trials of solanezumab in mild to moderate (Doody et al., 2014) and mild AD (Honig et al., 2018) failed to show any significant benefit. Aducanumab failed to meet its primary end points in several phase 3 trials on interim futility analyses, but interestingly a re-analysis by its manufacturer, Biogen which included additional data found benefits. At time of writing, this has lead the company to apply for regulatory approval for the use of aducanumab in the United States.

Deposition of A β within the brain begins many years before the clinical manifestations of AD are apparent, so it may be that such drugs need to be given earlier in the AD process, either when symptoms are mild (MCI or prodromal AD) or possibly even before symptoms begin (asymptomatic preclinical AD). Increasingly, biomarkers such as CSF amyloid and tau, and PET amyloid and tau functional imaging are being used in order to detect underlying AD pathology earlier, and trials in such individuals may be more effective. Other approaches are also important, such as targeting tau deposition in neurofibrillary tangles, as well as other aspects of the neurodegenerative disease process, including neuroprotective, anti-inflammatory, and metabolic approaches.

Pharmacological treatment of dementia

Currently available licensed drug treatments are generally only considered to be symptomatic therapies with no significant effect on halting or reversing the underlying disease process. However, a recent study with donepezil in people with suspected prodromal AD demonstrated a 45% reduction of the rate of hippocampal atrophy following one year of treatment compared with placebo, which is not something that would generally be expected in a purely symptomatic treatment (Dubois et al., 2015). The boundary between symptomatic and disease-modifying therapies may therefore be somewhat blurred, particularly in identifying the differences clinically. Current treatments certainly may change the disease course by delaying deterioration and, for example, entry to nursing homes (Lopez et al., 2009) without necessarily changing the disease itself.

It will be a significant hurdle for new therapies to be accepted as disease modifying. Such drugs will need to show clinical efficacy over a sustained period of time (12–18 months minimum), including possibly a change in the slope of decline and delay in reaching particular disease milestones, such as a change in disease severity (using a measure such as the Clinical Dementia Rating Scale), the transition from prodromal AD to Alzheimer's dementia, or loss of independence. Interestingly, if aducanumab is approved, then this would be counterflow to these expectations. Regardless, there are likely to be considerable challenges with administration of these drugs, as they may need initial monitoring for safety with MRI scans and may involve regular injections or infusions; cost-effectiveness will undoubtedly also be a consideration if they are to achieve widespread usage. However, such advances in treatment for people with AD and other dementias are essential, given the predicted increase worldwide in the numbers of older people and people with dementia.

Management of dementia

Chapter: Management of dementia

Author(s): Sarah Cullum and Tesema Taye

DOI: 10.1093/med/9780198807292.003.0036

Introduction

An estimated 50 million people are living with dementia worldwide in 2017 (Prince et al., 2015) and this number will reach 135 million by 2050. The worldwide costs of dementia are also increasing and it has been reported that dementia will be a trillion-dollar disease by 2018 (Prince et al., 2016). The majority of this cost is due to social care, as, despite substantial effort by the pharmaceutical industry, the prospect of finding a cure for dementia is not imminent (Cummings et al., 2017). Much of the social cost is borne by the families, as they are often unable to access assistance from agencies that are struggling to cope with demand (Bourne, 2007). For this reason, the management of dementia should focus on supporting and developing the care provided by family members and carers in the community, because their education and enablement will help to optimise the quality of life for people with dementia.

Management of dementia

Dementia encompasses a group of neurodegenerative disorders that are characterized by progressive loss of cognitive function and ability to perform activities of daily living (ADLs), and that can be accompanied by neuropsychiatric symptoms and challenging behaviours of varying type and severity. Dementia changes the way people with the disease interact with the world around them, as well as how the world (including friends, families, carers, communities, and services) responds to them. The social model of dementia (Kitwood and Bredin, 1997) helped to redefine dementia as a disability, produced by social exclusion, mostly due to fear and lack of understanding. The person-centred model of care that emerged in the 1980s promoted the understanding of the person behind the dementia, and the context in which he/she lives. Thus, the management of dementia is not limited to the management of individuals and the disease, but must also include their personal, physical, social, and cultural environments. This means that modern dementia services must understand the management issues in a variety of sociocultural settings, and also identify the specific needs of people with dementia and their carers, regardless of their age, class, ethnicity, religion, sexuality, or comorbid disability. These principles are reflected in the UK guidelines for dementia care produced by the National Institute for Health and Clinical Excellence and the Social Care Institute for Excellence (NICE-SCIE, 2006), which emphasize the importance of services being person-centred, relationship-centred, autonomy-centred, and providing good-quality, evidence-based care. These guidelines have been used to shape services in UK. More recently, the 2017 Lancet Commission on Dementia (Livingston et al., 2017) has collated the latest evidence for prevention, management, and care of dementia. We have therefore used both of these documents as reference sources to update this chapter on the management of dementia.

The dementias are progressive disorders and presentations change over time. People with dementia also have different needs at different stages of the disease, and their management needs (and those of their carers and environments) will vary accordingly. This chapter concentrates on the assessment and management of people with dementia in the early and later stages of the disorder. At both stages we consider engagement, autonomy, respect, protection, and ethical issues, as well as describe the clinical and psychosocial aspects of treatment. The emphasis is on the broader principles of management, which apply to people with dementia of any aetiology, their families, carers, and communities, and take into account the different settings in which they may present. More specific treatments are covered in other chapters (e.g. Chapters 13–19 and Chapter 35).

Early dementia

Management of dementia

Presentation of early dementia

People with early dementia may present in a number of different ways. They may notice changes in themselves and self-refer to health professionals in primary care, or their family members may become concerned and suggest that they have an assessment. Health and social care professionals sometimes suspect cognitive impairment in people referred to them for other reasons, and may then suggest a clinical assessment for dementia. Irrespective of the location and presentation, all people with suspected dementia and their families will benefit from a full and comprehensive diagnostic assessment and evaluation of their needs. Until recently, assessment and management of dementia in the UK was mostly conducted within specialist memory services (NICE-SCIE, 2006), which were generally run by mental health services (Department of Health, 2009). Over the past five years, there has been a global shift towards primary care services taking the lead in screening, assessment, diagnosis, and management of dementia. Evidence is emerging that, given the right level of training and resources, these services could provide comprehensive care for patients with dementia (Spenceley et al., 2015).

Assessment of early dementia

Assessment of early dementia includes a detailed description of the presenting problems, psychiatric and medical history, current medication, functional ability, living situation, the ability of significant others to provide care, plus a physical examination, mental state examination, and assessment of the risks of harm to self and others. If consent is given, it is useful to corroborate the history with a member of the family or someone who knows the person well, as even in mild dementia there may be subtle changes in memory, behaviour, or personality that the person with dementia has not noticed. Although people with dementia and their carers are typically seen together, it is also valuable to see them separately to allow both the opportunity to discuss any confidential matters. If the person does not speak English it is good practice to use an approved interpreter, rather than a member of the person's family, so that relatives' personal opinions do not overly influence the assessment (Moriarty et al., 2011). In the UK, the carers of people with dementia have the right to receive an assessment of their own needs, as set out in the Carers and Disabled Children Act 2000 and the Carers (Equal Opportunities) Act 2004.

Appropriate investigations help to confirm the diagnosis and aetiology of dementia, which enables a more accurate prediction of the natural course of the disease; this in turn facilitates information sharing, forward planning, and individually tailored management packages for people with dementia and their families. NICE-SCIE guidelines (2006) recommend that a basic dementia screen should be performed at the initial presentation, including routine haematology, inflammatory markers, serum B₁₂ and folate, and tests for electrolytes, calcium, glucose, liver,

Management of dementia

renal, and thyroid function. A urine sample is collected if a urinary tract infection is suspected. Testing for syphilis and HIV is also carried out if indicated as appropriate by the clinical history. Other physical investigations that help with the diagnosis and the aetiology or subtype of the dementia include neuroradiological imaging, both structural, e.g. magnetic resonance imaging (MRI) or computed tomography (CT), and functional, e.g. single-photon emission computed tomography (SPECT). Sometimes electroencephalography or cerebrospinal fluid examination can be helpful in elucidating the diagnosis. Molecular imaging techniques, amyloid, and tau-labelled positron emission tomography (PET) scans are not yet widely available in UK clinical services.

Brief tests such as the Mini Mental State Examination (MMSE) (Folstein et al., 1975) and the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005) are often used to assess cognitive function. In early dementia these tests can be misleading, as performance is affected by educational and sociocultural background, by functional illness (especially depression), and by non-Alzheimer's dementias. In frontotemporal dementia, changes in behaviour and personality often occur before cognitive decline, and in Lewy body dementia (LBD), memory is often initially spared. Thus, in early dementia, a more sensitive neuropsychological assessment is often required, e.g. the Addenbrookes Cognitive Examination-III (ACE-III) (Hsieh et al., 2013). Alternatively, a complete neuropsychological test battery can be administered, which evaluates specific domains of cognitive function, such as attention and concentration, orientation, short- and long-term memory, praxis, language, and executive function. Combined with the clinical findings and other investigations, a neuropsychological profile is generated that may help to identify a particular subtype of dementia.

The assessment of dementia is discussed in more detail in Chapter 9, Chapter 10, Chapter 23, and Chapter 28.

Management of early dementia

The assessment of the person with dementia identifies the unique circumstances and needs for that person and their family in order to create an individually tailored care plan to meet those needs. Once a diagnosis has been made and a management plan produced, most dementia will be managed by the family, assisted by primary care and social care services. The role of the dementia specialist is increasingly to educate and offer expert advice to workers in primary care, secondary care, social care, and residential care settings, in order to provide optimal care for the person with dementia (Department of Health and Care Services Improvement Partnership, 2005).

The main management tasks in early dementia of any aetiology are i) providing person-centred care, ii) disclosing the diagnosis, iii) optimizing

Management of dementia

quality of life in the present, iv) interventions for cognitive symptoms of dementia, and v) planning for the future.

Person-centred care

Person-centred care has become the cornerstone of the management of dementia. It upholds the idea that, throughout the course of their illness, people with dementia should remain valued as individual human beings with their own personal perspective on the world; they will require authentic and respectful communication from the people around them at all times (Kitwood, 1997). In early dementia, this approach requires an active process of respecting the person with dementia's right to autonomy in decision-making, while also maintaining duty of care. In the UK there is now a legal framework in place— the Mental Capacity Act (2005), which was implemented in 2007—that helps guide health and social care professionals. Under the Mental Capacity Act, people are assumed to have capacity to make decisions about their care until proved otherwise, and even if a person does not have capacity, then a decision made in that person's best interest must take into account his or her past and current preferences on the subject. In early dementia, the principle of respecting autonomy applies to diagnostic assessment, confidentiality, gaining consent to speak with family members, requesting physical investigations, disclosing the diagnosis, starting treatment with drugs, future planning, collaborative care, and more complex decisions, such as who should take responsibility when a person is no longer able to manage his or her finances. The majority of people with early dementia are likely to retain capacity to make decisions in most areas, but service providers can sometimes assume otherwise and undermine the autonomy of people with dementia. Hence health and social care providers are advised to support training of their employees regarding autonomy and capacity to consent in people with dementia, to ensure that they respect their legal and human rights (Department of Health, 2009).

Engaging the family of the person with dementia in collaborative planning for the present and for the future is vital. It is important to remember that consent should be obtained from the person with dementia to have the family member involved (NICE-SCIE, 2006), and, as the person's initial decision may change, requesting consent is a process that should be repeated frequently.

Disclosing the diagnosis

There is a common concern that the experience of diagnosis disclosure will be distressing for people with dementia, their family members, and for the healthcare professionals involved. Some practitioners are reluctant to impart a diagnosis for a progressive terminal disease with as yet no effective cure and uncertain prognosis (Robinson et al., 2011). However, most people with dementia wish to know their diagnosis (Pinner and Bouman, 2003), and disclosure may even reduce anxiety (Mormont et al., 2014). People with dementia and their families require adequate time

Management of dementia

to discuss the diagnosis and its implications. The disclosure of the diagnosis of dementia is best conducted over a series of contacts, rather than in a single interview, because patients and carers may not retain information about the diagnosis after the first disclosure. Eight key behaviours have been identified as 'best practice': preparing for disclosure, integrating family members, exploring the patient's perspective, disclosing the diagnosis, responding to patient reactions, focusing on quality of life and wellbeing, planning for the future, and communicating effectively (Lecouturier et al., 2008). Written information about the signs, symptoms, course, prognosis, and treatments for dementia is important, as is signposting people to local care and support services, financial advice, legal advice, and advocacy (NICE- SCIE, 2006). There are particularly good resources available online, e.g. Alzheimer's Society (<http://www.alzheimers.org.uk>).

Optimizing quality of life in early dementia

The main goal of management at this stage is to optimise the person with dementia's function and quality of life by identifying and treating any potentially reversible factors (physical, psychological, environmental, and/or sociocultural) that might have an adverse impact.

Reversible factors—physical

Although dementia is a progressive disorder, it usually presents in later life when there are many other factors—biological and non-biological—that affect the optimal function of both the brain and the body. The saying 'what's good for the body is good for the brain' is useful guidance to people with dementia. There is increasing evidence (Livingston et al., 2017)) that the benefits of good nutrition, regular sleep, exercise, reducing alcohol and tobacco intake, and keeping to a weekly and daily routine are likely to reduce the impact of the disease. More specific health interventions may include controlling high blood pressure, dyslipidaemia, diabetes, vascular risk factors, and managing chronic illnesses, e.g. osteoporosis and sensory impairment, all of which can also exacerbate the extent of cognitive and functional impairment in people with early dementia. Alcohol and substance use disorders should be considered as they are increasingly common in older people (Kuerbis et al., 2014) and are likely to worsen any cognitive impairment seen in an underlying dementia (Royal College of Psychiatrists, 2005).

Physical factors may also cause a delirium in a person with early dementia. Delirium can be thought of as 'acute brain failure' in response to a noxious insult (Inouye et al., 2014), which is most often physical but may also be psychological, social, and/or environmental. Common causes of delirium are infection (respiratory and urinary tract), heart failure, electrolyte or metabolic imbalance, and untreated pain. Many prescribed drugs can also worsen cognitive impairment, particularly those with anticholinergic side effects (e.g. tricyclic antidepressants and drugs prescribed for urinary frequency and bladder instability) as they may

Management of dementia

exacerbate the symptoms caused by the cholinergic deficit that is a feature of most dementing illnesses. Other medications that commonly cause confusion are opioids (including tramadol, fentanyl, and buprenorphine), but severe pain can also worsen cognitive impairment, so balancing the benefits versus the harm of potent analgesics can be challenging. If delirium is present, the severity of the underlying dementia may be over-diagnosed, so it is essential to obtain from someone who knows the patient well any collateral information about the level of cognitive function prior to the current illness. Recent sudden deterioration almost always indicates a delirium. In the UK, NICE guidelines recommend that all cases of previously undiagnosed dementia in the acute hospital be referred to a hospital mental health liaison service for a full assessment (Department of Health, 2009). The service will usually recommend prompt treatment of the underlying physical disorder, a swift discharge from hospital, with intermediate care if required, followed by a full assessment by the local memory service once the condition has stabilized. The aim of this approach is to return the patient to a familiar environment as quickly as possible, since hospital admission in dementia is associated with adverse outcomes, including increased length of stay, institutionalization, and mortality (Royal College of Psychiatrists, 2005; Sampson et al., 2009).

Reversible factors—psychological

Symptoms of depression and anxiety may arise secondary to the patient's insight into their diagnosis and concern about the changes associated with the early stages of dementia, or in response to the change in other people's behaviour towards them. NICE guidelines recommend that people with early dementia of all types should be given the opportunity to have post-diagnostic counselling to explore what the diagnosis means to them and to develop coping strategies (NICE-SCIE, 2006). In practice this rarely happened in hard-pressed services, but following the 2012 Prime Minister's Dementia Challenge there has been increased interest in providing good quality post-diagnostic support for both the person living with dementia and their families and a wide range of psychosocial interventions are now available (Guss et al., 2014).

Some people with early dementia will have a comorbid depressive illness. The prevalence of depression in people with dementia is approximately 20%, with the annual incidence rates of major and minor depression being reported as 10% and 30%, respectively (Ballard et al., 1996). People with early dementia who have a coexisting depressive illness are likely to present with characteristic symptoms including low mood, tearfulness, insomnia, lack of enjoyment, reduced motivation, and poor appetite, but the syndrome may additionally worsen their cognitive function and ADLs. As depression can present with similar symptoms to early dementia, a new diagnosis of dementia should usually be suspended until after the depressive illness is successfully treated. Recently, Petersen and colleagues (2017) reported that major depression in people with mild dementia more than doubled mortality rate at three-year follow-

Management of dementia

up. Given that depression is potentially treatable, it is important to assess for depressive symptoms and be proactive in its treatment. As there is frequently an overlap of physical symptoms, e.g. apathy and fatigue, between depression and dementia, it is important to identify target non-somatic symptoms, e.g. anhedonia and guilt, which can be monitored to ensure reduction in symptoms over time. Rating scales for depression, e.g. the 15-item Geriatric Depression Scale (GDS-15) (Sheikh and Yesavage, 1986), show validity for use in people with early dementia (Burke et al., 1989), and can be used to help assess the severity of depression prior to treatment and to examine treatment response.

Nonpharmacological interventions for depression in early dementia are the mainstay of treatment and include maintaining pleasurable activities, addressing relationship and environmental difficulties, exercise, as well as psychoeducation and psychological support. More specific psychological treatments, such as cognitive behavioural therapy for depression, are also effective in early dementia (Orgeta et al., 2014). There are insufficient high-quality RCTs to assess the efficacy of antidepressant medications in people with dementia (Orgeta et al., 2017) but they are effective for the treatment of depression in older people without dementia (Mottram et al., 2006) and should be considered as part of the management. Sequenced treatment plans are recommended in various guidelines (NICE, 2009). Usually a selective serotonin reuptake inhibitor (SSRI) is used first-line. If there is no response to the first class of antidepressant, then another from the same or a different class should be tried; or, if there is a partial response, then augmentation with another antidepressant can be used, e.g. adding mirtazapine to an SSRI. Robust treatment strategies are more likely to lead to successful outcomes and lessen therapeutic nihilism. If there is a past history of depressive illness, a previous good response to antidepressant medication usually predicts future response and it makes sense to try successful treatments again. Older patients on long-term antidepressant therapy may have taken tricyclic antidepressants for many years. As the anticholinergic side effects are likely to worsen the confusion seen in dementia, it may be necessary to switch the patient to either another tricyclic antidepressant with fewer anticholinergic side effects (e.g. lofepramine) or an antidepressant from an alternative class, such as an SSRI. Close monitoring is required as there are considerable risks associated with antidepressants in older people, including anticholinergic side effects, cardiotoxicity, gastrointestinal bleeding, hyponatraemia, falls, and fractures (Coupland et al., 2011). As with treatment of depression in any other patient group, the patient with dementia should be kept on a maintenance treatment regime using the drug and dose that resulted in effective remission of symptoms: 'the dose that gets you well, keeps you well'.

Occasionally, people with early dementia present with psychotic symptoms. People with psychosis may believe that people are trying to harm or steal from them. It should be remembered that sometimes the

Management of dementia

belief is true, but most often these delusions are the result of people with dementia trying to make sense of their world: if they are unable to find familiar items or money (often misplaced due to forgetfulness) they may conclude that they have been stolen. Other people may present with hallucinations, which are usually visual, well-formed, and detailed, and may be recognized as unreal and even pleasant by the person. Less commonly, in early dementia the emergence of hallucinations may be part of the syndrome associated with LBD (McKeith et al., 1996). If LBD is suspected, it is useful to enquire about other symptoms, such as fluctuating cognition, visual hallucinations, REM sleep disorder, parkinsonian symptoms, and sensitivity to dopamine antagonists, e.g. neuroleptics, but also antiemetics such as metoclopramide. The treatment of psychosis in dementia is discussed in more detail later in the chapter.

Reversible factors—environmental and sociocultural

In early dementia most ADLs remain intact, although there may be subtle changes in managing finances or remembering to take medication. The opinion of an informant who knows the patient well is useful, as people with dementia may not always have insight into their difficulties. An assessment carried out in the person's home creates the opportunity to make a quick evaluation of any environmental risks (e.g. out-of-date food or fire hazards, e.g. burnt saucepans) and the need for any aids, equipment, or adaptations in the house. Advice regarding enhancing ADLs can be sought from an occupational therapist and/or physiotherapist. Environmental modifications inside and outside the home may be required, e.g. the instalment of stair rails or shower facilities. Assistive technology can also help promote independence, e.g. an automatic pill dispenser can remind people with dementia when it is time to take their medication that might otherwise have been forgotten, particularly if they live alone and have no other means of being reminded. In the era of smart phones, smart homes, and the growing use of information and robotic technologies, there is increasing interest in the use of assistive technology to support people living in their own homes and to reassure family members about their safety. However, the associated ethical issues should always be considered as the new technology may compromise the person's right to privacy, and may also reduce access to real social contact.

Social care services can be engaged to provide home care and day care that will support independent living at home for as long as possible. People with early dementia may not recognize the extent of their difficulties and will sometimes send away the home care worker who arrives at their house to help them with food preparation, cleaning, or personal care. It is becoming part of the remit of specialist mental health services to educate staff in mainstream services so that they can recognize and provide good-quality care to the increasing number of people that they will see who will have a dementing illness (Department of Health and Care Services Improvement Partnership, 2005).

Management of dementia

The most important sociocultural interventions are those that support the family of people with dementia. Families will provide the majority of the care for the person with dementia, and therefore need to be supported from the beginning. They will face many difficult challenges, including coming to terms with the diagnosis themselves. They will gradually need to take over decision-making and will have to weigh up the balance of autonomy versus risk in the process, which may lead to disagreements and distress. This can happen even at early stages of dementia, with decisions about driving, for example. Carers may have problems looking after their own needs as well as those of the person with dementia. They may admit to frustration, along with verbal and sometimes physical aggression towards the person with dementia. Pre-existing ambivalence in the relationship may make adjustment more difficult and abuse more likely (Homer and Gilleard, 1990). As the disease progresses it has further psychological effects on the carer, in particular on the spouse, who often goes through a grieving process for aspects of his or her partner that disappear, while having to quickly adjust to new aspects that may emerge. It is essential that carers are supported with whatever they are dealing with, and do not feel they have to shoulder the burden alone. If the caregiver is supported to manage the challenges of caregiving, they will benefit, and the person with dementia benefits as well. Specific interventions for carers of people with early dementia include individual and group psychoeducation, peer support groups, support by telephone and via the Internet, training courses, problem-solving, communication courses, and cognitive behavioural therapy (Selwood, 2007). Family therapy has also been shown to be helpful in families of people with dementia, providing a space for stories to be heard and long-standing disputes to be resolved (Gilleard, 1996). Interventions designed to improve carers' mental health need to be individually tailored, rather than generic. Initiatives such as STRategies for RelaTives (START) help caregivers tackle their own particular challenges, plan for the future, and build in relaxation time; the carer leaves with a personalized manual to continue strategies they had found effective (Livingston et al., 2014a). START has been shown to reduce anxiety and depressive symptoms in carers and has been found to be cost-effective in both the short and long term.

Interventions for cognitive symptoms of dementia

The use of acetyl cholinesterase inhibitors in the management of dementia is discussed in Chapter 35 and will not be discussed in detail here. The three main cholinesterase inhibitors, donepezil, rivastigmine, and galantamine, are used in the treatment of Alzheimer's disease dementia and have similar efficacy in improving symptoms of cognition, function, and behaviour (Birks, 2006). Not all people with dementia will respond to treatment with cholinesterase inhibitors but, as it is not possible to predict those that will, all those without contraindications will be offered a trial of treatment. Cholinesterase inhibitors should be continued for people whose dementia has become severe as

Management of dementia

discontinuation results in a cognitive and functional decline, an increased likelihood of emergence of neuropsychiatric symptoms, and doubles the risk of admission to a care home (Howard et al., 2012, 2015). Memantine acts at different receptor sites to the cholinesterase inhibitors; its therapeutic action is thought to arise from blocking N-methyl-D-aspartate (NDMA) receptors, resulting in a neuroprotective effect on the brain. Memantine is well tolerated and confers some benefit on functional and cognitive outcomes in dementia (McShane et al., 2006); in the UK it is recommended for use in people with moderate AD in whom cholinesterase inhibitors are contraindicated or not tolerated due to adverse side effects (NICE, 2011).

There are also several nonpharmacological interventions aimed at improving the cognitive symptoms of early dementia. Cognitive stimulation therapy, a group-based reality orientation therapy, has the strongest evidence for improving cognitive function (Woods, 2012). Other interventions such as cognitive training, reminiscence therapy, validation therapy, and exercise are all helpful in reinforcing positive coping strategies, but most systematic reviews have concluded that there are insufficient robust studies to draw conclusive verdicts about their effectiveness (Livingston et al., 2017).

Planning for the future

Timely diagnosis of dementia allows the person with early dementia to be involved in planning for their future. Typical issues are decisions about stopping driving, financial management and advanced care planning. Decisions regarding driving ability can be a particularly challenging area as it is possibly the most significant issue that affects a person's independence. People with early dementia do not have to automatically give up driving, but even mild stages of dementia can increase the risk of failing a performance-based road test (Chee et al., 2017). A history of accidents or near misses (either given by the patient or by someone who knows them), evidence of executive dysfunction or visuospatial deficits on neuropsychological testing, and the new prescription of psychotropic medication may all affect ability to drive. In the UK, people with dementia are legally obliged (if advised by their doctor) to notify the Driver and Vehicle Licensing Agency (DVLA) and should also inform their motor insurance provider. If the clinician feels they have insufficient information about driving to advise the patient, they can suggest taking a disabled driving assessment at a local centre. In those who can continue to drive, it is sensible to advise that they avoid driving in heavy traffic, at night, or in bad weather and to drive accompanied if possible. Decisions regarding driving must be reviewed regularly, as dementia is a progressive disorder and thus driving ability will change. If the person with dementia refuses to stop driving, then the person's family may need to disable the car, or even involve the police to prevent unsafe driving becoming a hazard to the public.

Management of dementia

People with early dementia may be aware that they are beginning to find it difficult to manage their financial affairs, perhaps not paying their bills on time, or forgetting they have withdrawn money from the bank. They may become vulnerable to financial exploitation, whether due to consumer fraud or undue coercion by people known to them who aim to persuade them to use their assets against their best interests. For these reasons, a key aspect of management at this time is to discuss whom they would like to manage their financial affairs in the future. In the UK, people can make a Lasting Power of Attorney for Property and Financial Affairs (LPA(PFA)), which can either be used as soon as it is registered or when people lose capacity. They may also wish to appoint someone to make decisions about their future health and social care, in which case they can make a separate Lasting Power of Attorney for Health and Welfare (LPA(H&W)). These issues are covered in more detail in Chapter 52 and Chapter 58.

Later dementia

Presentation of later dementia

Some people with dementia do not present until later in the course of the disease. This is commonly because the person providing care for the individual with dementia believes that his/her behaviour is an inevitable part of ageing and is perhaps unaware that help and support are available. Sometimes the caregiver may delay seeking help for fear of the consequences of diagnosis, for example, placement in residential care. In these situations, presentation is often precipitated by a change in the caregiver's circumstances; the caregiver themselves may become too psychologically or physically unwell to be able to provide care any longer. Other people without carers but with fairly advanced dementia continue to live independently in their own homes without help for many years, particularly if they have well-established routines, having lived in the same house for many years, treading well-worn routes to the shops and other facilities in their local area. Likewise, people who have lived in residential care for many years may develop dementia but care staff do not recognize their gradual cognitive and functional decline. In both these scenarios the presentation is usually triggered by a physical, psychosocial, or environmental change in the person with dementia; they are liable to present in crisis or at immediate risk, and are thus more likely to require specialist dementia care from health and/or social care services.

Reasons for referral in later dementia are usually due to behaviours identified as high risk or challenging. These have been described as 'behaviours that challenge', because they are problematic for the people with the behaviour and to the people around them, including families, neighbours, co-residents, and care staff. They are also referred to as the behavioural and psychological symptoms of dementia (BPSD), and, for the sake of convenience, that term will be used here. If people with later dementia still live at home, BPSD may include wandering, leaving the

Management of dementia

front door open, poor hygiene, hoarding, incontinence, self-neglect, weight loss, and allegations about people stealing from them or harming them in some way. If they live in supported accommodation, residential care, or a nursing home, then their behaviours are likely to be those that staff and other residents find difficult to tolerate, and may include screaming, shouting, calling out, wandering, agitation, verbal or physical aggression, inappropriate incontinence, faecal smearing, and inappropriate sexual behaviour. Other symptoms may include delusions, hallucinations, anxiety, depression, apathy, misidentification, and disinhibition. At this stage of dementia, individuals are less likely to have capacity to make decisions about their care and, having little insight into the extent of their difficulties, may refuse help. The ethical issue of intervening in someone's life without their consent, possibly in response to third-party information, often has to be considered in these circumstances. Specialist input from community-based mental health and social care services may be required in the short term, but this should always be a collaborative process, working with families, primary healthcare professionals, social care services, and involving the person with dementia as much as possible in the decision-making process.

Assessment of later dementia

In later dementia it remains essential to carry out a comprehensive assessment of needs, accurately describing the target symptoms, in order to develop a robust management plan. Gathering all the information required can be challenging as people with dementia may not be able to communicate their difficulties easily, so an informant's history becomes increasingly important. If the person with dementia is living in a care home, it is important to bring together the views of both the care home staff and visiting family members or friends, as every perspective will be valuable. Care home staff are able to give details of day-to-day behaviours, but friends and family members are able to bring years of knowledge about the person and his or her usual ways of reacting to events. Involving families and carers in the assessment process has the added benefit of involving them in the management process too.

Physical investigations may be required to confirm the diagnosis and subtype of dementia, and to identify any reversible factors. A diagnosis can help explain patterns of behaviour and predict a treatment response to some pharmacological interventions. However, a person with later-stage dementia may be unable to tolerate having blood tests or neuroimaging, in which case it may be necessary to rely solely on clinical history, mental state examination, and observations from carers.

Assessment of BPSD

The behavioural and psychological symptoms of dementia (BPSD) are a complex group of behaviours that increase in frequency and severity as the dementia progresses (Savva et al., 2009; Brodaty et al., 2015), are strongly associated with carer distress (Black and Almeida, 2004), and

Management of dementia

adverse outcomes such as entry into institutional care (Brodaty et al., 2014) and prolonged length of stay in hospitals (Royal College of Psychiatrists, 2005). Therefore, it is important to assess and treat in order to improve patient and carer outcomes.

Assessment of BPSD requires understanding the behaviour as an attempt by the person to express an unmet need, which may be physical or psychological (Stokes, 2000), rather than as an inevitable (and thus untreatable) feature of later dementia. The behaviour needs to be understood as a method of communication that reflects the interaction between the person with dementia, the care giver, and the environment (Fig. 36.1); the challenge is to understand the communication. Failing to understand the communication, or worse, treating the behaviour as a nuisance, will only result in intensifying the behaviour intended to communicate the unmet need. To understand the behaviour, we need to first understand the individual—their personal and family background, their premorbid personality, their past medical and psychiatric history, their current physical and psychological problems, their communication difficulties in terms of speech and hearing, and their social situation. Second, we need to be able to make accurate and non-judgmental observations of a person's behaviour. The most commonly used approach is the 'ABC' method, in which the context or antecedent (A) of the behaviour is reported, the behaviour (B) itself is described, and then the consequences (C) of the behaviour are observed and documented. The understanding of BPSD depends upon the cooperation of carers, who are often under considerable stress themselves. As most carers have no training, this task can appear overwhelming and often futile. Dementia specialists undertake to enable and empower carers, family members, and significant others in the objective observation of behaviour without adding opinion or judgment. Once information has been gathered about the nature of the behaviours, they can, in the light of what they know about the person's background, create a hypothesis about what the behaviour means in terms of unmet need; after this, a management plan can be initiated, implemented, and evaluated.

Management of dementia

Fig. 36.1

The behaviour needs to be understood as a method of communication that reflects the interaction between the person with dementia, the care giver, and the environment.

The causes of BPSD, and therefore their management, can be broadly categorized into physical, psychological, social, and environmental factors. Describing the presenting symptoms is essential, as is actively seeking out their possible causes in all of these areas, before starting targeted treatment. Clinicians sometimes use tools such as the Neuropsychiatric Inventory-Questionnaire (Kaufer et al., 2000) to measure the baseline severity and distress caused by behavioural and psychological symptoms of dementia and which can also be used to monitor the response to interventions.

Physical causes of BPSD

As in early dementia, physical and pharmacological factors can have a detrimental effect in later dementia, and these should always be considered in BPSD. Pain, infection, dehydration, constipation, and adverse drug side-effects are all common causes of agitation and calling out in people who are unable to verbally express their discomfort. Many people with later dementia have painful conditions associated with ageing, so this cause of BPSD needs to be actively considered and treated with adequate analgesia. People with later dementia are at increased risk of delirium as brain reserve diminishes. The characteristic sign is a sudden change in behaviour, often recognized by people who know them well. A physical examination and review of medication is necessary, and a delirium screen including blood tests and a urine sample may be required. If the patient requires admission to general hospital for appropriate treatment of physical causes, hospital staff should be advised that the change in environment is sufficient to worsen confusion (and BPSD) in people with dementia.

Management of dementia

Psychological causes of BPSD

Depressive symptoms are common in later dementia and may present with challenging behaviours such as agitation, anxiety, irritability, calling out, crying, and clinging to people for reassurance. Risk factors for depression in dementia are family history, past history, younger age at onset of dementia, and female gender. An unhappy childhood may be relevant, particularly as people with later dementia are often reliving their childhood memories by this stage in the disease and no longer have the psychological defence mechanisms to protect themselves against emotional pain. Depression in dementia may be precipitated by a change in environment, particularly the move into a care facility. The prevalence of depression among older people in long-term care is up to 35% (Thakur and Blazer, 2008) and in general hospitals is approximately 20% (Royal College of Psychiatrists, 2005), compared to a community prevalence of 5–10% (Copeland et al., 1999). Relationship factors such as bereavement or carer stress may also trigger depression, even if the person with dementia seems to be unaware of them. Affective symptoms in later dementia are similar to those seen in people without dementia and include low mood, social withdrawal, poor appetite and weight loss, disturbed sleep, tearfulness and depressive content to speech, and an expressed wish to either die or end their life. There may be diurnal variation of mood or other BPSD (e.g. calling out or aggression that is worse in the mornings but diminishes by the end of the day). The Cornell Scale for Depression in Dementia (Alexopoulos et al., 1988) is a useful rating scale to assess the severity of depressive disorder and to monitor its response to treatment, as it utilizes the observations of carers and staff.

Psychosis is also a common feature in later dementia and can present as agitation. As communication may be challenging, clinical observation is an essential component of the assessment, for example, signs such as plucking at bedclothes can suggest the presence of visual hallucinations. Psychotic symptoms could indicate a delirium or affective disorder, but may also be a characteristic of the underlying dementia of any aetiology, but most commonly LBD. Hallucinations may be perceived as a threat so may result in behaviour aimed at self-defence, including verbal and physical aggression towards others or barricading themselves away from others.

Environmental and social causes of BPSD

Assessment of all dementia, but particularly dementia in the later stages, requires an evaluation of the context or system in which the person with dementia is living; assessments of the living situation and significant relationships are paramount. This applies whether the person is living in the family home, is in residential care, or in the general hospital. People with later dementia are easily disorientated, confused, and frightened by new environments and unfamiliar people. Changes can precipitate behaviours that challenge, particularly if staff do not understand why

Management of dementia

patients are fearful and aggressive, shouting for help, or perhaps urinating inappropriately because they cannot find the toilet. Behaviours such as aggression, agitation, apathy, and shouting also increase the potential risk of abuse from some carers—either through neglect of the person (particularly if staff do not know how to manage the behaviour) or by more deliberate acts, such as physical aggression or restraint, psychological bullying, or sexual exploitation. Furthermore, abusive behaviour from carers can often be overlooked as a *cause* of BPSD.

Management of later dementia

The progressive nature of dementia means that there are additional management issues in later stages. This section focuses on i) the ongoing requirement for person-centred and relationship-centred care in later dementia, ii) management of BPSD, iii) making decisions for people who no longer have capacity to do so for themselves, and iv) end-of-life care for people with end-stage dementia.

Person-centred and relationship-centred care

Person-centred care remains at the heart of the management of later dementia, but it can be challenging to maintain this approach with individuals who are unable to articulate their opinions about choices in life. Hence, the central task in the management of later dementia is to facilitate communication and respect for the person's life-long preferences as far as possible in all areas of decision-making, while also providing care that is safe, lawful, and optimizes quality of life for people with dementia and their caregivers. The concept of 'personhood', i.e. respecting and valuing each person regardless of the extent of impairment, is especially important in the later stages of the disease, and is fundamental to maintaining positive social relationships in dementia (Kitwood and Bredin, 1992). As people get older, their family and friends may pass away and with them the biography, life stories, and experiences of the person with advanced dementia. Unless there is a proactive attempt to preserve the people's identity by creating sufficient documentation of their existence, people with dementia can be left with no life context, which makes it much easier for other people to treat them as 'nonpersons', and increases the potential risk of neglect and abuse. One of the ways in which this can be achieved is by life story work, which aims to capture memories in imaginative ways that may include words, photographs, and music, which can be stored in various formats, e.g. in a scrapbook or on a DVD (Moos and Bjorn, 2006). In the UK many health and social care organizations use the Alzheimer's Society *This is Me* booklet, in which family and professionals can record details of a person's cultural and family background; events, people, and places from their lives; preferences, routines, and their personality. This enables health and social care professionals to tailor care specifically to the individual. For instance, if a person has a lifelong habit of walking or gardening, then an attempt to get outside does not have to be wrongly interpreted as an attempt to leave. These tools help caregivers to know the person behind

Management of dementia

the dementia, and allows them to respect the person's preferences for food, music, hobbies, and people, as well as his/her spirituality and religion.

Management of BPSD

Because of the complex causes of BPSD, a 'one size fits all' management solution does not exist (Kales et al., 2015). Management includes both nonpharmacological and pharmacological approaches that have to be tailored to the person with dementia, their caregivers, and the environment. This has been described as the DICE approach—*Describe the problem, Investigate the cause, Create a plan, Evaluate its effectiveness* (Kales et al., 2015).

Nonpharmacological management of BPSD

Nonpharmacological approaches are the first-line management for BPSD; they include person-centred care, caregiver support, and improving social interactions (Department of Health, 2009; Alzheimer's Society, 2011). Pharmacological approaches should only be considered first-line when there are clear indications, such as significant risk of harm to self or others, as exemplified in Fig. 36.2. Non-pharmacological interventions are essentially good quality care so can also be seen as effective in preventing BPSD. Environmental factors that have been identified in the assessment must also be addressed. If the person with dementia is living in a care home, then familiar items such as furniture and photographs can help to maintain a sense of security, trust, and comfort in an increasingly disorientating and confusing world. Equally important is the presence of a calm and friendly routine with familiar carers. Relating to the person with dementia rather than to the patient with a disease is particularly important, and requires the provision of good quality educational programmes. Box 36.1 demonstrates how good communication skills are essential during everyday tasks such as personal care. Specific non-drug treatments for BPSD recommended in the NICE dementia guidelines include aromatherapy, animal-assisted therapy, massage, multisensory stimulation, therapeutic dance, and music therapy. Two recent systematic reviews (Livingston et al., 2014b; Kale et al., 2015) found that, whether delivered by family caregivers or care home staff, individually tailored interventions involving person-centred care and communication skills training had the most effective long-term effect in reducing agitation in later dementia.

Management of dementia

Fig. 36.2

Pharmacological approaches should only be considered first-line when there are clear indications, such as significant risk of harm to self or others.

All rights reserved. DOI: [https://doi.org/10.1016/S0140-6736\(17\)31363-6](https://doi.org/10.1016/S0140-6736(17)31363-6).

Box 36.1 Example of communication skills and person-centred care for agitation during personal care

Communication skills and person-centred care involve considering what the person with dementia understands, is trying to say, and what they want, rather than being focused on completing a task, such as personal care, to help them. It involves verbal and non-verbal communication.

This example is about being aware that someone with dementia who requires personal care might not understand or remember this. When that happens, well intentioned, necessary care might be experienced as assault and the person could become agitated. The principles of communication are to:

- Identify yourself and others if the patient does not remember
- Explain what is happening, when it is happening, one step at a time (because the person with dementia might not remember)
- Use calm, reassuring tones

Management of dementia

- Ensure you can be heard
- Avoid negative words and tone
- Ask one thing at a time
- Speak slowly
- Allow the person with dementia sufficient time to respond
- Offer simple choices (no more than two at a time)
- Help the patient find words for self-expression (and check if you have understood correctly)
- Lightly touch to reassure, calm, or redirect
- Use relaxing sensory stimuli, such as music or soft lighting, if they enjoy it

Advanced dementia can have a devastating impact on family caregivers, who are often older and may be frail themselves. Without support, they frequently end up exhausted, isolated, and unable to cope. It is at this point that people with later dementia may present in crisis, when their carers can no longer look after them due to their own physical or psychological ill health. Specialist dementia care services can support carers by facilitating access to transport, sitting services, day care, domiciliary care, night sitting services, and respite care in the person's own home or in a care home, as well as provide psychosocial support for the carers themselves.

Pharmacological management of BPSD

Physical causes of BPSD should be considered and treated, for example, giving antibiotics for a respiratory or urinary tract infection. Pain is a common cause of BPSD and a recent trial reported that treating behavioural symptoms with a trial of stepped analgesia (most receiving paracetamol) significantly reduced agitation in people with moderate to severe dementia (Husebo et al., 2011).

If a depressive disorder is suspected, then treatment with antidepressants might be considered. There is little evidence that antidepressants are effective in depression in people with dementia (Farina, 2017) but studies are frequently statistically underpowered. A recent large UK study (Banerjee et al., 2011) that compared the effectiveness of sertraline and mirtazapine with placebo reported that the two antidepressants had no greater benefit and increased the risk of adverse events. However, all three treatment groups showed a consistent improvement in depression

Management of dementia

rating, indicating that non-drug treatments deployed by community mental health teams may be the most helpful intervention for depression in dementia. The most recent recommendations (Livingston et al., 2017) are that antidepressants should not be started in people with dementia, unless there is a history of depressive episodes before the dementia, or if the patient has not responded to social or psychological treatment and is moderately or severely depressed.

Antidepressants are sometimes used to treat agitation in later dementia (Farina et al., 2017). The SSRIs citalopram and sertraline, but *not* trazodone, are effective in reducing agitation, and the addition of a psychosocial intervention to citalopram was found to be more effective than the psychosocial intervention alone for both agitation and caregiver distress (Porsteinsson et al., 2014).

If BPSD continue to cause distress, or if there are significant risks to the person with dementia and/or others, then short-term treatment with other psychotropic medication may be considered. Antipsychotic drugs have the strongest evidence base (Kale et al., 2015) but, in recent years, there has been considerable concern about the risks associated with the use of antipsychotic drugs to control challenging behaviour. Antipsychotic medication has sometimes been used to treat the symptoms without addressing the cause of the behaviour: this is unacceptable and puts people with dementia at risk, as antipsychotics have been reported to increase the risk of cardiovascular events, extra-pyramidal side effects, and falls, as well as increasing mortality (Ballard and Waite, 2006; Banerjee, 2009). Thus, the only indication for the use of antipsychotic medication is where the patient is severely distressed and agitated and nonpharmacological methods have failed, and/or if the patient or others are at risk. Antipsychotics do not improve restlessness or non-aggressive behavioural symptoms in dementia but can reduce aggression and psychosis (Ballard and Waite, 2006). The two drugs with the best evidence of effectiveness are risperidone and aripiprazole, but other atypical antipsychotic drugs such as olanzapine and quetiapine are also used in practice. Current advice is that treatment should be targeted at specific symptoms, which should be precisely described at baseline and at frequent follow-up; and that treatment is reduced and discontinued within three months (Fig. 36.2; Banerjee, 2009; Alzheimer's Society, 2011). Antipsychotic medication should be avoided in LBD, as antipsychotics can cause acute dystonia and sudden death (McKeith et al., 1992). Cholinesterase inhibitors are usually used as a first-line treatment for psychosis in LBD, but if these are ineffective then the antipsychotic quetiapine may be tried as it appears to have the fewest side effects of the atypical antipsychotics and is sometimes effective (Zahodne and Fernandez, 2008). There is some evidence that the antipsychotic clozapine is useful in treating psychosis in Parkinson's disease dementia, but no studies have been carried out in LBD to date (Weintraub and Hurtig, 2007).

Management of dementia

Benzodiazepines are usually avoided in older people because they can increase confusion and the risk of falls. However, those with a shorter half-life, e.g. lorazepam, are sometimes used in the short-term treatment of agitation.

Cholinesterase inhibitors may be of benefit in non-cognitive symptoms, including depression, apathy, and anxiety, but not agitation or aggression (Howard et al., 2007). Rivastigmine and donepezil, and to a lesser extent galantamine, have all been shown to be effective in treating cognitive function and behavioural disturbances in LBD (Matusunaga et al., 2016). Post hoc analyses of trial data suggested that memantine may also be effective for the treatment of agitation in dementia but a trial designed to test this hypothesis (Fox et al., 2012) found that memantine did not improve agitation in mild to moderate Alzheimer's disease.

Anticonvulsants have been reported as effective in the treatment of aggression and agitation in some small trials. Carbamazepine has the best evidence (Yeh and Ouyang, 2012) but has a number of serious adverse side effects, so is usually avoided. Lonergan and Luxenberg (2009) reported in a Cochrane review that valproate was ineffective and was associated with an unacceptable rate of side effects.

Management of sexually inappropriate behaviour

Sexually inappropriate behaviours have been defined as 'sexual behaviours not suited for their context and which impair the care of the patient in a given environment' (Black et al., 2005). What constitutes appropriateness will depend on the participants' capacity to consent and the opinions and judgments of staff and relatives who are providing care. Sexually inappropriate behaviours, although present in only 7% of people with dementia (Burns et al., 1990), frequently cause concern, particularly in institutional settings. The behaviours include sexualized remarks, grabbing, exposing, public masturbation, fondling, sexual advances to staff or other residents, implied sexual acts (e.g. requesting unnecessary genital care), and attempts at genital contact or penetration. As with other BPSD, it is important to search for physical and psychological causes. Sexual contact may be a source of comfort in people with dementia who are anxious, depressed, or lonely. The choice of treatment depends on the urgency of the situation, the type of behaviours, and the underlying causes. Nonpharmacological approaches are used first-line, and include boundary setting: giving clear instructions for appropriate behaviour and provision of private rooms, as well as reducing the reinforcements of behaviour. Physical disorders, delirium, affective disorders, and psychosis can all trigger sexual behaviour, so should be assessed and treated. If the behaviour presents a risk to the person or others, then clinicians often resort to a variety of pharmacological agents, such as SSRIs, antipsychotics, or antiandrogens (De Giorgi, 2016).

Sexual behaviour between residents in care homes often causes concern. Some staff may feel that the behaviour is inappropriate, particularly if the person with dementia still has an involved partner, or that one or both

Management of dementia

residents are unable to consent to the behaviour. Others may feel it is every person's right to have a sexual relationship while ignoring potential vulnerability and risks. Health and social care professionals need to be able to establish the capacity of the people involved to consent to the sexual activity in the new relationship. If the person with dementia does not have capacity to consent, then a sensitive discussion with staff and family about the appropriateness of the relationship (taking best interests into account) is required. These matters are complex and raise emotive issues, so a frank discussion and subsequent shared agreement with all involved is a worthwhile exercise.

Risk assessment and risk management

Ongoing risk assessment and management is vital in later dementia, identifying the risks to the person with dementia and possibly also to others. If the person with dementia is living alone in his or her own home then self-neglect, wandering, fire risks, falls, and medicines management are the commonest risks to self. The person with dementia, and particularly with BPSD, may also be a risk to others. For example, there may be physical aggression towards a spouse who is no longer recognized and thought of as a stranger, or to a care home assistant who is trying to provide personal care. People with dementia may respond to hallucinations, delusions, or irritability associated with depression or pain, by making accusations or hitting out at those nearest to them. Those nearest could be family members or carers, but in a care home environment they might also include other residents, and even other residents' visitors, some of whom may strike back. Under these circumstances, in the UK, it is recommended to inform the appropriate local authorities regarding the safeguarding of the person with dementia and other vulnerable adults, and to ensure that appropriate action is taken to reduce the risks to the person with dementia and to other adults (Department of Health and Home Office, 2000; Association of Directors of Social Services, 2005). People with later dementia may also live with their families where young children are present. The risks to younger children should always be considered, including the risk of aggression and inappropriate sexual behaviour, but also the possible risk of neglect if children are left in the care of the person with dementia.

Some risks can be easily addressed, for example, arranging for medication to be supplied in a blister pack or dosette box, or setting up the delivery of 'meals on wheels'. Risks around aggression, psychosis, and suicidality can usually be managed by involving the community mental health team who will give support and advice to family members or carers to reduce the chance of harm to self or others. If the risk to themselves or others is substantial, then the person with dementia may require admission to an inpatient mental health unit for assessment and treatment. Other people with dementia do not require psychiatric admission but are no longer capable of taking care of themselves at home and require placement in institutional care. In the UK, the Mental Health Act (2007) can be used to require people (who are unable to give

Management of dementia

informed consent) to reside at a specified place in their best interests under a guardianship order. However, most people with dementia move into residential care without needing to employ these measures; the move is usually unproblematic if family and staff handle it sensitively. If the person with dementia expresses a wish to leave after the move has taken place, then, in the UK, the facility makes an application to the appropriate supervisory body for assessment under Deprivation of Liberty Safeguards (DoLs) to make a judgment as to whether the person who lacks capacity can be lawfully detained in the facility. These processes are necessary to protect the person with dementia but are both lengthy and cumbersome; the Law Commission has recommended streamlining the process with a new scheme called the Liberty Protection Safeguards (<http://researchbriefings.files.parliament.uk/documents/CBP-8095/CBP-8095.pdf>). This is discussed further in Chapter 58.

People with dementia are vulnerable to abuse and exploitation, and risk of abuse by others increases as the dementia progresses, as they become less able to protect themselves and less able to complain. A systematic review found that, globally, one in four vulnerable older people were at risk of abuse (Cooper et al., 2008), both in their own home and in institutional settings. The commonest forms of abuse of vulnerable adults are psychological, physical, neglect, sexual, financial, and discriminatory. Signs that might alert health and social care professionals to the possibility of abuse include fear or agitation in the presence of the abuser, bruising to the face and body, and the appearance of pressure ulcers. In the UK, the Mental Capacity Act (2005) has introduced significant new protections from abuse for people who lack capacity by creating the criminal offences of ill treatment or wilful neglect: these offences can be committed by anyone responsible for the person's care.

Making decisions for people who no longer have capacity

When people with dementia no longer have capacity to make decisions about their health, welfare, or financial matters and they have not made advance directives, then decisions have to be made in their best interests by proxy decision makers. Under the Mental Capacity Act (2005), health and social care professionals can work with families to come to decisions in the person's best interests. In the case of a person refusing pharmacological treatment, this may result in the decision to covertly administer medication to the person with dementia in order to improve his or her physical and/or psychological wellbeing. Best-interest decisions cannot be made for financial matters, so if advanced provision has not been made, then, in the UK, the family are advised to apply to the Court of Protection to ensure that they are legally protected to make financial decisions on behalf of the person with dementia.

Management of dementia

End-of-life care

The progressive nature of dementia means that a palliative care approach to management is employed throughout the course of the disease until death. This approach aims to optimize quality of life for people with dementia and their carers and to ensure that they are supported with both dignity and respect and treated as persons throughout. However, when a person with dementia is at the end of life, there are issues that are specific to dementia that need to be addressed. As people with end-stage dementia are unlikely to have capacity to make decisions about their healthcare, and have limited ability to communicate their needs, it will fall upon the carers of people with dementia to make choices in their best interests. This is best done using an individually tailored end of life care plans which aims to support both the person and the family in optimising quality of care at the end of life. A good plan includes timely decisions about place of care, nutrition, withdrawing or withholding treatment, and cardiopulmonary resuscitation. Advanced care planning allows the family to state clearly what their wishes are for their relative and to ensure that ethical and legal principles are upheld, thus safeguarding the person with dementia, themselves, and the healthcare team who are providing care. It can be difficult to recognize dying in end-stage dementia (compared to terminal cancer, for example) but it is an important skill, informing the family that death is imminent so that religious or spiritual needs can be met. Drugs used in end-of-life care are usually to manage symptoms such as terminal agitation and restlessness. Other drugs are usually discontinued, as long as this does not lead to distressing withdrawal effects. Respiratory tract secretions cause noisy breathing (the 'death rattle'), which may be upsetting for the family and carers; these can be managed by repositioning of the patient, suction if appropriate, and administration of hyoscine. The most important aspect of management is good communication with the family and primary care team to ensure people with dementia and their relatives experience a 'good death'.

Conclusion

The general management of dementia includes the understanding of not only complex medical problems, with interplay of physical and emotional wellbeing, but also complex social, ethical, and legal issues. Quality care cannot be achieved by families and unskilled workers alone. There is a need for education and support from skilled dementia specialists with broad-ranging knowledge and a willingness to educate others. Improved recognition of dementia will come about with improved public education about the disease. Better management of the disease will happen when society accepts the increasing likelihood that each and every individual will either suffer with dementia or know someone with dementia, and wants to improve the experience for all involved.

DOI: 10.1093/med/9780198807292.003.0037

Introduction

Delirium, described in medical texts since antiquity, is a neuropsychiatric disorder arising from an acute pathophysiological disturbance, which could include brain injury, physical disease or injury, drug treatment or drug withdrawal. Its core characterization is distinctively described as 'clouded consciousness', often operationalized as altered arousal and inattention, and associated with acute onset and fluctuating cognitive and perceptual changes. Most of the burden of delirium is in acute hospitals, but its prevalence is intimately related to high levels of frailty and prior cognitive impairment. Therefore, while it commonly presents to liaison psychiatry services, it also often presents in persons living with dementia in community settings, including care homes. Delirium is independently associated with poor outcomes, including increased mortality rates and incident dementia (Witlox et al., 2010, Davis et al., 2012).

Delirium

Despite the considerable patient and population impact, delirium is generally under-recognized, under-managed, and under-researched. This chapter discusses the definition of delirium and its operationalization in clinical and research contexts. We review some of the major theories underlying delirium pathophysiology, going on to discuss screening, prevention, and treatment, as well as delirium in specific situations, including care homes and in palliative care.

Definition

There are some differences in emphasis across the nosological classifications for delirium in the International Classification of Diseases (ICD) and Diagnostic and Statistical Manual (DSM), as well as historical evolution of the diagnostic criteria (Sepulveda et al., 2016), though all rely exclusively on clinical evaluation. In general, the DSM approach has been less restrictive than ICD, and the DSM-IV definition is the most widely used reference standard for research studies. This diagnostic drift makes comparisons for the purposes of psychiatric epidemiological studies more difficult, but there is a core constellation of symptoms that comprise the syndrome regardless of the classification system.

Essentially, four domains underlie the delirium construct. The first is that there must be a disturbance in consciousness, and this is operationalized to consider both *level* and *content* of consciousness (respectively, level of arousal and inattention). The second is that the disturbance is acute, usually evolving over hours and days, and that this tends to fluctuate. Thirdly, there must be changes in other cognitive, perceptual, or emotional/affective domains (e.g. memory impairment or psychotic features). Finally, it must be apparent that these changes are due to an underlying acute physiological disturbance, often medical, surgical, or anaesthetic. In general terms, delirium might be regarded as a decompensation of global cerebral function under the stress conditions of being unwell.

Each of these domains merits more detailed consideration, particularly because the boundaries of each criterion are not precisely defined (Davis et al., 2013). The notion of acute physiological disturbance is often straightforward but is important to note that there are often multiple contributing causes. In practice, management aims to identify and optimize as many physiological abnormalities as possible and assess the subsequent effect on delirium (see General principles of management). It is sometimes the case that the direct precipitant is difficult to uncover, or it may be inappropriate to investigate exhaustively (for example, in palliative care; see End-of-life delirium). Nonetheless, identifying and managing any physiological disturbance must take precedence (along with ensuring safety and relieving severe distress) in any differential diagnosis that includes delirium (including states such as behavioural and psychological symptoms of dementia or deterioration in Lewy body disease). In other words, it is safest to assume that crises or acute changes are due to delirium so as not to miss an underlying physical

Delirium

illness—at the same time being sensitive to the possibility that hospital admission and change in environment risks worsening delirium.

The requirement for additional domains in cognition to be disturbed reflects that delirium represents global brain dysfunction. Psychotic symptoms are not an essential criterion, though these may have most impact in terms of distress for patients and their families (Partridge et al., 2013). What is less clear is how much cognitive change needs to be demonstrated (or be certain of) in order to establish delirium onset. ‘Change’ is usually ascertained through taking the history (including collateral history from informants and/or care staff).

The time course and fluctuation of symptoms tends to be quite specific to delirium (though there are mimics). Usually, delirium onset evolves over hours and days, though whether it is possible for delirium to take several weeks to develop is not clear. In addition, the time course of delirium resolution is very variable. In some cases, delirium has been suggested to persist for several months or even years (Cole et al., 2009).

The aspect of delirium essential to appreciate is the ‘clouding of consciousness’. The specific term ‘clouding of consciousness’ was separated out into ‘awareness, attention, and arousal’ in DSM-5 to enable more a precise operationalization. However, it remains a useful concept particularly because it distinguishes delirium from dementia, at least in the latter’s mild-to-moderate stages. We emphasize that ‘altered consciousness’ represents a fundamentally dysfunctional physiological state (although, of course, attention may be poor when tired, sleep deprived, anxious, stressed, pre-occupied, or intoxicated). Being in clear consciousness—able to divide and focus attention—is a highly evolved, high-order function. Therefore, when this is disturbed for any reason, it is highly adverse. This is usually readily appreciated when head injury leads to abnormal consciousness, yet exactly the same state caused by dehydration or a respiratory tract infection does not always attract the same degree of clinical urgency. *Consciousness* is a distributed neurological function: there are bottom-up aspects arising from the reticular activating system (associated with arousal), and there are top-down aspects relating to the frontoparietal cortex that enable focused and sustained attention. These two aspects therefore relate to both *level* and *content* of consciousness respectively, and these are hierarchically related (European Delirium and American Delirium, 2014). In practice, this means that *content* of consciousness (attention) can only be assessed if *level* of consciousness (arousal) is sufficient. Detailed cognitive testing focused on establishing attentional deficits may not even be possible if altered arousal precludes testing. The corollary is that altered arousal (short of coma) itself should be considered to be a severe presentation of inattention and therefore could be delirium.

Delirium

Delirium subtypes

One of the most striking aspects of delirium presentations is the marked differences that may occur in motor-arousal subtypes. Hyperactive delirium—hyperarousal and psychomotor agitation—is the more easily recognized presentation. Hypoactive delirium is associated with reduced arousal and psychomotor retardation and is more likely to be missed as a diagnosis. It is possible that this lower recognition rate is associated with higher mortality because of unrecognized acute illness (Jackson et al., 2016b), though equally, it may reflect a predominantly brainstem (rather than cortical) disturbance. Overall, hyperactive presentations are less common than hypoactive ones (20% versus 80%; Kiely et al., 2007). However, over time, most delirium is mixed and will tend to fluctuate between the two states.

Delirium superimposed on dementia

Delirium is intimately associated with dementia. Dementia is the principal risk factor for delirium, and delirium reciprocally worsens dementia. Among hospital presentations with delirium, the majority of patients will have underlying dementia whether or not that dementia has been diagnosed (Jackson et al., 2016a). As such, people with delirium represent a pool highly likely to have dementia, with implications for future engagement with memory services. In addition, there is now emerging understanding the delirium itself is prospectively associated with worsening cognition and incident dementia (see Long-term cognitive outcomes).

Diagnosing delirium in patients with dementia is challenging. There is no definite reference standard which accounts for their co-presentation (Morandi et al., 2017). Indeed, DSM and ICD conceptualize the syndromes as being mutually exclusive ('deficits not otherwise attributable to delirium/neurocognitive disorder', respectively). Nonetheless, a presentation with abnormal arousal and attention usually indicates superimposed delirium, as arousal is often normal unless dementia is advanced, but even this can be difficult to detect. Probably the commonest presentation is of abrupt change in cognition or behaviour causing a crisis ('more confused'; 'newly agitated or aggressive'), and these cases should be assumed to represent delirium until proven otherwise.

Delirium epidemiology

The epidemiology of delirium has not been as comprehensively studied as other acute conditions of ageing such as stroke or cardiovascular disease. Community studies suggest that point prevalence of delirium is around 1% in older people, in essence highly associated with dementia prevalence (Davis et al., 2013). As such it is more common in older age groups and in care homes. Hospital studies of delirium are more common and suggest that 15 to 20% of the adult inpatient population has delirium at any one time, though this will be higher in acute medical admissions

Delirium

(30%), patients with hip fracture (15% at admission, 50% at any time), and in intensive and palliative care (50% or more) (Vasilevskis et al., 2012).

Pathophysiology

The heterogeneous aetiology, clinical presentation, and course of delirium suggest that it cannot be due to a single underlying neuropathological process. Whether 'delirium' is a label for an array of neuropsychiatric syndromes with similar clinical features but diverse underlying neurochemical disturbances, or whether there is a final common neurochemical pathway is yet to be determined. A number of plausible and complementary theories for the development of delirium have been postulated. It is likely that delirium pathogenesis is a complex hybrid of these, resulting from multiple disturbances in neurochemical signalling in the context of an acute insult to the brain.

There is an inverse relationship between the number or severity of predisposing and precipitating factors required to produce delirium (Inouye and Charpentier, 1996; Quinlan et al., 2011). In young healthy adults, the severity of acute insults needed to precipitate delirium is high, for example, meningitis or adult respiratory distress syndrome (as suggested by the high occurrence of delirium in patients treated in intensive care units (Salluh et al., 2010; Roberts et al., 2005; Cavallazzi et al., 2012)). However, in those who are older, frailer, or have pre-existing cognitive impairment, relatively trivial precipitating factors may be sufficient, for example, mild hyponatraemia, or a viral infection. At this end of the spectrum, frailty and pre-existing dementia are probably 'more important' than the precipitating factors and so particular concern should be raised when delirium is demonstrably due to minor physiological disturbance because this de facto indicates frailty (Dani et al., 2017; Eeles et al., 2012). Delirium can be provoked in those with previously healthy brains if the physiological insult is large enough. These observations suggest that likelihood of development of delirium is a continuous function of the underlying vulnerability and the size of the insult (see Fig. 37.1). A better understanding of the neuropathological processes that contribute to delirium is key to identifying biomarkers and potential drug targets. Key theories of delirium pathogenesis are outlined here; these have been reviewed in more depth elsewhere (Maldonado, 2008, 2013, 2018).

Direct toxic brain insults

Direct toxic insults to the brain (e.g. drugs, hypoxia, sepsis, metabolic disturbance, acute brain injury, or stroke) can disrupt brain functioning through dysregulation of normal neurotransmitter signalling and energy metabolism. If these insults are of significant magnitude, delirium may result even in those with previously 'normal' brains.

Neurotransmitter hypothesis

An imbalance in neurotransmitters has been postulated as being central to the development and clinical manifestations of delirium. Reduced acetylcholine, elevated catecholamines (dopamine and noradrenaline), and elevated glutamate and its derivative gamma-aminobutyric acid (GABA) may be implicated (Maldonado, 2013). The exact pattern of these disturbances may underlie arousal-motor subtypes, with relatively higher noradrenergic drive responsible for hyperactive presentations and hypocholinergic states linked to hypoactive delirium.

Acetylcholine is involved in attention and awareness and reduced acetylcholine has been identified as a potential 'common denominator' in development of delirium (Hsieh et al., 2008). Drugs that antagonize acetylcholine are potently deliriogenic, but the picture is not clear as

Delirium

attempts to prevent or treat delirium through increasing acetylcholine with cholinesterase inhibitors (e.g. donepezil) or pro-cholinergic drugs have been disappointing (see Pharmacological prevention). This could indicate that reduced acetylcholine frequently coexists or is a result of delirium, rather than being directly implicated in development of delirium (Schor et al., 1992; Marcantonio et al., 1994)

Elevated levels of the monoamines dopamine and noradrenaline have been associated with delirium. It has been suggested that dopamine is particularly implicated in development of psychotic features, a theory supported by the use of antipsychotic medications (haloperidol, olanzapine) to control these (van der Mast, 1998). Conversion of dopamine to noradrenaline is oxygen dependent, and degradation of excess dopamine cannot occur in the presence of toxic metabolites at times of cellular hypoxia (Maldonado, 2013). Dopamine potentiates the excitatory neurotransmitter glutamate and its calcium-mediated neurotoxic and deliriogenic effects through direct action on voltage-gated NMDA receptors (Maldonado, 2013; van der Mast, 1998). The inhibitory neurotransmitter GABA is a derivative of glutamate. These, the most prevalent neurotransmitters in the brain are closely involved with oxygen-dependent glucose metabolism and particularly susceptible to disruption at times of hypoxia (van der Mast, 1998). Drugs with GABA-ergic properties (e.g. benzodiazepines) have been shown to be particularly deliriogenic (Pandharipande et al., 2007).

Other neurotransmitters implicated in delirium include serotonin (5-HT) and histamine, either of which may be elevated or reduced during episodes of delirium.

Neuroinflammatory and exaggerated sickness behaviour hypothesis

Systemic inflammatory stimuli are relayed to the brain via neural and humoral pathways (e.g. via the vagus nerve, or circulating cytokines). In response to these stimuli, the blood-brain barrier may be compromised, resulting in neurochemical disturbance that presents as a 'sickness behaviour' response: withdrawal, malaise, lethargy, and, in those who are susceptible, delirium (Cunningham and MacLulich, 2013).

Microglia are the brain's macrophages. In a healthy brain, they migrate to areas of potential damage (e.g. during hypoxia), become activated, and mediate a coordinated neuroprotective inflammatory cascade (including release of cytokines) to phagocytose dead or dying neurones (Neumann et al., 2009). There is evidence from animal models that, in brains with neurodegeneration, microglia exist in a 'primed' pro-inflammatory state (Perry et al., 2010). This pro-inflammatory state causes microglia to over-respond to stimuli that would otherwise be well controlled in a brain without pathology—the activation response becomes dysregulated, exaggerated, and neurotoxic (Murray et al., 2012). Primed microglia are thought to play a role in neurodegenerative diseases such as Alzheimer's dementia, which may help to explain the propensity to delirium resulting

Delirium

from minimal insults in patients who have underlying neurodegenerative disease.

Oxidative stress hypothesis

Relative tissue hypoxia resulting from increased oxygen demand and cerebral hypoperfusion at times of acute illness may lead to accumulation of reactive oxygen species (ROS) (Maldonado, 2013). In the absence of sufficient antioxidant (e.g. at times of physiological stress) this results in redox imbalance, oxidative stress, failure of ATPase pumps, and destabilization of the cell membrane (Garbarino et al., 2015). A critical threshold of cerebral hypoperfusion has been suggested, below which a cascade of events results in inactivation of calcium ATPase pumps, excess intracellular calcium, and neurotransmitter failure (Aliev et al., 2003). This includes release of the excitatory monoamine neurotransmitters (dopamine, noradrenaline), which act on NMDA receptors and potentiate glutamate-mediated neuronal damage. Excess flux of calcium into the intracellular space may therefore be a key contributor to delirium (Maldonado, 2018).

Neuroendocrine hypothesis (hypothalamic-pituitary-adrenal (HPA) axis)

Excess circulating cortisol has been associated with delirium (Mu et al., 2010). The mechanisms are not well understood, although a direct effect on function of the hippocampus (Maldonado, 2013) or augmentation of pro-inflammatory and ischaemic damage may be implicated (Sorrells et al., 2009). The limbic system is central to the regulation of HPA function (Jankord and Herman, 2008), and it is vulnerable to early pathology in Alzheimer's disease. Frailty has been associated with dysregulation of the HPA axis, resulting in chronically elevated levels of cortisol and disrupted diurnal cortisol variation (Varadhan et al., 2008). It is plausible that this chronic elevation in circulating cortisol may result in a reduced threshold for delirium in those with dementia or frailty—thereby responding at times of metabolic stress (e.g. infection), which results in further increases in cortisol (Maldonado, 2013). This is evident in patients with neurodegenerative conditions who show prolonged elevation of cortisol after the acute response (Otte et al., 2005; Magri et al., 2006). Similarly, patients with delirium have been found to have elevated serum and CSF cortisol in the context of sepsis (Pfister et al., 2008), hip fractures (Pearson et al., 2010), and cardiac surgery (Plaschke et al., 2010).

Melatonin dysregulation hypothesis

Disrupted sleep patterns have been implicated in development of delirium (Figueroa-Ramos et al., 2009; Watson et al., 2012); and this is thought to be mediated through melatonin. Melatonin resets the circadian rhythm and regulates the sleep-wake cycle. It is a ROS scavenger, an antioxidant, and has anti-inflammatory action (Maldonado, 2013). Despite this, therapeutic trials of melatonin for delirium prevention have not

Delirium

demonstrated any significant benefit (see section Pharmacological prevention)

Delirium prevention and multicomponent interventions

Nonpharmacological prevention

Nonpharmacological multicomponent interventions are the mainstay of delirium prevention in hospitalized older people. These interventions comprise two or more components delivered to patients or staff with the aim of reducing incident delirium, through addressing modifiable risk factors (see Causes of delirium). There is convincing evidence supporting this approach with a clinically important treatment effect across several randomized controlled trials in medical and surgical settings. Meta-analysis of trials of multicomponent delirium prevention interventions has demonstrated a risk ratio of 0.69 (95% confidence interval 0.59–0.85, seven studies of moderate quality, 1950 participants for intervention vs control; Siddiqi et al., 2016). Widespread adoption of multicomponent interventions for the prevention of delirium in hospitalized older people was recommended in the 2010 National Institute for Health and Care Excellence (NICE) delirium prevention guidance (Young et al., 2010). However, despite the consistent treatment effect seen in these trials, the content (number and nature of components) of these interventions are not standardized, and an optimal implementation strategy is yet to be specified.

Multicomponent intervention content

In the seven randomized controlled trials, the number of components varied between two and 13 (Siddiqi et al., 2016). Most included early mobilization (6/7) and reorientation strategies (5/7). Attention to sensory deprivation, nutrition, and hydration and an individualized approach to care each featured in 4/7 trials. Sleep hygiene (recognizing and respecting circadian sleep patterns), bladder and bowel care, and pain control featured in 3/7 of the interventions, while families bringing in familiar objects, active identification of infection, medication review, and attention to physiological parameters (oxygenation and electrolytes) were also reported.

Multicomponent intervention delivery

Methods of delivering multicomponent interventions varied considerably between trials. Most advocated an individualized approach to care (4/7) and this may be key to the success of these interventions. Checklists and protocols were used in 3/7 trials, while only one trial adopted multidisciplinary team (MDT) care (Lundstrom et al., 2007). Despite this, implementation of multicomponent interventions through the MDT is the approach advocated by NICE in the 2010 guidance (Young et al., 2010). Staff education and training appears to be integral to the delivery of

multicomponent interventions for delirium prevention; 4/7 trials included this as an explicit component of the intervention.

In addition to these trials, there have been several non-randomized studies of multicomponent delirium prevention interventions performed in different countries and across patient groups. These studies have produced a more pronounced treatment effect when compared to randomized trials of other multicomponent interventions (effect sizes between 0.44 and 0.59) (Vidan et al., 2009; Chen et al., 2017); the reasons for the apparently exaggerated treatment effects in non-randomized studies are likely to be methodological.

The most familiar nonpharmacological multicomponent delirium prevention intervention is the Hospital Elder Life Program (HELP) (Chen et al., 2015). This intervention comprises protocols aimed at improving orientation, reducing sedative use for sleep, early mobilization, correction of vision and hearing, and improving hydration for prevention of delirium in hospitalized older people. In the original (non-randomized) study, a before and after change in risk factors between control and intervention groups was achieved in only two of these six protocols (reducing sedative use, and improving orientation; Inouye et al., 1999). Despite this, the odds of delirium in intervention vs control groups was 0.60 (95% confidence interval 0.39–0.92). It is thought that part of the consistency in effect seen with the HELP intervention is the rigid training and fidelity to the protocols that is required for implementation. Whether or not this effect is generalizable to a population of older people in hospital outside clinical trials is unclear, and there have been significant implementation challenges in routine adoption of multicomponent interventions in non-research settings (Godfrey et al., 2013).

Despite the efficacy of multicomponent interventions in reducing incident delirium, there is no corresponding reduction in the more distal outcomes of mortality and admission to long-term care—despite the well-recognized relationship between delirium and these adverse outcomes (Teale and Young, 2015). The causes for this disconnect are unclear, but may relate to different aetiopathological mechanisms. For example, older people with frailty are particularly susceptible to delirium (Fig. 37.1) and its adverse outcomes (mortality, care home admission); in a frail subgroup of patients, non-modifiable risk factors (e.g. dementia) may be more prominent, and prevention of long-term adverse events much harder to achieve.

Further work is required to determine the optimal multicomponent intervention (i.e. identification of a parsimonious set of ‘active ingredients’), and the best system of care within which these should be embedded, including consideration of the environment, personalized care, implementation strategies, training, and education (for patients, their carers, and staff).

Delirium

Pharmacological prevention

Trials of pharmacological agents have been undertaken based on putative theories of underlying delirium pathophysiology. Several trials have investigated the acetylcholinesterase inhibitors routinely used for enhancing cognition in Alzheimer's dementia. Acetylcholinesterase inhibitors increase the available synaptic and post-synaptic acetylcholine and this offers a biologically plausible rationale for delirium prevention based on the association between delirium and acetylcholine deficiency (see Pathophysiology). A Cochrane review meta-analysis of trials of acetylcholinesterase inhibitors for prevention of delirium in hospitalized non-intensive care patients was limited due to the paucity of data available (Siddiqi et al., 2016). Overall, no benefit was demonstrated (relative risk 0.66 (95% confidence intervals 0.17-2.62), two trials, 113 participants; overall quality of evidence was low). A subsequent trial of rivastigmine for delirium prevention in patients in intensive care was stopped early due to excess mortality in the treatment arm (van Eijk et al., 2010).

Other drugs investigated for delirium prevention include the typical and atypical antipsychotic drugs (for their role in dopamine metabolism), melatonin (as a regulator of the sleep-wake cycle), and citicoline (as a cell membrane stabilizer through action on removing oxygen free radicals). Results have been disappointing, with none of these drugs showing significant benefit in terms of reducing incident delirium (Siddiqi et al., 2016). More recently, the intravenous sedative agent dexmedetomidine (an alpha-2 agonist acting on the locus coeruleus, inhibiting release of noradrenaline) has been trialled in intensive care settings with good effect in reducing incident delirium in critically ill older surgical patients vs placebo (OR 0.35, (95% CI 0.22-0.54); Su et al., 2016). Patients in both arms of this trial received other potentially deliriogenic drugs during the course of the trial but this was largely balanced between groups: benzodiazepines were used intra-operatively if required and this was less frequent in the intervention group (173/350 control vs 153/350 intervention). Similarly, both arms had patient controlled opiate analgesia post-operatively if needed (316/350 control vs 311/350 intervention). Although the aetiology and pathogenesis of delirium are likely to be different in the ICU setting compared with frail older people in medical and surgical inpatient settings, the apparent efficacy of dexmedetomidine to reduce incident delirium offers useful insight into potential mechanistic pathways.

Screening and diagnosis

Diagnosis of delirium is based on identification of the core features outlined in the DSM-5 criteria (American Psychiatric Association, 2013). Usually, this involves a bedside assessment supported by collateral information from relatives, carers, and ward staff. Primarily, the diagnosis of delirium requires a history of sudden onset of change in cognition (over hours or days) in any domain, with evidence of fluctuation usually over

Delirium

minutes or hours. Acute onset and the presence of fluctuation over the course of a day can help to distinguish delirium from other psychiatric syndromes, e.g. depression or dementia. Inattention (distractibility, poor concentration, and difficulty switching between tasks) has been identified as a key feature of delirium, but can be difficult to detect in the presence of dementia and depression. There are few clinical signs and symptoms specific to delirium, although visual hallucinations in the context of other features are suggestive (see behavioural and psychological symptoms). The presence of carphology (picking at bedclothes) and floccillation (picking at the air in front of the face) are closely associated with the presence of underlying delirium if they are seen, although their absence does not exclude it (Holt et al., 2015)

During more lucid periods, people with delirium may self-report feeling muddled, having difficulty with concentration, or experiencing (usually visual) hallucinations, but are they unlikely to offer this information spontaneously. It is therefore important to ask patients explicitly if they have experienced hallucinations, and to probe for evidence of delusions. It may be evident that patients are hallucinating during assessment, especially if they are looking at the floor or ceiling or pointing into space. Those with delirium may experience persecutory delusions, for example, that they are part of a conspiracy or that staff are trying to harm them.

There are a number of tools available to assist in the detection of delirium: simpler methods are used for delirium screening, while diagnosis of delirium involves training and lengthier assessments. Often patients are too unwell to undergo formal cognitive testing for delirium and a presumptive diagnosis is made based on available evidence. More in-depth delirium assessments are often reserved for reference-standard delirium diagnosis in research trials where criterion-defined delirium is a requirement to ensure precision. However, in clinical practice, a more pragmatic approach may be adopted if formal diagnostic testing is not feasible. Here, we outline some of the common approaches and established screening tests.

Screening tools

SQiD

The Single Question in Delirium (SQiD—‘Do you feel *your relative* has been more confused lately’) is a simple screen for delirium which has been suggested as a method to identify delirium for the purposes of the UK NHS standard contract (Sands et al., 2010). When asked of an informant that knows the patient well, the SQiD offers 80% (95% CI 28–99%) sensitivity and 71% (95% CI: 42–92%) specificity for the detection of delirium when compared with the Confusion Assessment Method (Sands et al., 2010). These data were taken from a small study (21 patients) in a palliative care setting, so there is doubt regarding generalizability. However, the SQiD is a useful and pragmatic first-line

Delirium

question which serves as an *aide memoire* to prompt a dialogue with relatives regarding recent changes in cognition.

Tests for arousal

Delirium results in deficits in the level or content of consciousness. In order to test the content of consciousness (e.g. attention), it is first necessary to determine the level of consciousness (arousal) to complete the tests. This may be performed at the bedside through informal assessment (can you rouse them sufficiently to engage in assessment?). If patients with suspected delirium are too drowsy or attention is untestable, assume delirium is present until proven otherwise. This inclusive approach is advocated by the European Delirium Association, and the American Delirium Society in a joint statement published in response to the updated DSM-5 criteria and to minimize the likelihood of missed opportunity to detect and manage delirium (European Delirium and American Delirium, 2014). Arousal can be assessed using tools such as the Glasgow Coma Score or AVPU system ('alert, voice, pain, unresponsive'), or more formally using methods such as the Richmond Agitation Sedation Scale or the Observational Scale for Level of Arousal (Chester et al., 2012; Tieges et al., 2013)

Tests for attention

Testing attention at the bedside can be done through observation during conversation and assessment. Patients with delirium are easily distracted by sights, sounds, and even their own thoughts and may flit between topics during conversation. Attention may be assessed more formally using tests such as the Months of the Year Backwards (MOTYB) test where patients are required to recite the months of the year backwards from December (O'Regan et al., 2014). They may self-correct, but do not offer prompts. Inability to reach 'July' without error implies inattention (83% sensitivity, 91% specificity), although accuracy is reduced in the presence of comorbid dementia. (O'Regan et al., 2014). Other tests such as serial sevens, digit-span tests, or counting backwards may be useful depending on intellectual and cognitive functioning.

The 4AT

The 4AT is a validated, simple, and attractive delirium and cognitive impairment screening test that is undergoing further comprehensive validation in a large multicentre trial (Shenkin et al., 2018). The approach combines four simple bedside tests of delirium features to give the likelihood that an individual has delirium (Table 37.1).

Delirium

Table 37.1 The 4AT, Version 1.2

				Score
<i>Alertness</i>	Normal (0)	Mildly sleepy (0)	Clearly abnormal (4)	0–4
<i>AMT4</i>	No mistakes (0)	1 mistake (1)	2 or more mistakes / untestable (2)	0–2
<i>Attention (MOTYB)</i>	≥7 (0)	<7 or refuses to start (1)	Unable / untestable (2)	0–2
<i>Acute onset or fluctuating course</i>	No (0)	Yes (4)		0–4
<i>Total score</i>				0–12

Score for each component in parentheses

≥ 4 possible delirium +/- cognitive impairment, 1–3 = possible cognitive impairment, 0 = delirium or severe cognitive impairment unlikely (but delirium still possible if [4] information incomplete)

MOTYB—Months of the Year Backwards

Delirium

Delirium Observation Screening Scale

The Delirium Observation Screening (DOS) scale is a 13-item tool (Schuermans et al., 2003). It does not require formal cognitive testing, rather being based on objective assessment of behaviours exhibited by patients and observed by nursing staff over the course of their shift (recorded three times a day) and is therefore useful for detecting fluctuations. The DOS is well-validated, well-completed, and has been used in different settings internationally. It takes under three minutes to complete and, due to repeated measurements, is an attractive approach to detecting newly-evolving delirium.

Confusion Assessment Method (CAM)

The Confusion Assessment Method (CAM) is often used for delirium diagnosis both in clinical practice and research (Inouye et al., 1990). It takes around ten minutes to complete, and requires a brief test of cognitive function and consultation with informants. The CAM operationalized DSM-III criteria and has been extensively validated. Rigid adherence to the CAM scoring system according to the coding guide is required. In addition, administration of the CAM requires formal training (including observed administration of the instrument and tests of inter-rater reliability) in keeping with the CAM training manual and coding guide, which limits utility by non-specialists in general clinical settings (Inouye, 2014). A number of variations in the CAM have been developed and validated for use in different healthcare settings—for example the CAM-ICU for use in critical care settings, a short-form of the instrument (3D-CAM), which can be completed in a few minutes and which embeds structured cognitive testing (Marcantonio et al., 2014), and the CAM-S, which can be used to grade delirium severity (Inouye et al., 2014).

Diagnostic tools for delirium

Gold standard delirium diagnosis involves expert assessment to elicit features of delirium in keeping with DSM-5 criteria. Some assessment instruments such as the Memorial Delirium Assessment Scale (Breitbart et al., 1997) and the Delirium-Rating-Scale-Revised-98 (DRS-R-98) (Trzepacz et al., 2001) are considered to be diagnostic rather than screening tools. These are typically lengthy to complete, precluding their use in routine clinical practice and are usually reserved for research use.

Causes of delirium, and the search for a cause

The simplest approach to managing delirium is to ‘identify the cause and treat it’. If delirium is a secondary response to physical illness, injury, or drug treatment, identifying the cause is fundamental. To do this successfully requires a thorough and systematic approach, knowledge of which potential causes to seek, and with what priority (i.e. look for the common or serious causes first).

Delirium

However, the simple approach raises questions and contradictions:

- A model of causation by a single diagnosis is inadequate; the model of predisposition and precipitant requires consideration of both
- In many cases, probably over half, multiple potential causes are present (Laurila et al., 2008; George et al., 1997). All require diagnosis and treatment, but their relative importance will usually be unknown
- Although diagnostic criteria specify that a general medical cause be identified in order to make a diagnosis of delirium, in many cases (15–20%) where delirium (or probable delirium) is diagnosed clinically, a sufficient or credible underlying cause cannot be identified despite investigation (Harwood and Teale, 2017)
- Diagnosis can be difficult in the face of severe illness, agitation, multi-morbidity, disability, and frailty
- It is easy to be diagnostically lazy, and attribute changes in mental state to infections (especially urinary) with insufficient supporting evidence
- In very frail or dying people, clinical judgment is required on a proportionate and humane approach to investigation, and associated investigation or treatment burden
- Distinguishing delirium, delirium complicating dementia, and decompensation of dementia can be difficult (Fong et al., 2015). A combination of physical and mental symptoms, and interpersonal, social, or environmental aggravating factors is likely to contribute to the clinical presentation or ‘phenotype’. The term ‘formulation’ may be more helpful than ‘diagnosis’.

A diagnosis is an explanation, in biomedical terms, of a set of signs, symptoms, or other findings (such as imaging). In most, but not all, cases it implies a pathological process. Among older people with multiple comorbidities this can be more difficult, and requires experience and thoroughness. Delirium is one of several presentations of illness with functional consequences or ‘geriatric syndromes’ (alongside falls, immobility, incontinence, ‘not coping’). The approach to all of these is similar: identify what has changed, treat the treatable, palliate symptoms and distress, make explicit efforts to restore or maintain function, and try to prevent complications and other adverse outcomes. Almost any medical or surgical diagnosis, drug, or trauma can cause delirium (or any other geriatric syndrome; Table 37.2).

Table 37.2 Causes of delirium.

Group	Examples

Delirium

<i>Brain diseases</i>	Meningitis, encephalitis, infarction, haemorrhage, tumours, trauma, post-ictal, non-convulsive status epilepticus
<i>Infections</i>	Neurological or systemic; consider skin, intra-abdominal/biliary, bone/joint/discitis, endocarditis, liver abscess, chest, urinary
<i>Drugs</i>	Opiates, anticholinergics, dopamine agonists, anti-epileptic drugs, high dose steroids. Intoxication or overdose.
<i>Drug withdrawal</i>	Alcohol, opiates, benzodiazepines
<i>Hypoxic</i>	Lung disease, heart failure, hypoventilation
<i>Metabolic</i>	Hyponatraemia, hypoglycaemia, hyper or hypocalcaemia, uraemia, hepatic encephalopathy
<i>Acute severe illness</i>	Myocardial infarction, acute urinary retention
<i>Post-operative</i>	
<i>Intensive care</i>	
<i>Trauma</i>	Hip fracture, head injury
<i>End-of-life</i>	
<i>Rarer causes</i>	Wernicke's encephalopathy, neuroleptic malignant syndrome, inflammatory/autoimmune encephalitis, limbic encephalitis

The usual approach to diagnosis can be followed: history, observation and examination, laboratory tests, imaging, and evolution over time—but adaptations are required. Some people with delirium may be too ill to give any meaningful information, while others are able reliably to report (current) symptoms. Collateral information from family, other informal or professional carers, or care home staff is mandatory, both for making the diagnosis of delirium, and determining its underlying causes. Previous medical history, time-course and nature of decline, and manifest symptoms may be reported.

Delirium

Examination may be conventional, or may have to be opportunistic and reliant on observation if the person is agitated or uncooperative. At minimum, try to describe the mental state, and examine for level of alertness, temperature and vital signs, oxygenation, neck stiffness, observable neurological function (communication, eye movements, facial palsy, limb tone, and movements), abdominal tenderness or rigidity, shoulder, hip and knee movement (for fracture or infection), skin (including under bandages), and evidence of pain or distress during personal care, rolling in bed, or transfer from bed.

Blood tests should include full blood count, electrolytes including calcium, inflammatory markers such as C-reactive protein, renal, and liver function (plasma ammonia if hepatic encephalopathy is suspected). Dipstick urinalysis is only useful if negative (thereby excluding UTI); otherwise microscopy and culture is required. Chest X-ray is more sensitive than clinical examination, and should be routine. Blood, sputum, CSF, or other fluid culture should be done if there is suspicion of infection. Further examination and investigation are directed according to initial findings or possible causes (Table 37.3).

Table 37.3 Possible additional (or 'second line') investigations.

Test	Looking for
Lumbar puncture, CSF examination	Evidence of infection (bacterial, tuberculosis, viral), protein, cytology
Electro-encephalogram	Epilepsy, non-convulsive status epilepticus, Creutzfeldt-Jakob disease
Autoantibodies (e.g. ANA, ds-DNA, ANCA, anti-TPO, VGKC, VGCC, NMDA, anti-neuronal)	Vasculitis, inflammatory encephalopathy
CT Chest abdomen pelvis (+/- Positron Emission Tomography)	Occult malignancy, infection including biliary or abscess
MRI spine	Discitis, osteomyelitis, tumour
Echocardiography	Endocarditis
Heavy metals, Insecticides	Poisoning
CSF, cerebrospinal fluid; ANA, anti-nuclear antibodies; ds-DNA, double stranded deoxyribose nucleic acid; ANCA, anti-neutrophil cytoplasmic antibodies; anti-TPO, anti-thyroid peroxidase; VGKC, voltage gated	

Delirium

potassium channel; VGCC, voltage-gated calcium channel; NMDA, N-methyl-D-aspartate

Neuroimaging (CT or MRI brain) is often performed, and is not unreasonable given the high stakes, but diagnostic yield is low (Lai and Wong Tin Niam, 2012). This will usually be required in the work up of possible coexisting dementia, or prior to lumbar puncture. It is mandatory if there is headache, persistent drowsiness, or focal neurological findings.

Prescribed drugs, and those bought 'over-the-counter' in pharmacies off-prescription, must be carefully reviewed. Some drugs are well-known culprits, including those with anticholinergic effects. Many other drugs have low-level anticholinergic effects, which, in combination in the context of polypharmacy, can add up. As a general principle of good medicines management, all drug prescriptions should be reviewed critically and regularly. Several anticholinergic burden scales have been developed (Salahuddin et al., 2015), which can be used as an *aide memoire*, to quantify risk from drugs, and as a justification for stopping them (which can be controversial with medical colleagues and families). These scales are all slightly different, and have been derived from historical datasets, so may not include all currently used pharmaceuticals. Table 37.4 includes an example.

Table 37.4 An anticholinergic burden scale.

Group 1 (low)	Group 2 (moderate)	Group 3 (high)
Ampicillin	Alverine	Atropine, hyoscine
Atenolol, metoprolol	Amantadine	Chlorpheniramine
Aripiprazole	Baclofen	Chlorpromazine
Azathioprine	Carbamazepine	Dicyclomine
(Most) benzodiazepines	Cetirizine	Levomepromazine
Bisacodyl	Cimetidine	Oxybutinin
Bupropion	Dosulepin	Orphenadrine
Captopril, trandolopril	Fexofenadine	Procyclidine
Carbidopa (Sinemet)	Nefopam	Promethazine
Celecoxib, lumiracoxib	Olanzapine	Propantheline

Delirium

Chlortalidone, some other thiazides	Prochlorperazine	Solifenacin
Citalopram/escitalopram	Paroxetine	Tolterodine
Codeine	Quetiapine	(Most) tricyclic antidepressants
Digoxin	Tramadol	Trifluoperazine
Diltiazem, nifedipine		Tizanidine
Dipyridamole		Trihexyphenidyl
Domperidone		
Entacapone, selegiline		
Fentanyl		
Furosemide		
(Most) glucocorticosteroids		
Haloperidol		
Isosorbide preparations		
Loperamide		
Loratadine		
Metformin		
Metoclopramide		
Morphine, oxycodone		
Mirtazepine, venlafaxine		
Pramipexole, bromocriptine		

Delirium

Ranitidine		
Risperidone		
(Most) selective serotonin reuptake inhibitor antidepressants		
Trazodone		
Triampterene		
Warfarin		

Group 1 drugs each score one point; group 2 drugs score two points; group 3 drugs score three points. The Anticholinergic Burden score is the sum. A total score >3 points is clinically significant.

Adapted with permission from Salahudeen, M. S., Duffull, S. B., Nishtala, P. S. Anticholinergic burden quantified by anticholinergic risk scales and adverse outcomes in older people: a systematic review. *BMC Geriatrics*, 15(31). Copyright © 2015 Springer Nature. DOI: <https://doi.org/10.1186/s12877-015-0029-9>

Long-term drugs may be continued or temporarily or permanently stopped, depending on whether they are treating an immediately-evident problem (such as pain, or fast atrial fibrillation), causing problems (such as low blood pressure), or if taking oral medication is problematic. In the midst of delirium, it is reasonable to deprioritize long-term vascular preventative and bone-protection drugs, pending recovery.

Some 'non-diagnoses' may cause, contribute, to or exacerbate delirium, or cause symptoms similar to it, such as agitation or distractibility, in the absence of the full syndrome of delirium. It is unclear if these associations are truly causal, and if so, what the mechanism might be, or if delirium is caused by the underlying condition or associated treatment. Pain is strongly associated with delirium; delirium may be due directly to the pain, the condition causing the pain, or opiate analgesia. Likewise, sleep deprivation, constipation, and urinary catheterization are all associated with delirium, with the mechanism being causal, reverse-causal, confounded, or treatment-related. Whether causal or not, these conditions need to be explicitly sought and managed (investigated, cured, or palliated).

Delirium

Mimics and differential diagnosis

About half people over the age of 70 admitted to hospital are cognitively impaired, with 15–30% having diagnosable delirium. Of admissions, 10–15% are primarily due to ‘worsening confusion’ (Reynish et al., 2017; Pendlebury et al., 2015; Whittamore et al., 2014). Like any presenting symptom, accurate diagnosis is required to allow logical treatment and prognostication. While positive features of delirium should be identified, and diagnostic criteria confirmed (i.e. delirium is not a diagnosis of exclusion), it should be borne in mind that the diagnostic criteria include the caveat ‘not better explained by an alternative condition’. Alternative conditions must therefore be considered and excluded (Table 37.5).

Table 37.5 Mimics and differential diagnosis

Condition	Clues
<i>Vascular dementia</i>	Previous stepwise decline, or persisting new cognitive impairment after a stroke. Clinical or imaging evidence of cerebrovascular disease. Absence of specific features of delirium or concurrent acute physical illness. Failure to recover.
<i>Dementia with Lewy bodies</i>	Can be almost indistinguishable from delirium (fluctuation, including of alertness, delusions, hallucinations). Adverse drug effects common. Ascertain Parkinsonian features, longer-term problems, and decline, and recovery after treating concurrent physical illness. DAT scan if needed.
<i>Intoxication</i>	History of drug or alcohol ingestion, blood, or urine toxicology
<i>Coma</i>	Severe and persistent impairment of level of consciousness, neurological examination, and imaging findings
<i>Stroke, or brain tumour, especially aphasia</i>	Brain imaging. Can be difficult to assess. Stroke may cause delirium, or may represent a ‘better alternative explanation’.
<i>Post-ictal confusion</i>	History of seizures, rapid recovery

Delirium

<i>Rapidly progressive neurodegenerative conditions</i>	Index of suspicion, previous experience. Including CJD, PSP, CBD, DLB
<i>Functional psychosis</i>	Mental state examination, auditory hallucinations, systematized or mood-congruent delusions, overactivity in clear consciousness
<i>'Decompensation' of prior dementia</i>	Change of environment, loss of familiarity and routine, and discomfort or perceived threat in hospital can all produce changes in behaviour, sleep, and function.

CJD, Creutzfeldt-Jakob disease; PSP, Progressive supranuclear palsy; CBD, Cortico-basal degeneration, DLB, Dementia with Lewy bodies; DAT, Dopamine transporter.

General principles of management

The general approach of Comprehensive Geriatric Assessment (CGA) is required, including medical, functional, mental health, social, and environmental aspects (Ellis et al., 2017). Delivery of care is multiprofessional, requiring skilled doctors (usually a geriatrician and/or psychiatrist), general and/or mental health nurses, occupational therapists, and physiotherapists, with access to speech and language therapy, dietetics, and social work if needed.

The key elements of management are to:

- treat the underlying cause
- provide appropriate supportive care (physiology, hydration, nutrition, psychological, and emotional)
- maximize, maintain, or restore function
- avoid complications (falls, pressure sores, aspiration, deconditioning, injury or assault, post-traumatic stress disorder)
- engage families and other carers, explanation of unfamiliar phenomena
- wait; much delirium passes quickly (40% in 24h), but some recovers slowly (15% recovers between 4 and 26 weeks), or not at all (Cole et al., 2009).

People with delirium may be very ill; basic physiological and nutritional support is required to maintain body systems, while definitive medical treatment takes effect. This includes oxygenation, hydration, renal function, blood glucose, and heart rate control.

Delirium

The usual hospital ward does not provide a suitable environment for management or recovery of delirium (Jackson et al., 2017). They are unfamiliar, and disorientating (wards, bays, and rooms all look the same) with little privacy. They are often crowded, active, noisy places. Noise and activity often continue through the night, making sleep difficult. Patients can find these over-stimulating (noise and activity), under-stimulating (boredom), and overwhelming (incomprehensible or threatening). There are few opportunities for purposeful activity, exercise, or access to fresh air. Other patients with cognitive impairment, disinhibition, or displaying problem behaviours, such as calling out or interfering, provide further challenges. While individual practitioners have little immediate control over these, some may be avoided or mitigated (noise, opportunities for exercise, or activity), or process and environmental improvements can be advocated with management or hospital decision makers. Dedicated units are increasingly set up to address these and other system challenges (Goldberg et al., 2013; Flaherty et al., 2010).

All frail older people are at high risk of complications. Complications can prevent, undermine, or reverse recovery. Much of the benefit of specialized management is through the prevention, early detection, and aggressive management of complications.

Falls are a particular risk: physical illness, often on a background of dementia or other chronic disease, motor restlessness, autonomic instability (and low blood pressure), fear or paranoia, and impaired judgment all contribute to an increased risk of falling. Those who are hypoactive are at risk of pressure sores. Impaired swallowing may result in aspiration. Paranoia may result in assault or self-harm. Thorough risk assessment and action to reduce risk is required as part of a balanced and proportionate treatment plan; remembering that priorities may conflict, and preventing falls through inactivity or restraint is of little value if the result is deconditioning and immobility.

Delirium may result in incontinence. This should recover in parallel with delirium recovery, but comorbidities are frequent, especially incomplete bladder emptying, nocturnal polyuria, overactive bladder, cancer, and infection. These should be sought and managed. Most drugs used for managing overactive bladder are anticholinergic, and likely to worsen delirium, and so should be avoided. Trospium and mirabegron are the best options if needed. Urinary catheterization is indicated only for monitoring urine output in the critically ill, or for urinary retention. Catheterization is uncomfortable, provocative, and associated with complications (bladder spasms, infection, blockage, urethral trauma); and should not usually be used to contain incontinence, unless skin maceration is a problem.

Delirium is unfamiliar to the general population and many hospital staff. It often leads to dramatic, bizarre, or frightening changes that provoke bewilderment and anxiety. Family engagement is an important part of management. Families have information that healthcare professionals

Delirium

need (past medical and cognitive histories, how the acute problem developed, function and social support or care arrangements, home environment, routines, preferences, wishes, and values). Healthcare professionals have information that families need (explanation of the problem, treatment plan, and prognosis). Family members may want to help with sitting, occupation, or hands-on care, and should be encouraged to do so if willing and able. We need the advice of families in decision-making, care, and discharge planning. Pre-printed leaflets about delirium in plain English and other languages can help. Information on prognosis depends on context: while there is hope of recovery and restoration of cognitive and physical function, prognosis for both survival and recovery is rarely good, up to half may be dead within six months, and sometimes cognitive function does not recover. Families should be prepared for this. Such conversations may become discussions about end-of-life care.

Behavioural and psychological symptoms in delirium

Delirium includes cognitive change, delusions, or hallucinations in about half, and prominent emotional changes (fear, anxiety, depression, anger). These may result in behaviours that indicate distress (problem or challenging behaviours), such as calling out, agitation, aggression, resistance to care, unsafe attempts to walk, sleep disturbance, and anorexia. Managing delirium requires attention to mental health, psychological, and emotional care.

Plans cannot be made unless symptoms are ascertained, which is done by examining the mental state, observation, and obtaining reports over time from nurses, families, and other carers (especially about night-time). This includes explicitly assessing communication, understanding and expression, and psychosis. Hospital doctors vary in their ability to do this, representing a potential missed opportunity, and emphasizing the importance of liaison mental health services to support them.

Hallucinations are typically visual, formed (animals or people), and animated (moving), and may be distorted (incongruous, small, or giant) (O'Malley et al., 2008). Other sensory modalities may be involved, including tactile skin sensation (formication). Auditory hallucinations are unusual. Delusions are typically persecutory, involving the threat of harm. They are fleeting, fragmented, and changeable over time, rather than the more consistent delusional systems seen in other conditions. They are usually frightening, and associated with labile emotions, may result in expressed distress, attempts at defence (including aggression), or withdrawal. Also possible are illusions (real things appearing to be something else) and misinterpretations. Dreams may be vivid and frightening, and merge into daytime hallucinations. Communication impairment can make it hard to describe, share, or express these experiences; sometimes they have to be presumed from observations and behaviours. Often the behaviour (such as attempts to escape, reluctance to eat, or aggression during care) will be observed, but difficult to interpret without the corresponding psychopathology, and may be assumed

Delirium

to be wilful or 'part of dementia'. When assessing a person displaying challenging behaviours it is important to consider the possible presence of delirium, and examine the mental state for psychosis.

Physical illness, symptoms such as pain, constipation, or urinary symptoms, loss of ability, hunger or thirst, and separation from family and familiarity also evoke psychological and emotional responses. In addition, comorbid dementia, depression, anxiety, or other mental health problems are common. Together, the physical, mental, functional, social, and environmental elements provide a toxic mixture that can be threatening.

The philosophy of person-centred care was developed for use with people living with dementia, but the principles apply equally well in delirium, those with other vulnerabilities such as sensory impairment or intellectual disability, or at the end of life (Brooker and Latham, 2015). The first principle is of value or respect for the person with delirium: understanding their illness and its consequences, and not seeing these as wilful, nasty, or vindictive, or resenting their presence in a general hospital (Tadd et al., 2011). The second principle is to individualize care: including physical and mental health aspects, identifying problems and retained abilities, and taking account of sensory impairment (hearing, vision), personality, and preferences. The third principle is empathic understanding, seeing problems from the point of view of the patient. This is summed up in the axiom 'see behaviours as communicating distress or unmet need'. The healthcare professional's task is to identify the need or cause of distress. The final principle is to use relationships to bring comfort, inclusion, attachment, occupation, and to affirm identity. This requires a positive effort from the healthcare professional: to be friendly, encouraging, non-confrontational, and to avoid humiliation, infantilization, or embarrassment, using both words and body language (e.g. smiling, touch, posture). Language has to be adapted to account for deafness and communication impairment, and it is important to use clear and simple expressions, made with authority but acknowledging and minimizing anticipated difficulties.

A lot of the 'magic' of specialist practice in minimizing distress and difficult behaviour is achieved through the avoidance of problems, as much as the skill with which they are dealt. That is not to say that all problems are wholly avoidable: residual symptoms must be anticipated (through observation and care planning), tolerated (which may be the best approach, even to a risky or difficult situation), or managed (using talking, activity, or drugs).

The limit on this approach is the occurrence of immediate and serious risk to health or life. This will often take the form of episodes of aggression towards staff (for example, during personal or intimate care, or while redirecting from a risky situation), other patients or visitors (who are often vulnerable themselves), or to the individual (self-harm or falling). The occurrence of delirium is no different from other occasions of grave and immediate risk. In these cases, the situation must be rapidly

Delirium

appraised, other patients or visitors guided away from the incident, and attempt made to verbally de-escalate. An attempt should be made to identify the trigger for the problem, and address it if possible (such as pain or the need for the toilet). Physical restraint or separation may be required, and a rapid tranquillization regimen implemented (Harwood 2017).

Fortunately, most people who have an episode of delirium recall few, if any, details after the event. Some retain vivid and frightening memories, unable to distinguish or explain delusion from reality even many years after the event, despite insight and knowledge of what delirium is and does. Post-traumatic distress disorder can result (flashbacks, nightmares, anxiety, avoidance, isolation, and guilt). It is clear that delirium is highly distressing for some people. These have been better documented in critical care survivors, but distress from acute cognitive and perceptual disturbance can be a very prominent complication of the inpatient experience, particularly those living with dementia. 'Debriefing', explanation, and counselling may help: intensive care units now often follow-up patients to explore this.

Antipsychotics and other drugs

The role of drugs in delirium is complex. Drugs or their withdrawal may have caused the delirium in the first place. Other drugs may be used to treat acute or chronic illness, and these may cause or exacerbate delirium themselves (such as opiates given for pain). Drugs may also be used to try prevent or cure delirium, palliate delirium-related symptoms, or control behaviours.

Some trials have suggested that haloperidol might prevent delirium, or reduce its duration or severity when given in high-risk situations, such as hip fracture surgery, in advance of onset (Kalisvaart et al., 2005). However, subsequent trials have been disappointing, and a systematic review gives no support to this role (Neufeld et al., 2016).

A specific anti-delirious effect of antipsychotic drugs has been proposed (Meagher et al., 2013; Meagher et al., 2018). Historically, antipsychotic drugs have been used to 'treat' delirium. Nowadays, much lower doses are used than was once the case, and anecdotal experience suggests that low-dose, short-course antipsychotic prescription (such as haloperidol 0.5–1mg bd, or risperidone 0.5–1mg/d for five to seven days) can shorten the course of delirium. Alternatively, these cases may have been resolving anyway. Trial evidence mostly comes from intensive care unit settings, and is of uncertain applicability to frail older people in medical or trauma settings; however, there is little hard evidence to support efficacy of antipsychotic drugs in 'curing' delirium (Neufeld et al., 2016).

A logical use of antipsychotic medication in people with delirium would be to palliate psychotic symptoms, severe anxiety, or distress. Anecdotal evidence lends support to this practice, but trial evidence is lacking:

Delirium

indeed, there is evidence that antipsychotic drugs are ineffective. A sensible approach is 'trial and error': identify the target symptom, and choose a drug appropriate to control it, at a dose determined by body size, previous exposure to antipsychotic drugs, and intensity of symptoms, then reviewing for effect, tolerance, and adverse effects (in the case of delirium, daily or every few days). Over-sedation, extra-pyramidal motor effects, and risk of arrhythmias due to electrocardiographic prolonged QT interval leading to sudden death are the main adverse effects.

A final use of antipsychotic drugs is as a sedative in emergency control situations. In adult mental health practice lorazepam is now the preferred drug, but in delirium benzodiazepines are less effective and riskier in the light of possible paradoxical agitation, over-sedation, or risk of falls (apart from some specific indications). Antipsychotic drug doses tend to be higher in emergency situations (2.5–5mg haloperidol, delivered intramuscularly, every 20–30 minutes), in view of the need to achieve rapid control of a dangerous situation, with appropriate physical restraint, until control is achieved (Harwood, 2017).

There is no evidence to support use of pro-cholinergic drugs, or acetylcholinesterase inhibitors (Yu et al., 2018), and some evidence that these may cause harm.

In palliative care practice, haloperidol, levomepromazine (which is sedative and has analgesic as well as antipsychotic properties), or midazolam are often used, usually subcutaneously.

There are specific situations where benzodiazepines are indicated, especially alcohol withdrawal and delirium tremens. In opiate withdrawal, either provide supportive care alone, or restart an opiate and wean it down slowly. In some cases, clonidine may be indicated, though blood pressure needs close monitoring.

Delirium in the context of dementia with Lewy bodies or Parkinson's disease dementia represents an especial problem. Psychotropic drugs should be avoided, if at all possible. If distress or risk is severe, use lorazepam (0.5–1mg aliquots). These patients will often be given (or already be on) a cholinesterase inhibitor (oral donepezil or a rivastigmine patch).

Anxiety and low mood are very common, with a corresponding temptation to prescribe an antidepressant drug. There is little evidence to support effectiveness, and a theoretical risk of exacerbating delirium. Drug treatment is best avoided until the delirium has recovered; if distress is severe, a short-course of low dose antipsychotic might be tried, with appropriate review for effect and adverse effects.

Delirium

Persistent delirium

A third of delirium cases persist more than a month, a quarter more than three months, and 20% more than six months, most of which will never recover (Cole et al., 2009; Siddiqi et al., 2006). Persistent delirium represents a management problem; modern medicine operates at a fast pace, and a slow time-course of recovery conflicts with this model. Mental health services are cautious about delirium with its potential for severe underlying physical disease. Rehabilitation services are suspicious of mental health conditions, especially cognitive disorders with uncertain potential for recovery. Short-term care home placement can become a default setting, but without careful case-management this can easily become permanent, regardless of eventual recovery. Formal review by a geriatrician, community mental health team, or memory assessment service should be planned.

Persistent delirium requires careful on-going assessment and re-assessment. Possible causes include:

- failure to identify, or control the underlying cause
- failure to identify multiple causes
- recurrence of the underlying cause (such as an infection)
- a new intercurrent condition, complication, or drug adverse effect
- evolution of delirium into dementia ('delirium damages the brain')
- a mistaken diagnosis (decompensated existing dementia, progression of vascular dementia, or dementia with Lewy bodies)

As delirium resolves it changes; it often becomes less florid (fewer delusions or hallucinations, less agitation), but fluctuation and drowsiness may persist. The imperative continues to maintain or improve function (walking, continence, dressing, leisure or therapeutic activity), avoid complications, and relieve distress. Families and other carers should be regularly updated.

Delirium in care homes and community management of delirium

Delirium is frequently present on admission to hospital (prevalent delirium), and 'increased confusion' is a common presenting complaint. Those who are functionally independent at home with frailty or a degree of cognitive impairment (whether this is formally diagnosed or not) may decompensate in the presence of delirium or subsyndromal delirium, dipping below the threshold that allows them to manage in their own environment. Community prevalence of delirium is generally reported at less than 1%, with prevalence increasing tenfold for patients with coexisting dementia (Davis et al., 2013).

Dementia and frailty are both common comorbidities in care homes, and delirium is frequently seen in these settings due to presence of these as well as additional risk factors (pain, dehydration, constipation,

Delirium

polypharmacy, chest and urinary infections). Point prevalence of delirium in care home settings has been estimated at 33% and 14% for those with, and without dementia (McCusker et al., 2011; Siddiqi et al., 2010). Studies into delirium detection and prevention in care homes have provided estimates of incident delirium between 0.85 and 2.2 episodes per 100 person weeks—i.e. a 50-bed care home could expect roughly one to two new episodes of delirium a fortnight (Heaven et al., 2014; Teale et al., 2018).

Transition into hospital for patients in their own home or from care home settings where delirium is suspected may result in worsening of the delirium or increased distress due to moving from a familiar to an unfamiliar environment. This needs to be weighed up against the requirement for secondary care investigations and treatment.

Whether or not delirium can be managed in the community is dependent on a number of factors that form the basis of a risk/benefit assessment between healthcare professionals, patients, and their families or carers. Although these decisions should be made on a case-by-case basis, some points for consideration may include:

- Are the patient and their family in agreement with attempting to manage the patients in their own environment?
- Are the causes and precipitants of the delirium identified and can these be treated safely and effectively at home (a wish to remain at home should not preclude access to appropriate and necessary medical care and intervention, e.g. intravenous therapies, imaging)?
- Is 24-hour supervision required and available (i.e. is someone able to stay with the patient and monitor for features that warrant hospital admission)?
- Are there dangerous or risky behaviours that cannot be safely managed at home (e.g. night-time wandering, significant aggressive or violent outbursts, lack of awareness of hazards, e.g. gas fires, cookers)?
- Is specialist (secondary care) medical or nursing input required?
- Is there a strategy for regular medical review and a contingency plan if management at home is not working or in the event of clinical deterioration?

One strategy might be for rapid assessment in hospital to identify and treat factors contributing to the delirium aiming for early supported discharge home with ongoing input from community rapid response teams or virtual wards. Another is for initial assessment and management to be at home where 'hospital at home' schemes exist. Although managing delirium at home has theoretical advantages for patients, the efficacy, safety, and any health economic benefits have not been established through primary research.

Delirium

Special situations

Alcohol and drug withdrawal

Half of heavy alcohol drinkers will experience withdrawal symptoms between six and 24 hours after ceasing (craving, irritability, anxiety, tremor, headache, palpitation, nausea, and insomnia). Withdrawal seizures may occur between six and 48 hours after cessation, and often progresses to delirium tremens. Delirium tremens is a more severe variant, occurring in 5% of heavy drinkers usually three to ten days after stopping. It has physical and psychiatric features, including: visual, auditory or tactile hallucinations, illusions, and delusions; drowsiness; autonomic over-activity (tremor, tachycardia, sweating, high blood pressure, pyrexia); agitation, anxiety, or fear. Prevention is by tapering dose of oral long-acting benzodiazepines (over seven to ten days). Treatment is with intravenous benzodiazepines. High-dose parenteral B vitamins should also be given. Mortality is about 10%.

Wernicke's encephalopathy

This is caused by severe thiamine deficiency, typically in malnourished heavy alcohol users, or after refeeding someone who is chronically malnourished. The commonest symptom is delirium; other features include abnormal eye movement, nystagmus, cerebellar-type ataxia, and a long-term sequela, and Korsakoff's psychosis (persisting retrograde and anterograde amnesia with confabulation). Prevention and treatment are with intravenous high-dose B vitamins (gut absorption can be poor in alcoholism), followed by oral thiamine. Intravenous B vitamins must be given before any glucose-containing fluid, or a central lactic acidosis may be precipitated—worsening risk of Korsakoff's psychosis. Other aspects of 'refeeding syndrome' may also occur. Korsakoff's psychosis is especially disabling, often making independent living impossible.

Neuroleptic malignant syndrome (NMS)

This is a rare syndrome comprising delirium, with agitation, muscle rigidity, fever, and autonomic instability (tachycardia, incontinence, sweating, labile blood pressure). Plasma creatine kinase is greatly raised (often >10000U/l). It is caused by starting, or increasing the dose of, antipsychotic drugs, including atypical antipsychotics. It is hard to identify: the clinical picture looks like infection, which is much commoner. Treatment comprises withdrawing the culprit drug, and supportive care while recovery occurs over one to two weeks.

Hepatic encephalopathy

Caused by liver failure, hepatic encephalopathy is characterized by fluctuating confusion and drowsiness, lethargy, poor sleep, mood or personality changes, asterixis (motor 'flap'), and constructional apraxia (inability to draw a five-pointed star, although this is non-specific). It occurs in cirrhosis, although in some cases this is undiagnosed, and is

Delirium

often precipitated by intercurrent infection, electrolyte disturbance, gastrointestinal bleeding, or constipation. Plasma ammonia is raised, and EEG is characteristically (but non-specifically) abnormal. Jaundice may or may not be present. Treatment is with high-dose lactulose (which changes bowel bacterial flora), sometimes with broad spectrum non-absorbed antibiotics (rifaximin). Treatment can be dramatic and gratifying, but longer-term prognosis is poor, due to the underlying liver disease, although improved by abstinence from alcohol.

Autoimmune or inflammatory encephalopathies

Also rare, these are often dramatic or severe, but are potentially treatable. Features include drowsiness, delirium, seizures, psychosis, focal neurological signs, and involuntary movements, such as tremor or myoclonus. These diagnoses should be considered when no other likely cause of delirium is identified, or when there are atypical features such as seizures. They are caused by systemic or brain autoimmune or paraneoplastic disorders. Hashimoto's encephalopathy is associated with high titres of anti-thyroid peroxidase (anti-TPO) antibodies. Other autoantibodies are directed against neuronal membrane proteins such as anti-NMDA or voltage gated potassium channels. Limbic encephalitis is caused by anti-neuronal antibodies (e.g. anti-Hu), and is associated with lung and other cancers. Primary or secondary CNS vasculitis can also produce similar symptoms, usually associated with headache. CSF protein is raised, and there may be changes on brain MRI. Management requires specialist neurologist referral and high-dose steroid treatment.

Post-operative delirium

This is common among frail older people (and others) who have undergone hip fracture or joint replacement, open heart or abdominal surgery, or major trauma, but there is little fundamentally different about the causes or management. The underlying condition (trauma, intra-abdominal sepsis), anaesthetic agents, dehydration, treatment (opiate analgesia), medical comorbidities, or perioperative complications (such as wound or chest infection, heart attack, or stroke) can all contribute. Attention to preventative measures is important in these high-risk patients. There is evidence to support regional over general anaesthesia in preventing delirium. Collaborative management between surgeons and geriatricians reduces incident delirium (Marcantonio et al., 2001). Delirium occurs in up to 80% of ICU patients, and is increasingly recognized. Assessment is complicated by anaesthesia, sedation, or intubation, but tools such as the Richmond Agitation-Sedation Scale and CAM-ICU can be used to assist. Prognosis may be somewhat better than among general or geriatric medical patients, but later recall of symptoms and post-traumatic stress disorder can be particular problems. Some sedative agents (e.g. dexmedetomidine) are less prone to causing delirium than others.

Delirium

End-of-life delirium

Delirium may be almost universal at the end of life, due to the underlying condition or to treatment, especially with opiate analgesia and anticholinergic drugs used to control respiratory secretions. However, about half of cases may be reversed, especially if drugs or infections are the cause (Hosker and Bennett, 2016). Diagnosing the approach of the end of life can be difficult: people with hypoactive delirium often look like they are dying, and although prognosis after hypoactive delirium is poor, up to half may recover with appropriate treatment and support. Key management goals are the relief of distress, maximization of function, and open communication with patients and families. This can imply a trade-off: most people would prefer to remain conscious and sentient for as long as possible, but high doses of analgesia or sedation to relieve symptoms may compromise this. Distressing psychosis, anxiety, or agitation can be treated, usually in this setting using haloperidol, levomepromazine, or midazolam, but requires an open discussion about treatment options and goals.

Decision-making, judgment, proportionality, and compromise

There are several frameworks to guide decisions about what is the right thing to do, with overlapping legal and professional obligations, and cultural expectations. These frameworks divide into four main groups, although in practice we draw on all of them:

1. the consequences of an action (benefits and burdens, the expected good has to justify or outweigh any harm or risk)
2. rights and duties (in particular the right of autonomy, to decide for oneself, and the duties to use resources fairly and not to discriminate)
3. the disposition or intentions of the stakeholders (virtues)
4. the need to maintain open and trusting relationships.

Decisions may be about medical treatment, the adoption of end-of-life care, restrictive or drug treatment to treat behavioural and psychological symptoms or maintain safety, the taking or avoidance of risks, or decisions about returning home or moving to a care home.

The problem in delirium is that cognitive impairment can impair mental capacity to make decisions (the ability to understand, retain, and use relevant information to a decision, and communicate that decision). In this situation decisions may be made by a proxy (in the UK, a holder of a power of attorney, or court-appointed deputy), or by assessing 'best interests' (which takes into account the previous and current wishes and preferences of the individual, and of the family or friends of the patient). Added difficulties are that delirium, and mental capacity, can fluctuate, and recovery can be slow or uncertain. It is easy to make a wrong decision, or make an irreversible decision too soon.

Delirium

A patient with delirium may misunderstand the purpose of routine observations, even though these are required to detect deterioration. As a consequence, this attention may be seen as threatening, or may disturb the patient's sleep. Attempting to prevent a patient from falling often leads to them being immobilized in a bed or chair, which can then result in confrontation when the patient attempts to get up, and denial of opportunity for them to exercise, regain function, and avoid deconditioning. Pressure area care may involve alternating pressure mattresses, which can be uncomfortable and prevent sleep, and regular (two-hourly) turning, which also disturbs sleep. Low molecular weight heparin injection to prevent venous thromboembolism can be painful and an opportunity for confrontation, while distracting nurses from psychosocial care. In managing delirium individualization is important; delirium pathways must guide best practice while allowing for this.

Being aware of these pitfalls can help. Open communication, and shared decision-making (setting out the options, the pros and cons of each, and agreeing a process to reach consensus) are needed (Coulter and Collins, 2011). Difficult decisions may take time to make. In the face of uncertainty, keeping options open is wise. Try to maintain relationships even in the face of disagreement.

Modern hospital medicine emphasizes 'rescue' (identifying rapidly deteriorating patients for critical care intervention), 'safety' (avoiding healthcare-associated harm), and 'pathways' (standardizing care to achieve efficiency). This sits uneasily against the needs of complex and frail older people, especially those with delirium or other mental health problems. 'Risk enablement' or 'recovery model' approaches emphasize positive risk-taking and accepting failure with the goal of maximizing function and inclusion. Ideally, these issues are discussed within multiprofessional teams, and with families, albeit time-consuming and involving difficult (or impossible) judgment calls.

Management of delirium calls for skilled staff, with nurses drawing on expertise from both general and mental health practice, with appropriate education, right attitudes, in sufficient numbers, and with medical, nursing, and management leadership that appreciates complexity, and the value of professional judgment and shared-decision-making.

Outcomes from delirium

General outcomes

Delirium is clearly associated with increased mortality, with an approximately two-fold increased risk of death (95% CI 1.5–2.5), even after adjusting for chronic comorbidities and burden of acute illness (frailty) (Dani et al., 2017; Eeles et al., 2012; Witlox et al., 2010). Why this should be the case is not obviously clear other than to highlight that when the burden of acute and chronic precipitants results in delirium, then other things being equal, those patients are likely to be nearer death.

Delirium

Delirium is associated with adverse in-hospital patient safety issues (Reston and Schoelles, 2013). This includes inpatient falls, dehydration, poor nutritional intake, aspiration pneumonia, pressure sores, increased length of stay, increased need for one-to-one care, and increased rehabilitation needs. Delirium is associated with a twofold increase in the rate of institutionalization (Pitkala et al., 2005; Bellelli et al., 2008; Bickel et al., 2008). These outcomes therefore come with substantial health and social care costs. There are several estimates available from high income healthcare settings. In the UK, it is estimated that a single episode of delirium complicating inpatient admission costs £13,000 (Akunne et al., 2012). The total annual cost of delirium in the US been estimated to be at least \$38 billion (Leslie et al., 2008). This is consistent with other health economic analyses undertaken in Australia (Pezzullo et al., 2019).

Long-term cognitive outcomes

One recent focus of epidemiological studies of delirium has been the investigation of prospective associations with worsened cognitive decline and incident dementia. The central question has been to understand if delirium is simply unmasking unrecognized dementia, or if delirium itself could lead to chronic cognitive impairment. Studies in hospital cohorts have suggested a strong association with dementia at follow-up (OR 12.5 (95%CI 1.9–84.2)) (Witlox et al., 2010). However, this observation is problematic for two reasons. Firstly, there may be a selection bias insofar as not all delirium cases necessarily present to hospital and therefore the observed association may be skewed by more severe delirium. Secondly, the association may be confounded by unrecognized dementia, that is, cognitive deficits observed a follow-up may have in fact been present before delirium. Nonetheless, the notion that delirium could be associated with prospective, step-changes in cognition is plausible from clinical experience and sometimes families report that a relative is ‘never the same again’ after having delirium. Also, it is apparent that not all individuals fully recover from delirium, though how such a persistent delirium might evolve into a chronic dementia has not been well characterized.

Several cohort studies have tried to address this by aligning a retrospective diagnosis of delirium with trajectories of cognitive decline delineated through longitudinal follow-up of cognition. Although these studies vary in terms of setting, age range, outcome measure, and delirium ascertainment, delirium is consistently associated with accelerated cognitive decline, months and years beyond the index episode of delirium (Fong et al., 2009; Gross et al., 2012; Davis et al., 2014; Davis et al., 2012; Tsui et al., 2018).

There has been some attempt to understand these trajectories in relation to underlying dementia pathology. Because the entirety of described clinical (e.g. age, sex, education) and pathological (e.g. amyloid and tau protein) factors account for only 50% of dementia risk (Matthews et al., 2009), it is reasonable to consider if delirium accounts for some of this

Delirium

unexplained variance. In the few studies where there are measures of cognitive decline, delirium, and neuropathology, it appears that delirium is *not* associated with higher levels of any given dementia neuropathological marker (e.g. amyloid plaques, Braak stage) but evidence of delirium in the final years before death may make the cognitive expression of these pathologies more evident. Even if delirium does account for some of the variance between pathology and cognition in dementia, there is as yet no evidence that delirium interventions have any impact on secondary prevention of dementia (Teale and Young, 2015), though this strategy clearly merits systematic investigation.

Uncertainties and future directions

While there has been general progress in delirium research, much of it has had insufficient impact on patient care. There even remain fundamental questions on the nature of delirium, with uncertainty as to whether it is too heterogeneous a construct, or whether there could be a unifying pathophysiology. Nonetheless, some speculations on the future of delirium research may be possible.

Pathophysiology

There is no doubt that more experimental work is required, but establishing valid cognitive and behavioural animal models to test possible hypotheses has not been straightforward. There is likely to be a range of existing animal models in fields relevant to delirium, but not known to delirium investigators. Examples might include neuroinflammation in sepsis, small vessel disease in the blood-brain barrier, and microbiome impact on encephalopathy. Experimental researchers in these fields may be unaware of the clinical construct of delirium, leading to missed opportunities for translational collaboration. Ultimately, there is a need for an infrastructure to engage and cross-fertilize with experimental researchers in a range of fields. The eventual aspiration would be the development of robust experimental systems that might be able to dissect out pathophysiological pathways that could be targeted for specific delirium therapy or to mitigate some of the adverse sequelae.

Neuropsychology of delirium

Most clinicians approach delirium as primarily a disorder of *cognition*. However, emphasis is increasingly on delirium as a disorder of *arousal* (which in itself should be considered to on a continuum with *inattention*). This has implications for the construction and design of delirium assessment tools where quantifying change in arousal should be as important as demonstrating specific cognitive deficits. Acute illness, drugs, degree of prior cognitive impairment, and superimposed delirium all interact to affect level of arousal. Future research must seek to understand the extent to which each has an impact on cognitive and functional outcomes. With regard to the plurality of available assessment scales, research is needed to assess how the diagnostic accuracy varies

Delirium

with setting and degree of training. Specifically, tests to detect delirium in the context of comorbid dementia need to be better established.

Considering delirium in the context of frailty and multidisciplinary care

At present, much of the focus on delirium care is on the acute precipitant. However, of equal importance is the recognition and management of frailty that commonly accompanies delirium. Highlighting this leads to a wider consideration of the multidisciplinary aspects to delirium care, which have received hardly any research attention. For example, which physiotherapy-led mobility interventions might reduce delirium duration? Is there a role for clinical psychologists to develop post-delirium recovery programmes? Are there subtle linguistic or paralinguistic deficits that might lead to early detection by a speech and language therapist? How common is bulbar dysfunction in hypoactive delirium and how should this be safely managed? Which nurse-led family education programmes could prompt earlier presentation? Taken together, it becomes clear that there are many opportunities to improve multimodal aspects of delirium care if research can leverage the skillset of the multidisciplinary team.

Improving healthcare systems

The public health impact of dementia is becoming increasingly prominent. Some of this has arisen through aligning delirium with dementia care in acute hospital. Crucially, studies demonstrating that delirium care is cost effective will be a potent driver to change. Yet, there remains a general lack of integration of delirium care across primary, secondary, intermediate, and social care. For example, delirium follow-up clinics are by no means routine. Without doubt, if interventions for delirium can be shown to lead to secondary prevention of dementia, this would lead to a wholesale change in how acute care for older people is organized, with a major focus on preserving cognitive function.

Raising public awareness

Despite increasing awareness and expertise on delirium among health professionals, there have not been any large-scale attempts to engage the public on delirium. The term is hardly used among patients and families. Greater efforts from the scientific and clinical research communities, perhaps in conjunction with ageing-related third sector organizations, to increase public understanding are vital. Such efforts will be rewarded by highlighting need for research funding and step-changes in standards of care.

Conclusion

Delirium is a distressing and expensive clinical entity that is known to also influence cognitive and other health outcomes. It should be considered as a marker of acute brain injury commonly precipitated by a peripheral or systemic acute event. Both level and content of consciousness are important to assess. However, many of its features

Delirium

have not been fully characterized, formal measurement is still problematic, and underlying mechanisms are largely unknown. Given that it is potentially preventable and treatable, substantial clinical efforts should be directed to its management in its own right. Treating delirium hinges on addressing the underlying cause, brain optimization, and being vigilant for distress and providing symptom relief as needed.

The experience of depression: Anonymous

Chapter: The experience of depression: Anonymous

Author(s): Denning et

DOI: 10.1093/med/9780198807292.003.0038

Introduction

I have had episodes of depression intermittently all my life. As they are individual to me, I've supplemented my experience with an informal browse over other people's descriptions on the Internet. I've chosen to write anonymously, not because there are shocking revelations, but because I want the chapter to focus on the content rather than the author. You may still be tempted to try to identify me (I probably would in your situation!). If you do (and it is probably not difficult) please respect my privacy.

Context

I was the first and only male of four siblings. My father was a doctor and my mother a teacher. Both, in their very different ways, set me very high standards, built around good behaviour, modesty, and service, whilst eschewing greed and complaint. I think I was naturally bumptious and

The experience of depression: Anonymous

presumably recognized as bright because my mother often made the point that I shouldn't get big-headed. Religion was a big factor for my mother, who essentially lived her life on the basis that it was wrong to seek pleasure if there were people in the world worse off than oneself, and she did indeed devote herself to myriad good causes. My father was a quiet man who worked tirelessly and unconditionally for his patients. They were widely recognized as exceptional people and community role models. Living up to their standards was going to be hard!

My parents wanted the best for me, and at the time they thought that meant private education. So, from age ten, I was a boarder at a pleasant enough prep school, followed by a public school that I hated. I think the experience of not being at home for more than 50% of the time left me rootless and without a sense of belonging. Dormitory insomnia meant that, at age ten, I started a lifetime of intermittent, then continuous, use of sleeping pills. At my public school, in particular, the first half of each holiday was pleasant but followed by a period of increasing gloom and apprehension at the prospect of a return to school. In retrospect these were depressive episodes; likewise, the sense of vulnerability I associated with spring was probably Seasonal Affective Disorder (SAD). Previously a devout Christian, I gave up on religion, never to be quite forgiven by my mother, judged by her non-verbal communication. I became rebellious and anti-establishment. This change was emblematic, I now think, of a more general suspicion and questioning of received wisdom. Above all, I felt trapped in an environment I did not like. If I lived my life again, I would have loosened the stiff upper lip, mandated by values of the time, and left that school.

Questioning received wisdom, however, served me well at university, where thesis and antithesis were the stuff of life. This was one of the happiest periods of my life. Unfortunately, going to medical school felt like entering a time warp into an isolated world based on class and privilege with an unstimulating environment and a curriculum based on largely pointless rote learning. It felt like regressing to my school days. I was enmeshed in the establishment that I felt opposed to, which made it hard to form strong bonds of friendship with other members. Maybe, this was also a time to drop the stiff upper lip and change.

My career was seen by others as reasonably stellar. Whilst I now accept this intellectually, I still don't really own that experience, emotionally. It felt to me like a stressful time, marked by anxiety and indecision. I let many life changes to chance. In the short run, fate felt more comfortable than personal choice and commitment.

Experience

I don't know how many times I have been depressed and I don't have a particularly detailed memory, possibly because I unconsciously suppress memories of bad times. It is usually associated with a personal or professional crisis. An early sign is a feeling of deep visceral tension in

The experience of depression: Anonymous

my lower abdomen, associated with untargeted free-floating anxiety, formless feelings of guilt, and a nameless sense of impending doom. Internet posts that refer to feelings of panic are probably describing the same experience. It is said that depression is living in the past whilst anxiety is living in the future, but I think a feeling of apprehension about the future is a common component of the depressive experience. As well as this autonomic and emotional side, there is also an intellectual one. Well or ill, I have an ongoing internal monologue, predominantly evaluating what could go wrong with any situation, and the analysis becomes more pessimistic and questioning of certainties when I am depressed. When I am well, questioning of certainties has served my career well. However, when depressed I wish I could switch the pessimistic voice off.

With depression, life becomes colourless. Nothing gives pleasure or satisfaction so it becomes difficult to stir myself to any activity. The ruminating internal voice tries to assess routes back to pleasure, meaning, and enjoyment and finds them wanting. I know what activities (exercise, socializing, outings, etc.) should lift my mood, but it is an effort to initiate them and they don't work. Feelings of profound regret are common. This is well expressed by one of the Internet writers who said: 'Depression is sadness for times gone and chances never taken. It is missed opportunities and a missed future. It's missed friends.'

Churchill is well known to have called depression his black dog and it seems that others animate the experience similarly. Susan Calman writes of the crab of hate sitting on her shoulder. Nothing like that applies in my own case. Depression for me is the dark skies and looming catastrophe of Mordor. I can think of two major crises when the associated weather was just like that. One insight I have gained from writing this chapter is that the Sauron presiding over my Mordor is the dark, saturnine, cane-wielding headmaster of my school.

Consequences

When I am well, I work hard and indeed have the reputation for almost inexhaustible reserves of energy (don't call me manic depressive!) and significant creativity. When I am ill, accumulating commitments continue to mount as I slow down. I become inarticulate. Life goes on hold, and meetings, social events, travel, and engagements are cancelled. Mental capacity clouds over and seems to be associated with nasal congestion and a thick head. I cease to function professionally and I have lost leadership positions, papers, and grant opportunities because I am, for a while, incapable of meeting the standards required of me. When depressed, I have forgotten about important speaking events but, by the skin of my teeth and with as little as 12 hours' notice, I have persuaded colleagues to stand in (with hearty thanks to anyone who works out who we all are)!

The experience of depression: Anonymous

This is when personal and professional catastrophes occur, some causal, some consequential. The impending sense of doom becomes reality. The pessimistic internal voice is vindicated. Indeed, bad developments feel like prophecies foretold. I can think of two crises which overwhelmingly felt as if they were the concrete manifestation of the catastrophe that had hung over me all my life, the inescapable exposure of me as a fraudulent impostor. So the sense of foreboding is corroborated and reinforced. I become distant to my family and friends, but I also regress and develop childish dependence, which only makes the gulf between us worse. I don't often cry, but when I do it is explosive and prolonged. I feel rejected. I have never harboured thoughts of suicide. The violence of the death that would be effective frightens me. I feel for those with depressions that are severe and am thankful that mine is only moderate in severity.

Causes

As a (hyper)critical person, I have been suspicious of the idea of personal trauma as a cause of depression. Being a victim, I used to argue, is an easy self-indulgent alternative to finding a more honest answer and being big enough to deal with it. This perfectionist version of personal truth has also made me suspicious of the therapeutic notion of developing a positive personal narrative. However, dear reader, you are probably sufficiently far ahead of me to see I was wrong and to guess where all this may have come from.

There were three big influences. I was a brainy child, but didn't realize it and my parents discouraged big headedness. So when I got scholarships and awards, I developed a severe case of the impostor syndrome. In this state, you are convinced that a mistake has been made and you will be shown up to be a fraud. You feel vulnerable so you work harder, so the fraud is not noticed. This is counterproductive because it makes you more successful and acclaimed, so the sense that you are an impostor intensifies and you work harder still!

Being brainy landed me in classes with boys two years older than me, and this had two consequences. Being relatively immature, I struggled to understand and fit into their world. Isolated in an all-male boarding school limited the outlets for my new testosterone-driven adolescent impulses. Overall, an important piece of social learning did not happen, leaving me with permanent feelings of social inadequacy. I feel I am stuck in an immature phase in which gaining approval from and pleasing others is the dominant driver of my professional and personal activity.

So far so common, as I judge from others. The third consequence of these adolescent experiences seems not to be shared by many others.

Conditioned to see myself as a younger child in an adult world, I see virtually everybody as being older than me, even if they are 30 years my junior: a sort of anorexia nervosa of age estimation. I try to imagine how others younger than I am see me, particularly in the context of having a high professional status, but I cannot in any meaningful way. Other

The experience of depression: Anonymous

people find this hard to understand. Now that I am old, it is quite disorientating to see those who I had misperceived as older than me still active and indeed still alive!

The analysis of the unconscious effects of early life experience may sound trite and obvious, but it took many years to consider it relevant and many more to accept it emotionally!

In terms of transactional analysis, I am the child at the bottom of the chart! I think this feeling of inferiority has actually helped my clinical career, by mitigating some of the stereotypes that arise in the consulting rooms. The child sitting in the authority figure's chair may be seen as a more approachable equal. At other times, the child gets hurt by the actions and attitudes most commonly of competitor colleagues who pitch at the powerful stereotype.

Treatment and support

Along the way, I have seen counsellors, psychiatrists, and psychologists, starting with referral to a priest (me still an atheist!) whose approach was to lie on the floor and meditate! Talking through a crisis is usually helpful. Naturally, some sessions have been more helpful than others. I am not attracted to Internet chat rooms or fora, as their unfiltered comments are often incoherent, angry, or wrong and can feel aggressive, threatening, and indeed actively depressing when one's mood is low. It is also a great thief of time. However, I was interested to take a focused snapshot of the experience of depression, as posted on the Internet, where many posts assert that the worst thing to be told when depressed is to 'cheer up'. I recall colleagues trying to help by sketching out a positive pathway out of the pit. This can feel like a slightly impatient cajolement, especially in those with time pressures in their own life. Another Internet theme is the importance, at a time of crisis, of active listening by the therapist or counsellor. That would also be top of my list. Early on, I think active listening may be most effective if devoid of other agendas like diagnosis (only an approximation to individual experience) or therapeutic planning.

Then a time comes when one tries to think oneself out of the gloom. At this stage, I believe there can be a need for some at least partially didactic input from the therapist. There is often a reluctance to do this. I can see that encouraging a return to normality requires the patient to own the decisions, but when one is starting to do this whilst still vulnerable, some signposting from an external individual who probably has more insight would be helpful. It may be a bit demanding to ask for active listening transitioning to active planning by the therapist on behalf of the patient. All in good time!

Experience vs pharmacology

Most new consultations were triggered by a crisis. So what did I hope to gain from them? The truth is I didn't know at the time. I needed to unburden myself. I was certainly not seeking comprehensive self-analysis

The experience of depression: Anonymous

and indeed for a long time was implicitly sceptical to this approach. So I have taken psychoactive drugs for a long time. Tricyclics did not work. Of the SSRIs, paroxetine was most effective. They make the internal voice more positive. I was started on mirtazapine (fabulous dreams!) by my GP. I think he has forgotten it was to enable me to wean off the paroxetine. I doubt this would be possible and I feel in a better and more consistent mood than I have for a long time, so I am keeping my head down! If I'm addicted, so be it.

Many Internet posts are strongly hostile to psychoactive drugs. Those in favour are generally less strongly expressed. This polarization of opinion is not surprising as it interfaces with a broader view of what it is to be human. I can see pharmacology and experience as two windows on the same phenomenon.

Old age psychiatry

I was initially apprehensive about referral to an old age psychiatry service. Would it not be an exercise in assessment for Alzheimer's disease? I rapidly realized this caricature is misplaced. Depression is common in old age and usually has a long development in early and middle life. I'm wary of assessing one's own self-esteem, but I suppose mine is low. After all, what's not to dislike about an emotionally immature person, unsure where he belongs, who was not brave enough to break free of his personal chains and choose Robert Frost's road less travelled, and whose success in life was built on accidental by-products of his personal weaknesses? The accidental professor! I have been even more wary of describing the formative events I describe as traumatic. Compared to child sexual abuse, it seems pretty mild, but as I have grown older with greater insight it seems capricious not to acknowledge a probable relationship. As I've aged, I have, like most people of my age, dropped the impetus to change, and started to accept myself and my psychological warts! It is just my story and writing it at this stage of my life has been therapeutic!

Depression in older people

Chapter: Depression in older people

Author(s): Alan Thomas

DOI: 10.1093/med/9780198807292.003.0039

What is depression and how common is it?

Depression seems to have become a Humpty Dumpty term, one that can mean whatever the speaker wants it to mean—transient sadness, misery due to stress, a collection of symptoms on a check-list, or a clinical syndrome. It is easy to forget this important truth and proceed as if findings from research (predominantly on DSM- defined (unipolar) major depressive disorder (MDD)) can simply be applied to anything labelled ‘depression’. DSM MDD is diagnosed when someone has one or more major depressive episodes, which are episodes of depressed mood and/or anhedonia plus at least four other key symptoms from a list of nine (total of at least five symptoms). Its prevalence has been repeatedly reported at 1–3%, a rate similar to that in younger adults (Beekman et al., 1999).

Importantly the DSM-5 criteria are not simply a checklist of symptoms, since the DSM manual details these clinical features, which need to persist over at least two weeks, and this collection of symptoms needs to

Depression in older people

produce clinically important impairment in everyday functioning. An important change from DSM-IV is the removal of the bereavement criterion for MDD. Previously, DSM discouraged the diagnosis of MDD following the death of a loved one, recognizing that depressive symptoms for more than two weeks are common following bereavement and do not necessarily signify illness. Although the concern to encourage identification and treatment of depression is understandable, the removal of the bereavement criterion may encourage the medicalization of normal grief. And more widely it may discourage clinicians from placing someone's depressive symptoms in their personal and social context. That is, depressive symptoms precipitated by grim circumstances need to be understood as related to these and managed accordingly. A diagnosis of DSM MDD should not lead straight to the prescription pad. There is a wide range of severities of MDD and although MDD is widely regarded as 'severe depression', many people with milder illnesses meet the criteria and may be managed without medication (indeed DSM-5 MDD has mild, moderate, and severe subtypes, and severe with psychosis).

The UK NICE Clinical Guideline on the management of depression in adults (CG 90) emphasizes that duration and disability due to depression should be carefully assessed when determining the appropriate management (which then follows a rational stepped care approach) (NICE, 2009), in which psychosocial interventions are advocated for milder and more transient episodes and medication encouraged for persistent and/or moderate to severe episodes (which should approximate to moderate and severe DSM MDD).

The other main category of depressive disorder in DSM-5 is persistent depressive disorder (dysthymia), which is diagnosed when depressive symptoms persist for over two years without meeting criteria for MDD or where someone with a previous episode of MDD has persistent symptoms. DSM-5 persists in its current version (DSM-5) in not recognizing a 'minor depressive disorder', which would best capture many people with 'depression' in primary care whose most appropriate treatment following NICE's approach is psychosocial. This omission is, apparently, due to American insurance companies not supporting any condition deemed 'minor', rather than for good clinical reasons (Shorter, 2013).

Minor depression would also seem to capture a large group of older people with less well-defined depressions, sometimes termed 'subsyndromal depression'. This term derives from the fact that individuals with such depression fall short of the full criteria for MDD, but they do so for different reasons: some have partially responded to treatment; others have partially spontaneously recovered; some have never attained MDD status and wax and wane in symptom severity and frequency; some have chronic, low-grade symptoms. Studies of these ill-defined categories, essentially assessing the presence of substantial depressive symptoms yield prevalence rates about three times higher than for MDD (Meeks et al., 2011). However, it should be emphasized that

Depression in older people

symptom duration and related disability are crucial for informing management.

The next broad category of depression in older people is depression comorbid with other illnesses. Depression is recognized to occur at high levels in people with physical illnesses generally (Goodwin, 2006) but, as might be predicted, it is especially associated with brain diseases. It occurs in 20–40% of people with Parkinson's disease (PD) (Lieberman, 2006), in 25–50% of people with dementia (Ballard et al., 1996a), and about a third of people after stroke (Gaete and Bogousslavsky, 2008). Related to this is that rates of depression in older people in residential care facilities are about three times higher than in the community (Blazer, 2003).

It seems clear that, unlike dementia which shows a clear association with increasing age, MDD does not increase with age and, if organic disorders such as dementia are excluded and disability is controlled for, depression more broadly does not appear to change in prevalence with age (Blazer, 1999; Jenkins et al., 1997; Roberts et al., 1997). Females are still more likely to be affected than males, though this sex difference may narrow with increasing age (Bebbington et al., 1998; Jorm, 1987). The lack of association with ageing contradicts widespread views that ageing itself is a risk factor for depression.

Clinical features of late-life depression

It has often been suggested there is a different symptom profile characteristic of depression in the elderly. Evidence for this is limited and, reviewing the literature, Baldwin (1994) concluded there was little evidence for phenomenological differences between older and younger depressed patients. However, certainty is hampered by much of the research being done using DSM criteria for MDD, which arguably might conceal differences in symptoms patterns in younger and older people; such findings of no differences may therefore be somewhat self-fulfilling. Certain clinical features may be more characteristic of older people, but this is not necessarily due to depressive illness. For example, the concept of 'masked depression', in which elderly people complain of somatic problems and not low mood, has not generally been supported and the idea may reflect a cohort effect, with older people not wishing to bother their doctor, or only do so for physical symptoms (Baldwin, 1994).

Some studies have directly compared symptoms in older and younger adults with depression. One reported the older group to be more severely depressed and to have significantly more delusions, agitation and appetite loss (Brodaty et al., 1991), and the other also found older patients to be more severely depressed and to have more psychomotor disturbance, psychosis (both hallucinations and delusions), and melancholia, and also more appetite loss and weight loss (Brodaty et al., 1997). Other studies report an increase in somatic complaints, insomnia (Husain et al., 2005), and hypochondriasis (Gurland et al., 1976). Other

Depression in older people

symptoms such as irritability, hypersomnia, and pessimism may become less frequent (Husain et al., 2005). Other studies have, however, noted few age-related differences (Blazer, 2003). Study bias is likely to play a role in such studies as they emanate from specialist units and it is not clear how well they generalize to other situations and cohort biases may also be present (that is, older people report symptoms differently). The one type of clinical feature which is clearly more prominent in older people with depression is cognitive impairment. While cognitive symptoms are not themselves diagnostic symptoms of depression, they are a critical element to examine when assessing older people with depression and we discuss later the complex relationship between depression and cognitive impairment.

Early onset and late onset depression

An alternative way to approach depression in older people is to distinguish depression beginning earlier in life (early onset depression, EOD) from depression presenting for the first time in older people (late onset depression, LOD). Different studies have employed different age cut-offs but LOD is most commonly, but arbitrarily, defined as a first episode after age 60. These studies all assume that people accurately recall age at depression onset, which is unlikely to be true. Although it is often thought that LOD has a different symptom profile, a systematic review found this is not the case (Grayson and Thomas, 2013).

In summary, the symptoms used for diagnosing depression remain the same in older people, which makes detecting any possible differences in symptoms difficult. It is not clear that any specific depressive symptom occurs more or less frequently in older people, although in selected hospitalized subjects, psychotic and psychomotor symptoms may be more common. The only symptoms which are more severe in late-life depression are cognitive impairments, but these are not used for diagnosis and usually specialized tests are needed to identify them.

Assessment of depression

Chapter 9 discusses assessment in detail, and therefore only key points relevant to depression are discussed here. A major difficulty in assessing depression in older adults is comorbidity (that is, depression coexisting with physical illness). Both DSM and ICD take an aetiological approach, so that people whose symptoms can be attributed to physical illness are not diagnosed as having depression by these criteria. While this appears conceptually reasonable it is often difficult in practice for a clinician to determine whether a symptom, such as insomnia, is due to depression or the physical illness, such as discomfort arising from shortness of breath. A careful history, paying attention to the onset of depressive symptoms in relation to the comorbid illness, is essential but frequently it will not be possible to attribute symptoms to depression with much certainty.

Depression in older people

This difficulty in deciding whether to attribute a symptom to the physical illness or depression is compounded by the recognition that frequently older people with depression complain of somatic symptoms rather than low mood. Pain complaints in all ages are a well-recognized presentation of depression (Katona et al., 2005). These are typically non-specific, including headache, abdominal pain, and back ache, and may be multiple. The high prevalence of pathologies potentially causing such pain in older people, e.g. lumbar osteoarthritis, makes it especially difficult to distinguish physical from psychological causation and a mood-related exacerbation of such pathological pain is common. In practice, complaints of pain and other somatic symptoms in the absence of a clearly attributable physical cause should raise the strong suspicion of depression and lead to appropriate mood related questions.

Similarly the emergence (or significant worsening) of anxiety or obsessional symptoms in an older adult should lead to questions about mood as the onset of a pure anxiety disorder is unusual in old age but it has long been recognized by clinicians that anxiety, agitation, and obsessional symptoms are frequent features of depressive illness later in life (Post, 1972). Late-life depression can present as an anxiety disorder and lead the unwary to not recognize depression and treat this appropriately. Deliberate self-harm may be less frequent in older people but it should always lead to careful investigation for depression (or other mental illness) because such acts are more likely to be associated with mental illness and to presage a more serious suicidal act (Manthorpe and Iliffe, 2010). Older men (>75) are the group at highest risk of suicide and most older people who commit suicide have major depression (Manthorpe and Iliffe, 2010). As in younger adults, it is precarious to try to gauge the seriousness of the act from its objective level of risk and close supervision, usually as an inpatient, and treatment is required in such cases (this important topic is considered in more detail in Chapter 40). Behavioural change in an older person may also be a consequence of depression. In such cases it is well recognized that a careful cognitive assessment is needed since the behaviour may be an aspect of an early dementia, but mood assessment is also important especially where no evidence of cognitive decline is evident. A key behavioural change to consider is the emergence in later life of alcohol dependence, which may be a manifestation of a maladaptive strategy for dealing with a depression.

Cognitive impairment, depression, and dementia

Perhaps the most important clinical difference in depression in older people is that cognitive impairment is more prominent. The complexity of the relationship of depression to cognitive impairment and dementia is well known and four main relationships between them may be recognized (Fig. 39.1; Thomas and O'Brien, 2008).

Depression in older people

Fig. 39.1

Four types of relationship of between depression and dementia.

Depression in pre-existing dementia

People with dementia commonly have depressive symptoms, with one review reporting a prevalence of 42% in Alzheimer's disease (AD) (Zhao et al., 2016). Most studies are in AD but the few studies examining subtypes have found depression is more frequent in vascular dementia (VaD) and dementia with Lewy bodies (DLB). For example, one study reported major depression in 10% of subjects with AD but 29% with VaD (Reichman and Coyne, 1995) and major depression was found significantly more often in DLB (33%) compared with 13% in AD (Ballard et al., 1999). There is marked variation in reported figures due to the use of different samples and assessments, but also a difficulty in assessing major depression arises from the aetiological approach to diagnosis in DSM, since distinguishing symptoms due to depression from those due to dementia is inevitably inexact and subject to variation between raters. One consequence is that specific criteria have been proposed for diagnosing depression in the presence of AD (Olin et al., 2002), which include symptoms not emphasized in ICD or DSM, such as reduced positive affect, social isolation, and withdrawal.

Depression as a prodrome of dementia

Major depression, especially when presenting for the first time in later life (LOD), can also turn out to be a prodromal presentation of a dementia. In secondary care the conversion rate was reported as four- to fivefold greater than in non-depressed elderly (Alexopoulos et al., 1993a), while in a primary care study it was found to be one- to twofold increased (Lenoir et al., 2011). Thus, those presenting for the first time with depression in old age should be carefully assessed for cognitive and functional impairment, with a view to trying to determine whether the extent of such impairments is consistent with the severity of mood symptoms. In some cases, it can be recognized that this is not the case

Depression in older people

and more detailed neurocognitive and neuroimaging assessments may be indicated to identify a dementia. In other cases, while there may be a strong suspicion, regular review will be needed to monitor the course of these impairments and their relationship to mood symptoms. Although significant improvement in mood with antidepressant treatment can be associated with improvements in cognition, this is not necessarily the case and when it does occur it should not rule out an underlying dementing illness. Even in those with unipolar disorder, cognitive impairments are now known to persist after depression itself remits.

Depression is a risk factor for dementia

Meta-analyses of depression studies have shown that depression is associated with a doubling of the risk for subsequent dementia even when it occurs many years before the onset of the dementia; that is depression, even in middle age, is an independent risk factor for dementia (Ownby et al., 2006). It is not clear, however, whether this increased risk applies equally to all types of dementia. For example, a nine-year follow-up study finding depression to be a risk factor for dementia reported that depression increased the risk of VaD by threefold but did not increase the risk of AD (Kohler et al., 2011).

Cognitive impairment (and 'pseudodementia') as a feature of depression

It is established that in adults of all ages without dementia who develop depression and who do not progress to dementia over the following few years, cognitive impairment is a common feature and arguably is part of the core of depressive illness (Austin et al., 2001). Various terms have been applied to the clinical complex of cognitive impairment occurring in the context of depression, of which 'pseudodementia' is the most well known. 'Pseudodementia' is poorly defined, which may be related to its widespread use. It may mean simply someone with depression who complains of 'memory problems' and is said to be forgetful; or when someone with depression scores in the mid-20s on the MMSE; or when someone with depression has clinically significant impairment on testing with associated functional impairments (i.e. they appear to have a true dementia associated with the depression); or it may be used when detailed neurocognitive testing reveals deficits which are greater than expected for age. The term pseudodementia is therefore best avoided because of its vagueness.

Clinically it is important to examine not just a score on a cognitive test but the pattern of the deficits. Neurocognitive impairment in depression has a characteristic pattern of inattention, executive and amnesic deficits but aphasia, agraphia, apraxia, and acalculia/alexia all suggest the presence of a dementia (Butters et al., 2004; O'Brien et al., 2004). Consistent with the view that neurocognitive impairment is a core feature of depression it persists after remission of clinical symptoms (Bhalla et al., 2006) for up to at least four years (Kohler et al., 2010a). Although in some cases this impairment may only be detectable by detailed

Depression in older people

neuropsychological examination, in other cases it is apparent at interview and fitting with this longstanding clinical observation of cognitive impairments in older people with depression a large proportion (40% (O'Brien et al., 2004) and 54% (Lee et al., 2007)) of those with late-life depression were found to meet criteria for mild cognitive impairment (MCI).

This pattern (poorer information processing, amnesia, and executive dysfunction) is very similar to that of ageing (Austin et al., 1999) and thus as expected age explains a larger portion of these deficits (Kohler et al., 2010a; Sheline et al., 2006). This raises the question as to whether the greater severity of cognitive impairment characteristic of late-life depression compared with depression in younger adults is simply due to ageing effects? This does not seem to be the case. Studies that have carefully excluded people with early dementia and compared older and younger adults with depression matched for depression severity have found that, even after controlling for the age-related increase in impairment, adults with late-life depression have more severe impairments in memory and executive functions (Lockwood et al., 2002, Thomas et al., 2009).

Thus, people with late-life depression who are not developing dementia have more severe neurocognitive impairments due to factors associated with depression in older age, in addition to the well-recognized age-related increases. What might these depression related factors be? Some studies have related cognitive impairment to dysfunction in the hypothalamic pituitary adrenal axis (HPA axis) and associated hypercortisolaemia (O'Hara et al., 2007) and possession of the short allele of the serotonin transporter has also been linked to cognitive deficits (Hickie et al., 2007; O'Hara et al., 2007). The most robust and consistent relationship is between white matter hyperintensities (WMH) and these deficits (Thomas and O'Brien, 2008). Most studies have been cross-sectional but WMH at baseline also are the best predictor of persistence of these impairments over the following years (Kohler et al., 2010b). Apart from WMH, detailed studies examining correlates between regional and structural brain changes and cognition have not been reported, nor have correlations between functional brain changes in the frontal lobe and impaired cognition been shown.

Differential diagnosis of depression, mild cognitive impairment, and dementia

A clinical conundrum is differentiating from among patients with 'mixed depression and dementia' those who have major depression with associated cognitive impairment (and are not in prodromal dementia) from those who have an early dementia and prominent depressive symptoms (or a true double diagnosis of depression and dementia).

Depression in older people

Research studies involve a quality and depth of cognitive testing beyond what can usually be carried out in clinical practice. As above, such studies are able to identify both prominent impairments, which might be identified in the clinic, and more subtle abnormalities. In clinical practice impaired information processing may manifest itself as poor concentration, and memory and executive problems may be identified by routine tests in clinic, but these typically appear much milder than is found in people with (even early) dementia. Where such deficits are more marked, then a prodromal dementia should be carefully considered. In such cases, special attention should be paid to identifying the timing of the onset of mood symptoms in relation to the cognitive impairments and to assessing the impact on everyday living, where more marked problems are typical of those with early dementia. However, the pattern of cognitive deficits is often more helpful in distinguishing depression related impairments from those occurring in an early and prodromal dementia. Problems with praxis and language (dyspraxias and dysphasias) are characteristic of early dementia and rarely detectable in 'pure' depression and thus the presence of either and especially both strongly suggests an underlying dementia is present and this should then be investigated accordingly with neuroimaging and more detailed neurocognitive assessment.

Aetiology

The reason why some older people develop depression and others do not is not understood. Most of the risk (and protective) factors considered below affect far more people than those who develop depression (see Box 39.1 and Box 39.2). For this reason, the genesis of a depressive disorder is widely considered to be multifactorial, involving a complex and poorly understood interaction between vulnerability factors, which predispose people to developing depression, and precipitating factors which initiate a depressive episode; in many cases these precipitating factors can act to perpetuate the episode too. Vulnerability factors are often permanent (e.g. sex and other genetic risk) or at least difficult to alter (e.g. social isolation, disability, and white matter ischaemia), becoming factors that persist beyond a specific episode.

Depression in older people

Box 39.1 Risk factors for depression

Lack of intimacy	Female
Poor social support	Family history of depression
Being a carer	Physical illness
Bereavement	Brain disease

Box 39.2 Protective factors for depression

Self-efficacy
Mastery of environment
Wisdom
Religious practice

The evidence supporting different aetiological factors in late-life depression is pragmatically divided into two categories. The first groups together social risk factors, personality factors, and life events because these factors are generally recognized to be inter-related and because research in these areas has tended to investigate subjects with milder, more broadly defined levels of depression. The second group of biological factors also interact with each other and research into these risk factors has generally focused on more severe major depression, usually drawn from secondary care samples. This division is not intended to suggest there are two different types of depression or that factors in one category are not relevant to those in the other.

Social factors, personality, and life events

There has been little research into the relationship of personality to the risk of developing depression in old age and evidence points to (different) personality traits as being both risk factors (Box 39.1) and protective factors (Box 39.2). Historically, experts have claimed older people with depression have had stronger personalities than younger adults growing old with depression, indicating these were not risk factors in the development of their depression (Roth, 1955) or that older people with less severe community-type depression had more abnormal personality traits than older people with major depression (Post, 1972). Such views

Depression in older people

are close to a more widespread opinion that more severe depression (major depression) is more biological in its development, while less severe forms of depression are more influenced by personality and psychosocial risk factors. A difficulty in interpreting the limited data in this field is that the direction of causality between these risk factors and depression is unclear as most studies have been cross-sectional and thus unable to determine whether a depression preceded or followed the event.

Lifelong lack of capacity for intimacy has been reported as a risk factor for late-life depression in both sexes (Murphy, 1982), in men only (Emmerson et al., 1989), or women only (Pakhala, 1990). While 'capacity for intimacy' is not itself a personality variable it is related to personality but also to one's social situation, which in turn is related to personality making assessment of this difficult. Such assessments are also confounded by current mood state. Another study failed to identify any relationship with intimacy but found depression associated with a lack of general social contact (Henderson et al., 1986) and the perception that depression in older people is frequently related to loneliness and social isolation is common (Blazer and Hybels, 2005). More positively self-efficacy and mastery over one's environment are reported to be protective factors for late-life depression (Blazer and Hybels, 2005). Along the same lines is evidence that psychological resilience (an ability to properly interpret and understand events and persevere through them) and adaptive coping styles reduce the risk of depression after adverse life events (Arean and Reynolds, 2005). Wisdom in older people—which, like capacity for intimacy and psychological resilience, is an ill-defined but generally understood concept—has also been reported to be associated with greater life satisfaction (Reichstadt et al., 2010) and to be protective against depression (Blazer and Hybels, 2005). Such personality factors are not only difficult to define and influenced by one's social setting, upbringing, and experience, but in terms of the development of depression they interact with life events. That is, different people handle the same life events differently and thus not everyone who loses a loved one or suffers other adverse life events develops depression. And although research generally examines negative life events, people experience positive ones, e.g. marriages of children or births of grandchildren, which can be mood elevating.

The role of social isolation and lack of social support in influencing the development of depression has been mentioned and this is a risk factor in African (Gureje et al., 2011) and Japanese (Kaji et al., 2010) as well as western societies. Poverty and being a victim of crime, which are inter-related, have also been reported to be risk factors (Arean and Reynolds, 2005). Being a carer of someone, an increasingly common experience for older people, is another important risk factor for depression, with one study reporting that a quarter of carers of people with dementia were depressed (Ballard et al., 1996b). Religious practice has been reported to

Depression in older people

protect against depression in older adults in both western (Braam et al., 2001) and eastern cultures (Bosworth et al., 2003).

Life events have been associated with the development of depression in older people, although it is important to remember that the impact of life-events on mood is mediated by cognitive coping style (Meyer et al., 2010). One study reported that 48% of depressed older people had had at least one severe life event in the previous year compared with 23% of their non-depressed peers (Murphy, 1982). These events included death of a loved one, life-threatening illness to somebody close, major financial problems, and having suddenly to give up one's home. Although broadly similar to findings in younger adults, an important difference was the role of physical illness, either a chronic disabling one or a severe and recent illness. The former relationship is supported by other findings of a relationship between disability and handicap and depression. A study in London of 654 people over 65 found broadly defined depression associated with living alone, low income, and low social support, but that the strongest association was with disablement, particularly handicap (Prince et al., 1997a). Life events (most strongly bereavement, personal illness, and theft), especially in the preceding six months, also had associations with depression (Prince et al., 1997b). Handicap may simply be a summary factor for all the social disadvantage and chronic difficulties associated with depression, but a prospective analysis of this cohort found disablement, especially handicap, to be strongly predictive of incident depression (Prince et al., 1997b). The problem is how to interpret this broadly defined construct since it appears to include contributions from all the physical illness and psychosocial factors which have been shown to be risk factors for depression. Life events in childhood, as well as recent life events, have been associated with an increased risk of depression, but the former did not increase the risk of the latter producing depression; that is, childhood events did not confer vulnerability for late-life depression (Comijs et al., 2007).

Bereavement is reported as a frequent precipitant of depression in older people. However, the relationship of bereavement to depression is complex and appears to be mediated by social context and personality factors (Pai and Carr, 2010). First, there is the need to distinguish symptoms of normal grief from similar symptoms of depression. In the first month of bereavement, most people experience low mood, anorexia, insomnia, episodes of weeping, fatigue, loss of interest, and guilt. Such symptoms tend not to be as persistent or severe as in depression and when guilt is present the focus is on perceived failures towards the deceased, and generalized pessimism and suicidal thinking are rare. These symptoms gradually wane as grief is dealt with and by about a year are largely gone. However, in older people who have lost a spouse after many years of marriage, it is understandable that some grief symptoms continue for a long time episodically following the loss, e.g. occasional weeping when reminded of the loved one. Such symptoms are likely to worsen at key dates, e.g. the wedding anniversary. Importantly, normally

Depression in older people

the bereaved person is able to return to a pre-bereavement level of functioning and while such low-level grief symptoms may return from time to time, they are not continuous and the persistence of symptoms, especially when they affect day-to-day functioning, suggests a depression has developed. In addition to such a failure to resolve grief symptoms, other markers of concern are generalized guilt, severe feelings of worthlessness, wishing one were dead, suicidal thinking, psychomotor changes, and 'mummification' (where grief is perpetuated by a failure to adapt one's lifestyle appropriately to the loss). In interpreting the impact of bereavement, it is important to remember that grief is a highly personal and individual experience. Thus, loss of a spouse may be a major blow to one man who had enjoyed a warm and supportive relationship with his wife, but a relief to another who had endured many years of tension, arguments, and violence. Furthermore, different people have differing levels of social support to help buffer the impact of grief and different personality traits, which, as mentioned, may either confer resistance to developing depression or vulnerability. Thus, a quarter of those experiencing a major adverse event did so without developing depression. It is clear not all adverse events are followed by depression and not all depressive episodes are preceded by adverse life events. As discussed, the concern regarding the removal in DSM-5 of the bereavement criterion is that its removal may *discourage* the careful analysis of the relationship between adverse events and depression, whereas good clinical practice involves such a careful evaluation.

Medical and biological factors

Depression in all ages occurs more frequently in women (Cole and Dendukuri, 2003) and a previous history of either major depression or dysthymia increases the risk of developing another depressive episode in old age (Cole and Dendukuri, 2003). It is often said that genetic risk for depression declines with age, but it is important to clarify that if present this decreased risk applies to LOD. Studies comparing people with a first episode of depression in old age with those whose first episode was earlier in life have consistently reported that the former have fewer relatives with depression, e.g. (Baldwin and Tomenson, 1995; Brodaty et al., 1997; Brodaty et al., 1991; Hopkinson, 1964) and this has been confirmed by systematic review (Levinson, 2006). In contrast, a large Danish twin study found no change in the heritability of depression with increasing age (Johnson et al., 2002) and a Genome Wide Association Study (GWAS) of over 3,500 subjects also found no change in heritability of depression with increasing age (Demirkan et al., 2011). As has long been reported, this study confirmed that heritability in depression at all ages appears to be due to multiple genetic loci of small effect rather than it being related to a few genes of large effect (Flint and Kendler, 2014). Although candidate genes related to monoamine systems have been linked to major depression in some studies and other genetic loci implicated, e.g. polymorphism of the serotonin transporter promoter

Depression in older people

region (5-HTTLPR), there remains no convincing evidence for a significant effect on depression from any single gene (Levinson, 2006).

Several major diseases have been associated with high rates of depression. As noted, neurological disorders, especially those causing dementia, are strongly associated with high rates of depression. But vascular diseases and risk factors have an especially strong relationship with depression. Ischaemic heart disease (IHD) is associated with a two- to threefold increase in depression and stroke disease with a similar increased risk, and it has long been clear that the relationship between each of these and depression is bidirectional, with depression being an independent risk factor for IHD and stroke as well as these predicting increases in subsequent prevalence rates of depression (Valkanova and Ebmeier, 2013). It is also now clear that the same is true of diabetes (Rotella and Mannucci, 2013), with depression being a stronger risk factor for the development of diabetes than diabetes is for depression (Mezuk et al., 2008), and also hypertension, with depression increasing the risk of high blood pressure by about 40% (Meng et al., 2012).

The cause of the relationship of these to depression varies and involves several components. In some cases (especially the neurological and vascular disorders) there is good evidence for a biological relationship (see *Neurobiology of late-life depression*). In others pain and discomfort related to physical ill health, including to hip fracture and chronic painful conditions such as rheumatoid arthritis, appears to mediate depression via psychological pathways, which are thought to be bidirectional (Lin et al., 2003). Another aspect of the complex relationship between depression and physical ill health is that involving the handicap induced by the illness. The physical impairments of a significant illness create disability, which in turn places the sick person at a societal disadvantage, which constitutes their handicap (Prince et al., 1998). Thus, an impairment induced by an illness will produce differing degrees of handicap in different people because of their differing social situations. For example, one person with chronic obstructive pulmonary disease living alone may become highly socially isolated and depressed due to this loss of personal contact, while another person with the same condition living with a spouse is able to get out and about and enjoy company at home. Understanding the relationship of physical illness to depression involves careful consideration for each individual of the interplay between these biological, psychological, and social elements.

The possible role of drugs, for older people mainly medication and alcohol, should also be considered. Alcohol may lower mood and high alcohol intake may lead to depression or aggravate it, but often excess alcohol consumption is a consequence of a depression, with it being consumed to try to minimize the painful depression-related feelings. Assessment of depression should always include a sensitive consideration of the role of alcohol. Some reports have claimed different types of prescribed medication are associated with depression. For example, an epidemiological study from the Netherlands estimated the Population

Depression in older people

Attributable Risk percentage (PAR%, the proportion of depression in the population attributed to a drug) for a range of common treatments and found the PAR% for β -blockers was 2.5%, for calcium antagonists 5%, and for benzodiazepines 15.42% (Dhondt et al., 2002). However, such data is very difficult to interpret because people are taking medication for pre-existing diseases, which are themselves related to depression, and detailed assessments trying to tease out the contribution due to drugs themselves have not clearly supported a role for them in causing depression. For example, after reports that calcium channel blockers were associated with depression, a review of these demonstrated this was not the case (Dunn et al., 1999) and secondary analyses of studies in hypertension have reported possible benefits of calcium channel blockers on mood (Ried et al., 2005). While it is prudent to reflect on the possible role of medication when depression appears to start after a treatment is commenced, it would be rash to consider switching medication unless a convincing relationship is present given the precarious nature of the current evidence base. Since most older people are on multiple medications, it is likely to be difficult to decide which, if any, medication may be worth stopping or changing.

Neurobiology of late-life depression

The most widely known neurobiological abnormalities are those which involve the monoaminergic neurotransmitters serotonin and noradrenaline, because all conventional antidepressants target these two neurochemicals. However, research on monoamines is only a small part of the much wider evidence identifying neurobiological abnormalities in older people with depression, although most of the evidence comes from studies of major depression.

Neuroanatomy

Neuroimaging research in psychiatry has been central to the recognition that several neurally linked key brain areas underpin the symptomatology of depression and much of this research has focused on late-life depression. Studies in primates initially identified five frontal-subcortical circuits (FSC) and three of these, involving the dorsolateral prefrontal cortex (DLPFC)-head of caudate nucleus (DLPFC circuit), the anterior cingulate cortex (ACC)-nucleus accumbens (ACC circuit), and the orbitofrontal cortex (OFC)-head of caudate nucleus (OFC circuit) have been implicated in the regulation of mood (Lichter and Cummings, 2001). Evidence implicates dysfunction in these circuits in the onset and outcome of late-life depression (Alexopoulos, 2005), with changes most pronounced in late onset cases (Lloyd et al., 2004).

Structural imaging studies have shown that frontal lobe volume is reduced in depression (Sexton et al., 2013). Structural studies have identified specific areas of the prefrontal cortex as reduced in volume and functional imaging has confirmed these areas have reduced activity and/or blood flow in depression. Thus the ACC is smaller (Drevets et al., 1997)

Depression in older people

and has reduced blood flow (Drevets et al., 1997; Mayberg et al., 1997; Mayberg et al., 1999). The DLPFC is smaller (Chang et al., 2011) and has reduced blood flow (Baxter et al., 1989; Bench et al., 1992) and the OFC is smaller (Ballmaier et al., 2004; Bremner et al., 2002). Subcortically, decreased grey matter volumes in limbic and striatal structures have also been described in older depressed subjects in amygdala, thalamus (Andreescu et al., 2008), and hippocampus (Andreescu et al., 2008; O'Brien et al., 2004; Bell-McGinty et al., 2002; Steffens et al., 2011), as well as caudate (Butters et al., 2009; Krishnan et al., 1992; Parashos et al., 1998) and putamen (Andreescu et al., 2008).

The role of the FSC in the development of late-life depression is further supported by other areas of research. Thus ischaemic WMH are especially prominent in the frontal lobes and basal ganglia (Herrmann et al., 2008) and diffusion tensor imaging studies have reported white matter abnormalities in these same frontal areas (Wise et al., 2016). Neuropathological abnormalities have also been identified in these same brain areas (discussed in more detail later) (Khundakar and Thomas, 2009). As mentioned, studies of neurocognitive impairment in late-life depression have also shown a pattern (impaired information processing, memory, and executive function) consistent with this neuroanatomy and direct evidence of a relationship between the anatomical location of WMH and this neurocognitive impairment has been reported (Sheline et al., 2008).

These neurobiological investigations in late-life depression implicating the FSC have not focussed on the monoaminergic nuclei in the brainstem. The raphe nuclei (serotonin) and locus coeruleus (noradrenaline) in the brainstem are the other key brain areas forming the neuroanatomical substrates for depression.

Neurochemistry

The neurotransmitters relevant to depression can be conceived of as having executive and modulatory components. The former are the main neurotransmitters of the major projection neurones in the FSC, glutamate and gamma-amino butyric acid (GABA), and some evidence implicates abnormalities in these in depression (Sanacora and Saricicek, 2007; Zarate et al., 2010). The modulatory neurotransmitters are the monoamines (serotonin, noradrenaline, and also dopamine) projecting from their brainstem nuclei to widespread parts of the cortex, having dense input to the FSC areas. Abnormalities in serotonergic and noradrenergic neurotransmission are undoubtedly present in late-life depression, and this is most clearly supported by the proven efficacy of antidepressants which all target these transmitter systems (see Management of depression). Dopaminergic changes also may be present (Nestler and Carlezon, 2006) and may be especially relevant where apathy is present, reflecting loss of initiative and drive subsequent to loss of dopaminergic function; this is often the case in 'vascular depression' (discussed later). Although impairments in monoaminergic

Depression in older people

neurotransmission are present in late-life depression it is not clear there are any age-associated changes in these neurochemicals that might make older people more or less vulnerable to depression (Veith and Raskind, 1988). And the failure of a significant proportion of older depressed people to respond to the conventional monoamine-based antidepressants indicates not only that other transmitters may also need to be targeted, e.g. GABA and dopamine, but that other pathophysiological processes are likely to be important, including those affecting vascular, immune, and neuroendocrine systems.

Neuroendocrine

Dysfunction in the HPA axis is recognized to occur at all ages in depression and is associated with hypercortisolaemia, non-suppression on the dexamethasone suppression test, and a loss of the characteristic circadian rhythm of the HPA axis (Stetler and Miller, 2011). In addition, ageing itself is associated with a similar pattern of changes (Alexopoulos et al., 1984) so that HPA axis dysfunction is more marked in late-life depression (O'Brien et al., 1993).

Animal studies indicate that prolonged exposure to glucocorticoids may reduce dendritic density and increase neuronal death, and since the hippocampus has the highest concentration of glucocorticoid and mineralocorticoid steroid receptors in the brain, it may be especially vulnerable to such toxicity. High cortisol levels have also been reported to lower brain derived neurotrophic factor (BDNF) in the hippocampus, with antidepressants reversing this change (Sen et al., 2008). As mentioned, hippocampal atrophy has been frequently reported in depression in older people and amnesia is a prominent problem on detailed cognitive assessment. Thus, HPA axis dysfunction may help explain the prominence of amnesic deficits in late-life depression. Although one study reported a relationship between potential exposure to high levels of cortisol and hippocampal atrophy (Sheline et al., 1996), other studies have not replicated this (O'Brien et al., 2004), nor is it apparent that amnesic deficits are related to HPA axis dysfunction and so it is not clear how important this mechanism is in late-life depression.

Immune and inflammatory

The suggestion of a relationship between depression and the immune system dates back to at least 200 AD when Galen claimed that melancholic women were more susceptible to breast cancer due to immune deficiency. Research during the last two decades has made it clear that the nervous, endocrine, and immune systems are so closely connected that it is suggested that they should be regarded as a single network, and their intimate relationship has led to the development of the new discipline of psychoneuroimmunology. Initially it was thought that psychological stress and depression compromised immune function (Irwin et al., 1990), but studies failed to replicate initial findings and more recent studies indicate depression is associated with immune activation,

Depression in older people

including increased peripheral blood mononuclear cells (such as neutrophils, monocytes, and activated T-lymphocytes), increased secretion of prostaglandin E2, and the presence of a moderate acute phase reaction (with increased haptoglobin, C-reactive protein and α 1-antitrypsin) (Dowlati et al., 2010).

Linked to this immune response is evidence of increases in pro-inflammatory cytokines and reductions in anti-inflammatory cytokines in depression (Dowlati et al., 2010). Cytokines are proteins (such as interleukins, tumour necrosis factor, and interferons) secreted by a variety of cells, including glial cells in the CNS, which play a key role in mediating immune and inflammatory responses. Brain cytokines have a broad range of immunological, neurochemical, neuroendocrine, and behavioural effects (Rothwell and Luheshi, 2000) and their release during illness is associated with so-called 'sickness behaviour' including symptoms such as fatigue, anorexia, depressed mood, hopelessness, anhedonia, and poor concentration. Most studies in depression demonstrating increases in cytokines have been on younger adults but in late-life depression, similar changes have been observed. IL-1 β , IL-6, and TNF- α have all been reported to be raised in both depression and dysthymia in both community (Dentino et al., 1999; Penninx et al., 2003) and hospital-based studies (Thomas et al., 2005) and there appears to be a dose-related effect (Dentino et al., 1999; Penninx et al., 2003; Thomas et al., 2005).

Neuropathology

The neuroimaging evidence identifying structural and functional changes in FSC in depression led to post-mortem neuropathological investigations seeking to identify the cellular correlates of these abnormalities. These studies utilized unbiased stereological methods, to estimate changes in the size of neurons and density of neurons and glia (Khundakar and Thomas, 2009). In younger adults such studies have consistently reported a reduction in glial density in major depression in the ACC (Cotter et al., 2001; Ongur et al., 1998), DLPFC (Rajkowska et al., 1999), and OFC (Rajkowska et al., 1999), but no differences in neuronal density or number. In contrast studies of late-life MDD have reported no evidence of reduced glial density in cortical areas (Khundakar and Thomas, 2009). Overall the findings are suggestive, but not conclusive, that subtle neuronal abnormalities, reductions in pyramidal cell volume, may be present in key areas of the FSC in late-life depression (Khundakar and Thomas, 2009). The prefrontal pyramidal neurones are mainly glutamatergic, and as well as projecting to other cortical areas, also project to the striatum and it may be that ischaemic WMH affect the axons of these neurons inducing these subtle changes.

Other neuropathological investigations have directly examined WMH to assess their pathology. In a study comparing 20 people with late-life depression and 20 age-matched controls, deep WMH were identified on post-mortem imaging and then examined microscopically. While some

Depression in older people

lesions in controls were due to myelin pallor that was not ischaemic, all WMH in depression were ischaemic and the difference from controls was most marked in the DLPFC (Thomas et al., 2002b). This indicates that not only are deep WMH increased in late-life depression but that such deep WMH are due to cerebrovascular disease and that such disease is more frequent in late-life depression. In contrast to these findings in deep WMH, examination of periventricular WMH found most, whether in control or depressed subjects, were not ischaemic but due usually to disruption of the ependymal lining of the ventricles (Thomas et al., 2003). These findings support earlier work on the relationship of vascular risk factors (VRFs) to WMH, which indicates that while deep WMH are strongly related to VRFs and are due to brain ischaemia, PVH are not. Other studies identified an increase in cell adhesion molecules, markers of an ischaemia induced inflammatory reaction, in the DLPFC in late-life depression in both the grey and white matter, suggesting ischaemic brain disease in late-life major depression extends beyond WMH into other white matter and grey matter (Thomas et al., 2002a; Thomas et al., 2000).

Post-mortem studies have also identified evidence of an increase in atheromatous disease in depression in older people (Thomas et al., 2001), which was present even though subjects were matched for vascular risk factors and this was supported by a clinical study also identifying an increase in atheroma in late-life depression (Tiemeier et al., 2004). Although such studies provide evidence of an increase in vascular and cerebrovascular disease there is no evidence of an increase in neurodegenerative disease in late-life depression in subjects who were cognitively intact at death in either the cortex (O'Brien et al., 2001; Tsopelas et al., 2011) or brainstem (Hendricksen et al., 2004; Syed et al., 2005). These autopsy findings are supported by PET amyloid imaging studies reporting no differences in amyloid deposition in late-life depression compared with age-matched healthy controls, e.g. (De Winter et al., 2017).

White matter hyperintensities

Cerebral white matter lesions, usually referred to as WMH, identified on magnetic resonance imaging (MRI) are frequently reported in older people (Jeerakathil et al., 2004) but many studies have demonstrated they are increased in depression in older people (Herrmann et al., 2008). Box 39.3 summarizes their relationship to depression in older people. Although most of the research has been on major depression from hospital-derived samples, several community-based studies of depression in older people have also reported increases in WMH (de Groot et al., 2000; Steffens et al., 1999). WMH are more common in LOD than EOD (Herrmann et al., 2008; Teodorczuk et al., 2007). These lesions have frequently been associated with hypertension (Dufouil et al., 2001; Jeerakathil et al., 2004) and other vascular risk factors, such as carotid atherosclerosis (Pico et al., 2002) and smoking (Jeerakathil et al., 2004). WMH have been associated with VRFs in depression specifically (Smith et al., 2010; O'Brien et al., 1996) and additionally in late-life depression

Depression in older people

WMH have been associated with orthostatic hypotension and drops in systolic blood pressure (Richardson et al., 2009; Vasudev et al., 2011). They have therefore been widely regarded as due to cerebrovascular disease and this has been demonstrated to usually but not always be the case in post-mortem studies (Fernando et al., 2006; Thomas et al., 2003; Thomas et al., 2002b) and in late-life major depression WMH are more frequently due to cerebral ischaemia than in age matched controls (Thomas et al., 2002b). WMH are especially increased in the frontal lobes and basal ganglia in older people with depression (Herrmann et al., 2008), and have been related to the neurocognitive impairments characteristic of depression (Sheline et al., 2008).

Box 39.3 MRI white matter hyperintensities and depression

- Increased in volume
- Increase in volume over time
- More prevalent in frontal-subcortical areas
- Associated with vascular risk factors
- Due to ischaemic brain disease
- Predict future depressive symptoms and episodes
- Associated with poorer remission rates
- Predict chronic cognitive impairment

Prospective studies have reported WMH to increase in volume over time in older people with depression (Taylor et al., 2003) and that these lesions have a bidirectional relationship with late-life depression. Baseline severity of WMH predicts the development (Godin et al., 2008) and worsening of depression (Teodorczuk et al., 2010, Teodorczuk et al., 2007) but depression also predicts the worsening of WMH (Godin et al., 2008). Although the impact of antidepressants on the development and progression of WMH has not been examined, it has been reported that antihypertensive treatment reduces the progression of WMH (Dufouil et al., 2005; Firbank et al., 2007). Since it is clear WMH have an adverse impact on treatment response and longer-term outcomes (see Management) then the amelioration of these lesions by medication raises the hope that their likely role in the development and maintenance of depression could be attenuated.

Depression in older people

‘Vascular depression’

Evidence clearly demonstrates depression has a bidirectional relationship with vascular disease (Thomas et al., 2004). Prospective studies of vascular diseases have reported that previous major depression or depressive symptoms predicts a two- to threefold increase in coronary heart disease, e.g. (Ford et al., 1998; Pratt et al., 1996) and stroke disease, e.g. (Jonas and Mussolino, 2000; Salaycik et al., 2007). The increase in WMH, which are ischaemic lesions, in late-life depression provides direct evidence for a role of cerebral ischaemia and this is further strengthened by reports from diffusion tensor imaging studies of increased diffusivity in late-life depression (Wise et al., 2016), which is a further indicator of the presence of white matter tract disruption due to cerebral ischaemia. This increased diffusivity occurs in areas without WMH, suggesting a more widespread impact of cerebrovascular disease than that identified by MRI WMH, and this is further supported by neuropathology reports of increased cell adhesion molecule expression in the DLPFC, showing vascular changes in frontal grey as well as white matter (Thomas et al., 2002a).

This evidence led to and provided support for the ‘vascular depression’ hypothesis (Alexopoulos, 1997, p. 118), which postulates that cerebral ischaemic damage to frontal-subcortical circuits predisposes to and/or perpetuates depression in older people. This concept has received criticism because delineation of a recognizable sub-group of ‘vascular depression’ has proven difficult (Baldwin, 2005). More importantly several community studies of late-life depression have not identified an increase in clinically determined VRFs (Kim et al., 2004; Lyness et al., 1998; Lyness et al., 1999; Naarding et al., 2007), casting further doubt on the importance of specific VRFs in the genesis of late-life depression. It is important to note, however, that the same cohorts followed prospectively have reported an association of depression with some VRFs (Kim et al., 2006; Lyness et al., 2000) and that the increases in WMH occur independently of the association with VRFs (Herrmann et al., 2008). This has been directly demonstrated in a large study matching depressed and control groups for VRFs (Sheline et al., 2008). The explanation for these discrepant findings probably reflects the insensitivity of (peripherally measured) conventional VRFs for actual ischaemic disease in the brain and the differences in samples, with the MRI and pathology studies assessing major depression in secondary care patients while the community studies sample milder cases of depression. The ‘vascular depression’ model postulates that cerebrovascular disease is an important aetiological factor in late-life depression and likely to be an important one in a proportion of such people, but does not propose a unifying mechanism involving vascular disease for *all* late-life depression. Estimates of the proportion of people with late-life major depression where vascular disease is important indicate this is likely to be the case in about 50% (Sneed et al., 2008a) and this delineation was based on utilizing evidence of significant WMH on MRI, rather than VRFs. Two

Depression in older people

intervention studies using the calcium channel blocker nimodipine have also provided encouraging results (Taragano et al., 2001, Taragano et al., 2005) suggesting the 'vascular depression' model may provide a way of developing new treatment approaches in late-life depression.

Management of Depression

The clinical management of depression requires a thorough assessment and diagnosis, since diagnosis in older people is frequently difficult because of confounding cognitive impairments and physical illnesses and because one neglected reason for non-response to treatment and treatment resistance is misdiagnosis. Assessment should aim to generate an understanding of the individual impact of the current depressive episode on the patient and his everyday life, and not merely be a process of identifying and counting depressive symptoms, since the number of symptoms is not a good guide to the severity of depression. Assessing the degree of functional impairment or disability related to the depression is key to developing a good management strategy. This allows the potential benefits and risks of treatment to be carefully weighed. This approach was proposed in the British Association of Psychopharmacology guidelines (Anderson et al., 2008) and has been adopted by NICE in its Guidelines for the Management of Depression (NICE, 2009). These both emphasize that identifying duration of symptoms and the disability associated with them is crucial to informing rational management and leads to a stepped care approach based on the combination of burden of symptoms, duration of illness, and depression-related functional impairment.

Assessment has been discussed in detail in Chapter 9 and earlier in this chapter and here a few brief points relevant to depression management are emphasized. A careful risk assessment, including sensitive questioning about suicidal thinking and previous acts, is an integral part of the assessment of depression. When depression is severe, suicidal thinking should be suspected and careful monitoring instituted even where such thinking is not volunteered. In such cases it is also important to probe for symptoms of psychosis, especially mood congruent delusions. A cognitive assessment should be carried out whenever there is suspicion of cognitive impairment; however, this need not always be the case and in those presenting with a 'pure' depression this may be unhelpful, and suggesting a dementia is suspected that might damage the therapeutic relationship. In those with a previous history of depression it is important to obtain details of treatments for these earlier episodes, whether they were successful or unsuccessful, as this can be very helpful in guiding treatment of the current episode because patients tend to respond, or not respond, to the same treatments.

Depression in older people

General principles of management

As when treating younger adults it is helpful to consider treatment as having three stages: an acute phase, a continuation phase, and a maintenance phase (Frank et al., 1991). The stepped care approach recommended by NICE and BAP applies to the acute phase, and ties in with an important finding in clinical trials of antidepressants: the more severe the depression, the stronger the evidence for efficacy and the greater the benefit from using this medication (Khan et al., 2002; Kirsch et al., 2008). This increased benefit comes both from antidepressants having a larger reduction in depression when depressive illness is more severe and from placebo having a smaller impact on depressive symptoms in the more severely ill (Khan et al., 2002). The conclusion from this is that a clinician needs to weigh up the severity of the depressive illness when considering whether to use antidepressants and how vigorously to treat. Thus, following the stepped care approach, those with few symptoms ('subthreshold') and little impact on everyday functioning should not be offered antidepressants, but instead be given supportive and low-intensity psychosocial interventions. In those with so-called mild major depression, better 'minor depression', a more intensive psychological treatment is indicated but antidepressants are unlikely to be of benefit. In such cases antidepressants should be reserved for when such interventions fail and disability is significant. Those with moderate or severe major depression are those most likely to benefit from antidepressants and medication is then indicated as first-line treatment, and combining medication with intensive psychological treatments is often appropriate. This leads back to the British Association of Psychopharmacology recommendations of its 'dimensional' approach to prescribing antidepressants (Cleare et al., 2015). Those with MDD and significant severity (taking into account both symptoms and the impact on everyday living) should be treated robustly. Similarly, when someone presents with a longer illness, say over three months, even though the severity is milder antidepressants are indicated because spontaneous recovery or improvement is less likely.

There are several goals in the management of depression, but aiming to achieve clinical remission, rather than simply symptom reduction, is vital because persistence of depressive symptoms ('residual depression') is strongly associated with high rates of relapse. During the acute phase of treatment, management of suicide risk and possibly self-neglect are important and treatment aims at more than symptom relief by trying to achieve a restoration of previous levels of everyday functioning. Once this is achieved, then the management focus moves to reducing the likelihood of future depressive episodes through continuation and maintenance treatment. Continuation treatment usually means continuing with whatever treatment got someone well for at least six months after remission. While in younger adults with a first episode treatment may then be withdrawn, it is argued below that for major depression in older adults, continuation should always be followed by maintenance; all late-

Depression in older people

life major depression (but not necessarily milder forms of depression) needs lifelong treatment.

Prescribing in late-life depression

There are several general topics that need consideration when prescribing antidepressant medication in older adults. With ageing there are pharmacokinetic changes which alter the bioavailability of drugs. These are considered in detail in Chapter 13 and so only key aspects are summarized here. There is reduction in hepatic metabolism, which reduces biotransformation and the impact of first pass metabolism allowing more active drug to enter the systemic circulation; volume of distribution is typically increased with ageing due to the relative increase in adipose tissue; and, most importantly, there is an age-related reduction in glomerular filtration rate. Together, these changes lead to higher plasma and brain levels of active drug per unit dose compared with younger adults and consequently the need for lower doses. However, there is much variability in these changes and clinicians are used to observing such variability. Some 75-year-olds are much 'younger' physically than others and such 'younger' older people are likely to need and to tolerate higher doses; it is prudent to remember this if someone is not responding to a typical dose for an older adult.

A related factor which affects dosing at all ages is genetic variability. Polymorphisms in key enzymes of the cytochrome P450 system, which metabolize psychotropic drugs, can lead to a wide range of plasma levels for the same drug dose. Of course, in regular practice the clinician does not know which polymorphisms a patient possesses but it is helpful to be aware they exist because, as with variability in age-related pharmacokinetic changes, inadequate response to a standard or even 'high' dose of antidepressant may be because a 'high metabolizer' is being undertreated.

Pharmacodynamic changes also occur with ageing and are probably due to age-related changes in dendritic and synaptic density and may explain why some older people are more prone to adverse effects, e.g. antipsychotic-induced tardive dyskinesia (Jeste, 2000), even at low drug levels. And pharmacodynamic changes may also explain the propensity of older people to develop disabling tremor even with low serum levels of lithium.

In a different category from these biological alterations is polypharmacy. This continues to be a major issue in older adults and, given the large and increasing numbers of effective available treatments for illnesses strongly associated with ageing (statins, angiotensin receptor blockers, proton pump inhibitors, etc), it seems impossible to avoid. Awareness that the likelihood of adverse drug-drug interactions and related problems is proportional to the number of prescribed drugs should encourage regular medication review, especially where new symptoms develop when a new drug is added (Chrischilles et al., 2009). The number of psychotropic

Depression in older people

drugs being prescribed has increased significantly, making this an increasing problem (Mojtabai and Olfson, 2010). For example, the prescribing of antidepressants in nursing homes in the US more than doubled from 21.9% to 47.5% over the last ten years; interestingly, increased involvement by nursing staff was associated with an increase in antidepressant prescribing whereas more visits by physicians was associated with lower prescribing, perhaps due to a better understanding of depression and benefits from antidepressants in the latter group (Hanlon et al., 2010). Levels of polypharmacy remain very high. In India, a study of two teaching hospitals reported that over 90% of those over 60 were prescribed five or more medications and 45% were receiving ten or more (Harugeri et al., 2010). A survey of over 13,000 residents of nursing homes in the US found over 40% were being prescribed nine or more drugs (Dwyer et al., 2010).

Polypharmacy also raises the likelihood of clinically important additive side-effects, whereby common side effects may be tolerated from one medication but not when several are used together (Carnahan et al., 2006). For example, when prescribing a serotonin reuptake inhibitor (SSRI) it is important to check for other medication that can also cause gastric erosions and bleeding, especially because treatments such as aspirin, donepezil, NSAIDs, and steroids with such properties are commonly prescribed in older people. If after review it is concluded all such treatments are needed, then it will be necessary to also prescribe something such as a proton pump inhibitor for gastroprotection.

Finally, consideration should be given to frailty and reduction in homeostatic reserve. These are two related, but poorly defined and yet widely used, terms that point to the disproportionate impact side-effects can have on older people. Frailty means older people are less robust and so, for example, anticholinergic effects from paroxetine (especially if combined with other medication with anticholinergic effects, such as valproate, carbamazepine, or olanzapine) which may pass unnoticed in a healthy younger adult, may induce delirium in an older adult with depression.

Acute phase drug treatment of late-life major depression

The great majority of pharmacological studies of antidepressants have been conducted in people diagnosed as having major depressive disorder. It is important to remember this because it is not clear the abundant evidence for efficacy of antidepressants in this group can be extrapolated to the other types of depression occurring in older people. This is, of course, not an issue unique to late-life depression. In its guidelines for the drug treatment of depression, the British Association of Psychopharmacology recommends a 'dimensional' approach to prescribing antidepressants for depression (Cleare et al., 2015). This encourages clinicians to see the diagnosis of depression as a starting point, but not one that itself indicates that an antidepressant should be prescribed. Essentially the same approach is used by NICE in their

Depression in older people

clinical guidelines on depression management (NICE, 2009). This means combining evidence of depression severity with the duration of the illness, rather than simply making a diagnosis of depression and prescribing if someone meets this diagnosis. Such a nuanced approach is perhaps especially important in older patients, where the risk/benefit ratio is less clear due to the increased propensity of older people to develop adverse drug effects.

Meta-analytic systematic reviews have reported clear benefits from the use of antidepressants in late-life major depression (Kok et al., 2012; Nelson et al., 2008; Wilson et al., 2009a) and similar response and remission rates across the different antidepressant classes (Kok et al., 2012). However, the reported trials have been far from unanimous in this verdict and it is important to consider reasons why findings are heterogeneous. Some of the earlier trials were less well designed, especially those of tricyclic antidepressants, and in particular were often underpowered (Wilson et al., 2009a). However, these older antidepressants are used infrequently nowadays and so here we provide closer examination of 'modern' compounds that are widely prescribed for older people.

Specific SSRIs have the largest evidence base and overall are clearly efficacious in MDD although some trials have been negative (Nelson et al., 2008). An important reason for this in one trial in the 'old-old' (all subjects were over 75) was very large variation in outcome between different trial sites, which created so much noise in the outcome data that the signal of sertraline efficacy could not be detected. This problem is probably widespread in clinical trials and likely had an impact on another negative trial of fluoxetine and escitalopram (Kasper et al., 2005), which utilized 73 sites. Another important factor precipitating negative outcomes is the presence of cognitive impairment. In a systematic review of randomized controlled trials (RCTs) of non-tricyclic antidepressants in late-life depression (Nelson et al., 2008) it is noteworthy that those studies reporting no favourable outcome of medication over placebo (including the agents escitalopram, citalopram, fluoxetine, and venlafaxine) included subjects with a significant amount of cognitive impairment. This is likely to have contributed to the negative outcomes because neurocognitive impairment is associated with poorer outcomes generally. Indeed, a re-analysis of the data from one of these trials identified executive dysfunction as a predictor of poorer response to citalopram, with those without such impairments responding better than placebo (Sneed et al., 2010). It is worth adding the wider context including trials from younger adults. A network meta-analysis of 522 RCTs (Cipriani et al., 2018) including 116,477 subjects reported all antidepressants to be better than placebo and in head-to-head studies agomelatine, amitriptyline, escitalopram, mirtazapine, paroxetine, venlafaxine, and vortioxetine performed better against other antidepressants, supporting the view that the negative trials of these agents in older people are probably due to other effects such as the

Depression in older people

presence of cognitive impairment. For newer non-SSRIs the evidence base is much smaller in late-life MDD but it seems reasonable to extrapolate this evidence from younger adults since the evidence for SSRIs and TCAs has been shown to reliably apply to older adults too.

There are now a large number of antidepressants to choose from, emanating from several distinct drug classes. In general terms, in making a choice one should consider tolerability, safety, side effects, drug interactions, and contraindications, and where relevant, previous history of antidepressant use. Achieving adherence to antidepressants is clearly important since merely prescribing an antidepressant will achieve nothing unless the patient is convinced of the need for taking it and does so. Older people frequently do not adhere to medication in general and this is likely to be especially the case for antidepressants. Hence, engagement of the patient during assessment, sensitive explanation of the diagnosis, and education about the benefits and side-effects of antidepressants is crucial. Antidepressants may still be confused with benzodiazepines and so thought to be 'addictive' and reassurance that this is not the case may be needed. Dose-related and common side-effects should be spelled out and encouragement given that persistence with the treatment is often associated with these waning. In the author's experience, patients often read and are upset by the much larger number of potential adverse effects listed on the drug insert in the box and it is helpful to explain that these consist largely of common everyday symptoms that are not necessarily related to the drug at all. Education about the speed of response to antidepressants should also be given, since people may expect the same kind of rapid response they have experienced with antibiotics and so become discouraged when this does not happen. At this stage a medication review is worthwhile because simplifying the medication regime is not only helpful for adherence to antidepressants, but also can improve adherence more generally and reduce the number of drugs being taken. Often treatments have been added in from time to time over years and, in liaison with the GP, some can often be stopped and a once daily or twice daily treatment regime can helpfully replace a more complex one.

Regarding the specific antidepressant to use, then guidelines indicate the first antidepressant should be an SSRI, unless the patient has a clear history of response to a drug from another class and/or failure to respond to or poor tolerability of an SSRI. This recommendation is supported by the above trials evidence in older adults and SSRIs are generally better tolerated than earlier antidepressants, especially tricyclic agents. SSRIs are generally free from significant interactions with other drugs, an important consideration in older adults who are usually on other medication, and are particularly appropriate where tiredness and excessive sleep is a problem because of their alerting properties. Mirtazapine, reported to be one of the four most efficacious antidepressants in depression (Cipriani et al., 2009), has a side-effect profile which is particularly suited for use in older people. Its main

Depression in older people

adverse effects are weight gain and sedation but in older people in whom sleep disturbance and weight loss are frequently problematic these can be helpful rather than problematic and the clinical experience of mirtazapine is that it is very well tolerated. It has the added advantage that its pharmacological profile complements that of SSRIs (and Selective serotonin and noradrenaline reuptake inhibitors (SNRIs)) as it has antagonism of 5-HT₃ and 5-HT₂ receptors which counteract the potential adverse effects of sexual dysfunction and nausea. For these reasons, mirtazapine has become a very widely prescribed antidepressant in late-life depression and is frequently used second line or in combination with an SSRI. SNRIs (duloxetine and venlafaxine) have similar side-effect profiles to SSRIs and may be especially helpful in those resistant to SSRIs where their dual action can prove helpful, and like SSRIs they can be combined well with mirtazapine.

An important caveat to the extrapolation of results from clinical trials in younger adults is that the data may only be valid in older adults who are healthy and cognitively intact, i.e. biologically like younger adults. Physical illness morbidity has been shown to predict poor response to antidepressants (Reynolds et al., 2006) and cerebral ischaemic white matter disease (demonstrated by the presence of WMHs on magnetic resonance imaging) is associated with a poorer response to antidepressants (Alexopoulos et al., 2002; Alexopoulos et al., 2008), poorer longer term outcome and increased relapse rates (Hickie et al., 1996; O'Brien et al., 1998), and persistent cognitive impairment up to four years (Kohler et al., 2010b). Since WMHs are associated with executive dysfunction it is not surprising that such impairment is itself associated with poorer response to antidepressants and increased relapse rates (Alexopoulos et al., 2000; Kalayam and Alexopoulos, 1999). Such findings are consistent with evidence indicating antidepressants are ineffective in depression in dementia (discussed later) and with the studies indicated earlier in which those enrolling subjects with (mild) cognitive impairments showed equivocal benefits for antidepressants. While the evidence may not be robust enough to indicate that antidepressants should not be used in such patients, it does suggest that more careful consideration is needed and that, if used, higher doses, augmentation, and combination strategies may be needed.

Acute phase psychological treatments of late-life depression

The quality of the evidence for using psychotherapies in late-life depression remains poor and the number of well-designed studies in this field continues to be disappointingly low. There are several particular problems in evaluating the evidence. Much of the evidence that is cited in support of psychotherapy for late-life depression is from non-randomized studies, and it has been shown that the design of such studies inflates the outcomes in favour of the intervention (Sneed et al., 2008b). Thus, for example, in one review (which did not include several important recent antidepressant studies included in the above meta-analysis (Nelson et al., 2008)) it was reported that the effect size in favour of psychotherapy in

Depression in older people

broadly defined late-life depression was 1.09 compared with only 0.69 for antidepressants (Pinquart et al., 2006). However, this was really an 'apples vs oranges' comparison, since randomized blinded antidepressant trials were compared with unblinded, non-randomized psychotherapy studies. Its findings also contrast with those of the Cochrane review (Wilson et al., 2009b) of psychotherapy in late-life depression that identified only 12 studies of sufficient quality to include, and even then had to include reports comparing psychotherapeutic interventions with waiting list controls. Most of the studies also included people with depression whose baseline HAM-D score only had to exceed 9 points (a low score, since <10 is often used as a definition of remission in drug studies). The largest and best designed study (Williams et al., 2000) found no benefit of problem solving therapy over placebo (though paroxetine did have significant benefits) and overall the review concluded the evidence for using psychotherapy in late-life depression is weak. It was also observed that the patients included in these studies did not appear to be representative of those usually attending health services, since most had been recruited through adverts, which appears consistent with the low score on the HAM-D for inclusion. Currently there is clearly a need for larger, better designed studies which enrol depressed subjects more typical of those seen in primary care and psychiatric services. It can also be argued that in the meantime the findings from studies in younger adults with depression can be extrapolated to older adults as with drug studies, though the same caveats apply about this probably only being valid for healthy, cognitively intact older adults.

When psychotherapy is needed there are added difficulties with availability and therapist experience. Availability of specific psychological interventions is still limited, especially in older adults, and identifying someone expert in the required therapy, e.g. cognitive behavioural therapy (CBT), can be especially difficult. When prescribing medication the treatment is the same regardless of the prescriber but in psychotherapy there is large variation in the experience and expertise of therapists and this has been reported to directly affect the efficacy of the intervention (Williams et al., 2000). Thus, even when psychotherapy is indicated it can be difficult to ensure a quality of therapy is provided comparable to that in the published literature.

An important issue not covered in the literature is anxiety management in the context of depression. So-called comorbid anxiety is common in late-life depression and frequently persists once (other) depression symptoms have resolved. Anxiety management, involving psychoeducation on anxiety symptoms and techniques such as controlled relaxation, can in such circumstances be helpful and delivered by nurses or occupational therapists from local services.

Depression in older people

Multifaceted interventions

In contrast to the disappointing quality and quantity of the evidence for using specific psychotherapies in late-life depression, there are an increasing number of studies examining a combination of psychotherapeutic and other interventions to provide structured packages of care. Various 'packages' have been investigated but almost all of these studies have provided encouraging findings. One study of home-based treatment for older people with depression, for example, compared PEARLS (combined problem solving therapy, increased physical activity, and increased socialization) with usual care and found a 50% depression symptom reduction was achieved by 43% of the PEARLS group, compared with 15% with usual care and remission rates were 36% and 12%, respectively (Ciechanowski et al., 2004). The largest study (involving 1,802 patients) of such an approach is the IMPACT study, which compared usual care with a care management package, with patients being able to select between antidepressants and problem-solving therapy (PST). At 12 months, 45% of intervention patients had achieved a 50% reduction in symptoms, compared to 19% in the usual care group (Unutzer et al., 2002). The PROSPECT study, using a collaborative intervention based in primary care, has reported improved remission rates in late-life major depression at 6, 12, and 24 months and reduced suicidal ideation (Alexopoulos et al., 2009). A similar but flexible approach was used in a study in Austria comparing home-based treatment by a multidisciplinary team with usual care and reporting significant improvements in depressive symptoms, quality of life, and overall function, and a reduction in admissions to hospital and nursing homes over one year (Klug et al., 2010). Similarly, the use of a dedicated depression care management approach in primary care led to markedly improved outcomes (effect size 0.8) compared with usual care (Chen et al., 2015).

These multifaceted interventions often include 'exercise therapy' of different kinds and the evidence for benefit from exercise in depression is similar to that for specific psychotherapies in that most of the studies in the literature are of poor quality and a systematic review found only 15 randomized studies, most of which were not blinded and had inadequate follow-up (Sjosten and Kivela, 2006). The review concluded that the evidence justifying exercise therapy is modest and its role is probably best within such a multifaceted approach. Overall these multifaceted studies have applied their interventions in outpatients (Sirey et al., 2005), community patients (Banerjee et al., 1996; Ciechanowski et al., 2004; Unutzer et al., 2002) and even in residential care (Llewellyn-Jones et al., 1999) and consistently reported benefits. These findings provide robust evidence for enhancing the quality of community-based care by applying such structured interventions in regular clinical practice, though unfortunately this is often difficult to achieve.

Depression in older people

ECT and other interventions

The other major treatment regularly used in clinical practice for late-life depression is electroconvulsive therapy (ECT). Its use is reserved for those who remain ill and disabled after other interventions have been tried and those with life-threatening illness (including high suicide risk). Concerns about using ECT in older people are often expressed, mainly about precipitating confusion and the alleged increased risks of other physical adverse effects, but the evidence strongly supports its use. Well-conducted studies (comparing real ECT with sham ECT, in which electrodes are placed on the head but no electricity is applied, have demonstrated the efficacy of ECT in depression, with improvements on the HAM-D of over 5 points greater than antidepressants (UK ECT Review Group, 2003).

The quality and strength of this evidence has made the conduct of such studies in older adults with depression unethical. However, studies have directly compared ECT by age. One, examining 268 adults with MDD who all had a HAM-D of greater than 20, found ECT to be of greater benefit in adults between 60 and 74 and in those 75 and over compared with younger adults (Tew et al., 1999). Another of 253 adults, again with MDD and a HAM-D score of over 20, reported ECT to be non-significantly more beneficial in adults of 47 to 64 and in those 65 and over compared with younger adults, and reported a positive correlation between symptom improvement and age (O'Connor et al., 2001). Importantly, both studies found no age-associated increase in adverse effects. A meta-analysis confirmed that ECT is more effective in older people (greater remission and response), and safe and better outcomes also occur in those with psychosis (van Diermen et al., 2018). These findings are very encouraging and support a confident use of ECT in late-life depression, though the patients in such trials were by definition those who were physically fit enough in the first place.

A clinical dilemma with ECT is what to do once someone is well again. Relapse rates after remission with ECT are high. A study in adults of all ages found continuation ECT and pharmacotherapy provided similar reductions in relapse rates, both much better than historic relapse rates on no treatment (Kellner et al., 2006). However, a limitation in this study was that ECT was a fixed ten-treatment regime that did not allow flexibility by clinical response and thus did not perhaps reflect real-world practice. A more recent large randomized trial, which included only older people with major depression, employed four continuation ECT treatments in the month following remission and then flexible further ECT determined by clinical symptoms (Kellner et al., 2016). All ECT subjects also had continuation and maintenance pharmacotherapy with venlafaxine and lithium. Encouragingly, this found that compared with continuation and maintenance pharmacotherapy alone, the ECT arm had lower depression scores and more patients who remained well. This supports the practice of many clinicians, based on experience, that

Depression in older people

maintenance ECT is effective in this selected group of ECT-treated patients.

Other stimulation treatments are available for depression but there is little good-quality evidence to justify their use and none specifically in late-life depression. Transcranial magnetic stimulation (TMS) has received most attention and has good evidence for efficacy in depression (Slotema et al., 2010). However, its efficacy is significantly less than that of ECT (Slotema et al., 2010) and it is therefore unclear which patients should receive it. In late-life treatment-resistant depression, one study reported benefit (Fabre et al., 2004) from TMS but another did not (Mosimann et al., 2002). TMS also has limited availability and while it is unclear which patients might be selected for its use, it is difficult to justify providing it in clinical services. Vagal nerve stimulation has some evidence for its benefit in selected patients with treatment resistance to antidepressants (Sackeim et al., 2001) but is expensive and very limited in its availability. Similarly, deep brain stimulation (DBS) is only available at a few selected centres. DBS involves surgically placing an electrode in a selected brain area (such as the nucleus accumbens or subcallosal cingulate gyrus). The electrode is connected by a wire to a neurostimulator placed subcutaneously in the chest wall which is then operated by an external device to set the frequency of stimulation. It can be effective in highly selected treatment-resistant patients (Blomstedt et al., 2011) but there are currently very few studies and there are ethical concerns about its use in depression (Synofzik and Schlaepfer, 2011). A similar group of patients might be considered for psychosurgery, which also has some evidence of benefit, but it is only available in specialist centres and attracts similar ethical concerns; DBS appears to be replacing psychosurgery in such treatment refractory patients (Sachdev and Chen, 2009).

Achieving remission in late-life depression

The clinician managing someone with depression should be aiming to achieve remission, rather than simply symptomatic improvement, and so should persist and utilize a range of strategies to achieve this and restore people to normal functioning and a symptom-free state. Persistence in applying a logical and structured approach results in over 80% achieving remission (Rush, 2007). As discussed earlier, the management strategy used should be tailored to the severity level of depression and stepped up if remission is not achieved at the starting level. But once several treatments have been utilized at different levels in the stepped care process, then a structured and persistent approach is needed to combat the danger of fatalism and despair developing and such a strategy largely involves pharmacotherapy.

First and most obviously the antidepressant can be increased in dose or prolonged in its use. When dealing with older patients there remains a tendency to use lower doses and increase them cautiously (applying the old age psychiatrist's adage of 'start low, go slow'). While appropriate

Depression in older people

with the frail elderly, this is probably too cautious an approach for adults who are chronologically 'old' but biologically 'young'. For example, in the open-label acute treatment phase of a maintenance study in late-life depression using citalopram it was reported that 50% of subjects tolerated 40mg and many had 60mg (Klysner et al., 2002). An additional caveat to this approach is to consider a patient's previous history and especially the risk of relapse, so that earlier and more robust treatment should be used in those with depressive episodes earlier in life whose symptoms are now returning.

How quickly should an older person with depression respond to treatment? While it is often said that it takes four to six weeks for antidepressants to work, it is important to be clear what this means and to distinguish between response and remission. Thus in general it is expected that some improvement in symptoms (that is there will be evidence of response to treatment) will occur within a couple of weeks and such early response is predictive of stable later response (van Calker et al., 2009); the disappearance of all or nearly all symptoms (remission) will take some weeks longer. But are these timelines also applicable to late-life depression? Two studies directly comparing response and remission in older and middle-aged depressed adults reported no differences (Alexopoulos et al., 1996; Reynolds et al., 1996) and a review of the literature reached the same conclusion (Whyte et al., 2004). Predictors of a slower response are greater severity of depression, comorbid anxiety and late-age at onset of the illness (Alexopoulos et al., 1996; Whyte et al., 2004). However, these encouraging findings need to be qualified by acknowledging that the underlying research was conducted in physically healthy and cognitively intact older adults who were relatively young (almost all under 80). Other data indicates neurocognitive impairment and physical illness are also associated with poorer response and remission rates. Thus, in the 'younger-old' the same approach can be taken as with younger adults but for people with these comorbidities a slower response and lower remission rates are expected. A related issue is of possible differences in EOD versus LOD. Here the evidence is mixed, with studies reporting no differences (Reynolds et al., 1998), LOD to have a worse prognosis (Alexopoulos et al., 1993b), and EOD to have poorer prognosis (Brodaty et al., 1993). While differences in the groups studied are likely to explain such discrepant findings it makes it difficult to draw firm conclusions. The wider evidence for increases in WMHs on MRI imaging in LOD (Herrmann et al., 2008) and the robust evidence associating such lesions with poorer outcomes (Alexopoulos, 2002; Alexopoulos et al., 2008; Kohler et al., 2010b; O'Brien et al., 1998) leads the author to conclude LOD responds more slowly, and this is corroborated by clinical experience.

How long should you wait before adjusting antidepressant treatment? In 'younger-old' people with late-life depression then if there is no apparent change at all by two weeks then, assuming no adverse effects, the dose should be increased and increased to the maximum tolerated dose. In

Depression in older people

those with LOD and/or with cognitive impairment and/or physical morbidity it is prudent to wait until perhaps four weeks. If there is symptom improvement then treatment should be continued and the dose increased if further improvement ceases. An important factor is duration of treatment since it has been shown that the longer a trial lasts the greater the difference between drug and placebo; that is, when a trial is conducted over a longer period a larger proportion of people achieve response and more importantly remission on medication, thereby creating a larger difference from placebo and clearer evidence of benefit. Thus in a systematic analysis of this it was reported that in clinical trials of six to eight weeks' duration the odds ratio in favour of antidepressants was 1.2, whereas in those studies with outcomes at between ten and 12 weeks after baseline, the odds ratio was substantially increased to 1.73 (Nelson et al., 2008). Such evidence supports persistence with a treatment rather than quickly switching to an alternative because improvement seems to be too slow. In practice, a treating doctor can come under both internal ('I need to do something') and external pressure to change treatment and is then in danger of losing gains by switching to an alternative or unnecessarily adding in a new treatment through impatience, thereby exposing the patient to a higher risk of adverse effects. Patient explanation and support and utilization of other aspects of treatment, e.g. group activity or problem-solving therapy, are perhaps better responses in such circumstances. Switching to an alternative antidepressant should be carried out as soon as it is clear no benefit at all is being achieved (if some benefit is apparent then augmentation or combination approaches are indicated) or more commonly when adverse effects preclude its continuation.

If the strategies of increasing the dose and prolonging the duration of treatment are not successful and remission is not achieved on the maximum tolerated dose then combination and augmentation strategies should be considered. Unfortunately, as with switching and increasing the dose, the evidence for such strategies is limited. A combination approach (adding a second antidepressant) is very popular but has little empirical evidence to support it. Clinical experience supports it and a popular combination involves adding mirtazapine to an SSRI, since the latter is in most cases the initial antidepressant. For the pharmacological reasons discussed above this is rational strategy and experience suggests it is frequently helpful. Again, the mirtazapine, or other combination agent, should be increased to the maximum tolerated dose and other treatment aspects (group CBT, anxiety management, etc) explored during this treatment phase.

The alternative is to augment the first line antidepressant with a non-antidepressant. The best evidence is for antipsychotic augmentation with a well-designed study randomizing 181 people who did not remit on venlafaxine (and in most cases a pre-trial SSRI) to aripiprazole or placebo augmentation (Lenze et al., 2015). They found that by four months significantly more people remitted on aripiprazole compared with placebo

Depression in older people

(44% vs 29%), which is clinically important with a Number Needed to Treat of 6.6. the aripiprazole was generally well tolerated, with most people being on 6–10mg and having fewer dropouts than in the placebo arm. More people did develop parkinsonism and akathisia on aripiprazole, but a careful assessment of weight, lipid, and cardiac profiles showed no differences from placebo. The propensity of aripiprazole to increase agitation and akathisia may be problematic in older people for whom anxiety/agitation is part of the clinical presentation, and in such cases an alternative antipsychotic with more sedative properties, e.g. olanzapine, may be preferred.

Historically lithium has been the most frequently used augmentation agent. There is evidence to support this, though mainly from smaller, lower-quality studies (Crossley et al., 2007), including replicated evidence of benefit in late-life depression (Cooper et al., 2011). However, lithium has well-recognized adverse effects and it is not clear what serum level of lithium is appropriate for augmentation. Generally, in older adults one should aim for lower lithium doses and lower serum levels of around 0.4mmol/L, but this is mainly driven by a desire to avoid or minimize adverse effects rather than by empirical evidence. Older patients appear especially susceptible to lithium side-effects with one study reporting polydipsia (50–74%), polyuria (25–58%), tremor (33–58%), and dry mouth (53%) as the most frequent adverse effects, but a worryingly large percentage (11–23%) developed lithium toxicity (Foster, 1992). In the author's experience, tremor can be particularly problematic and disabling and although dosage reduction often helps, in some cases it prohibits continued use of lithium. Lithium augmentation has become less popular, probably because of the extra effort involved in monitoring and these concerns about toxicity, and because of the development of additional classes of antidepressants encouraging combination strategies ahead of augmentation. One well-designed study has examined 'augmentation' in late-life depression, though since the 'augmentation' agents used included nortriptyline and bupropion (as well as lithium), it really assessed both combination and augmentation. These second-line treatments were added to paroxetine (combined with IPT) and encouragingly an extra 20% (over half those receiving 'augmentation') then achieved recovery (Dew et al., 2007). The cholinesterase inhibitor donepezil has also been studied as an augmentation strategy in late-life depression, though only as an add-on in the maintenance phase. Unfortunately, it was found that, while donepezil produced some modest and transient improvements in cognition, its use was associated with a significantly higher relapse rate (Reynolds et al., 2011). Methylphenidate has also been investigated in a complex study when it was added to citalopram (Lavretsky et al., 2015). Augmentation with methylphenidate produced possible modest improvements compared with monotherapy, but interpretation of the findings is difficult due to the absence of a placebo arm.

Depression in older people

Beyond augmentation and combination with single agents there are options of adding in other augmentation and antidepressant agents. Evidence from the STAR-D study suggests, as might be expected, a law of diminishing returns applies as more treatments are added, but that remission can be achieved in about 80% (Menza, 2006), with similar results in studies of late-life depression alone (Cooper et al., 2011). However, this does leave 20%, a considerable proportion, who remain unwell, and in such treatment-resistant subjects it is prudent to revisit the diagnosis, considering for example the extent to which persistent symptoms may be related to a physical illness or a personality disorder. At this point ECT should also be considered, if it has not already been employed earlier due to severity and persistence of depression. After soliciting a second opinion, the more exotic stimulation and surgical treatment options might be investigated.

Continuation and maintenance treatment

Once remission is achieved the clinical issue becomes keeping the patient well. It is clear that in a first episode of depression the successful treatment should be continued (Geddes et al., 2003). Since the risk of relapse is highest in the first six months this continuation treatment should be for at least six to nine months for a first uncomplicated episode from when they achieve remission, and for at least in year in other situations (Cleare et al., 2015). In younger adults, maintenance treatment (that is, continuation of antidepressant treatment beyond this continuation phase) is not recommended after a single episode of depression, but the situation is different for older adults. Full-dose maintenance treatment is effective, with evidence supporting its use up to three years. Several of the key studies have specifically been conducted in late-life depression and a meta-analysis of eight double blind trials reported the number needed to treat to prevent one additional relapse or recurrence to be only three (Kok et al., 2011).

These maintenance studies highlighted that, even in those with a first episode of LOD, the risk of relapse after treatment is stopped is very high—an important issue familiar to those working with older people with depression. When one cohort of such LOD patients was followed-up when treatment was stopped after two years, over 60% had a further episode in the following two years (Flint and Rifat, 1999). When considering maintenance treatment, the impact of another depressive episode should be weighed, and in older people with relatively few remaining years the impact is disproportionately high. The consideration in younger adults about exposing someone for many years to unnecessary antidepressant treatment does not apply. Thus, in general, even when someone has a first episode of LOD, they should be put on maintenance treatment and, by extension, so should all people with late-life depression. As evidence from studies of major depressive disorder shows, the important caveat to this is that for those with less severe depression who have received antidepressants, such long-term use might not be warranted.

Depression in older people

When planning continuation (and especially maintenance treatment) education of the patient and significant others about illness and the risk of future relapse is crucial. Many older patients are reluctant to take medication, especially antidepressants, and many stop taking the medication when they feel well. Thus, discussing the impact of the illness, the benefits of antidepressants, explaining the high risk of relapse, and how this risk can be substantially reduced by taking antidepressants long-term is vital. By engaging the patient in managing the illness we can maximize the likelihood of long-term adherence to treatment.

Most of the literature has examined maintenance pharmacotherapy, but two major studies have examined interpersonal therapy (IPT), both alone and in combination with maintenance drug treatment, for maintenance in late-life depression. Monthly IPT was reported in the first study to reduce relapse rates compared with routine follow-up, and combined IPT and nortriptyline was even more effective (Reynolds et al., 1999). However, the second study, involving the same design but substituting paroxetine for nortriptyline, found no benefit of IPT alone or in combination in the maintenance phase (Reynolds et al., 2006). It is worth noting, however, that this second study was on patients who on average were about ten years older and included a significant proportion with LOD, which may have reduced the potential benefit from IPT.

Depression in the context of other illnesses

Depression is highly prevalent in association with physical illness in general and with specific (brain) disorders, e.g. PD, in particular. The difficulty diagnosing depression as a separate entity when other illnesses are present was discussed earlier. Antidepressants are frequently prescribed in such circumstances in spite of the diagnostic difficulties, but evidence supporting their use in such situations is limited. An analysis of one large maintenance trial in outpatients reported that a high burden of physical illness predicted a higher depression recurrence rate (Reynolds et al., 2006) and this also applied to augmentation (Dew et al., 2007).

Depression in dementia is frequent and major issue and different classes of antidepressants have been tried in several clinical trials. However, these trials were often of poor quality and conducted in small numbers of subjects. Thus, while systematic reviews found no evidence of benefit from using antidepressants, these conclusions were recognized to be subject to a type 2 error. But two large studies found no benefit from using antidepressants in people with depression in the context of dementia. DIADS-2, a multicentre US randomized trial of sertraline 100mg versus placebo in depression in AD, found no evidence of improvement in symptoms, response rates, or remission rates on sertraline at either 12 weeks (Rosenberg et al., 2010) or 24 weeks (Weintraub et al., 2010). Furthermore, those on sertraline suffered a higher frequency of adverse effects. The UK SADD study was a nine-month randomized study at nine centres across England and compared

Depression in older people

sertraline, mirtazapine, and placebo for depression in dementia; it also reported no evidence of benefit from either antidepressant but an increase in adverse effects on medication (Banerjee et al., 2011). These findings strongly caution against the widespread use of antidepressants for depression occurring in people with dementia. However, these studies necessarily did not include people with more severe depression, including those at significant suicide risk, for whom antidepressants might still be appropriate; this is especially the case if there is a previous history of major depression.

Studies of antidepressants in stroke disease have reported evidence of efficacy but this is offset by an increase in adverse effects in those on antidepressants (Hackett et al., 2008). Thus, the clinician needs to carefully weigh up the potential benefits, determined by the severity of the current depressive episode and the history of previous episodes of depression and their response to treatment, with these risks of adverse events. Three randomized trials of psychotherapy in post-stroke depression found no evidence of benefit on any outcomes (Hackett et al., 2008). SSRIs are the most appropriate antidepressant to use in post-stroke depression, not only because the best evidence from trials is for this drug class, but also because they have been demonstrated to be safe to use in people with coronary heart disease and, by extension, vascular disease more broadly (Glassman et al., 2002). As with the management of major depressive disorder, the key issue is when to initiate such treatment, given the need to balance exposure to predictable adverse drug effects with potential benefits on mood. Again, when depressive symptoms are not severe or persistent it seems prudent to withhold medication as the risk/benefit ratio is likely to be unfavourable, and because spontaneous remission is common in this group. Conversely, if a post-stroke depression is severe or persistent then SSRIs should be initiated, closely monitored, and titrated to achieve maximum effect.

Post-stroke emotionalism is often confused with depression. Here, people with stroke disease have outbursts of tearfulness, or more rarely euphoria and laughter, which are triggered by insignificant emotional stimuli or no apparent stimuli. Unlike depression, the mood changes are rapid and typically not associated with the appropriate subjective emotional experience, e.g. they don't feel sad while crying. Although not well characterized or recognized in psychiatric classifications, it is a frequently encountered clinical problem and antidepressants have been studied in small trials. Overall, all classes of antidepressants seem to produce significant benefits, which typically occur more rapidly than with response in depressive disorders (Hackett et al., 2010).

There have also been few studies investigating the benefits of treatment of depression occurring in PD. As with early studies in depression in dementia, the few studies have been small and produced equivocal results. The Cochrane review reported no evidence of benefit from CBT or ECT and equivocal evidence for antidepressants (Ghazi-Noori et al., 2003). However, this was based on three small antidepressant trials and

Depression in older people

since this, two larger studies have been reported. The first, in 52 subjects, found nortriptyline to produce larger improvements in depression symptoms than either paroxetine or placebo over eight weeks (Menza et al., 2009). The other in 287 people found pramipexole produced a statistically greater, but clinically unimportant (<2 point difference), improvement on the Beck Depression Inventory at 12 weeks than placebo. But there were no differences on the Geriatric Depression Scale and of note is that depression was defined as having a low GDS score of only >5 (Bxarone et al., 2010). Currently it is not clear whether antidepressants or antiparkinson's treatments produce significant clinical benefits for people with depression in PD.

Prevention of late-life depression

Since depression is so highly prevalent there has been increasing interest in preventing the development of depression, including late-life depression, in the first place (Beekman et al., 2010; Cuijpers et al., 2008). Unsurprisingly, strategies aimed at the general population (universal prevention) do not appear effective (Beekman et al., 2010), but those targeting older people with subthreshold depressive symptoms do reduce the development of depressive and anxiety episodes at both one year (van't Veer-Tazelaar et al., 2009) and two years (van't Veer-Tazelaar et al., 2011). Targeting high-risk individuals (those living alone, having two or more chronic illnesses, significant anxiety symptoms, lack of mastery over their environment) also appears to reduce the development of depressive syndromes (Smits et al., 2008). With both 'high risk' and 'subthreshold' groups, depression was reduced in primary care settings by 'watchful waiting' followed by bibliotherapy, problem-solving therapy, and, if necessary, medication. A review of nonpharmacological approaches to depression prevention suggested modest effectiveness with a NNT of 20 (van Zoonen et al., 2014).

Prognosis in late-life depression

In contrast to outcome findings from research, which are based on aggregated data from follow-up studies on cohorts of patients, the clinician is usually asked to predict the prognosis for a *specific* patient with his *unique* combination of individual characteristics. Such a transformation requires combining a knowledge of the relevant research findings, familiarity with the specific patient's features, and the wisdom acquired from clinical experience; it is an area where such medicine-based evidence is especially required to modify the research-driven evidence. In theory, outcome data would come from both naturalistic studies of treatment-free patients and from treatment studies prospectively examining outcomes. In practice there is very little purely naturalistic data available and what was reported (e.g. Post, 1972), emanated from specialist inpatient units making it difficult to compare with later data derived from very different clinical settings.

Outcome of depression

Depression in older people

Reports from studies examining outcome comment on both the high mortality in late-life depression and the generally poor prognosis. For example, a meta-analysis of community depression in older people (mean age over 60) involving a total of 1,268 patients found that at two years after the index episode of depression, 33% were well, 33% were still depressed, and 21% were dead. The rest were classified as 'other' and appeared to represent a poor outcome group, including people who developed dementia and had only partial remissions (Cole et al., 1999). Although most of the studies had weaknesses, the two largest and best executed studies reported similar findings (Copeland et al., 1992; Kennedy et al., 1991). A more detailed prospective analysis of community depression over six years and including 14 assessments had more encouraging, though still poor, findings (Beekman et al., 2002), with 23% having persistent remission, 12% remission with recurrence, 33% a chronic-intermittent course, and 33% had chronic depression. They also reported that outcome was related to baseline diagnosis with sub-threshold depression having the best outcome, major depression and dysthymia intermediate outcomes, and 'double depression' (major depression on top of dysthymia) having the poorest outcome. Older primary care patients with depression were found to have episodes lasting a median of 18 months and after one year of illness only 35% were well; by two years 60% and by three years 68%. Physical ill health and depression severity at baseline were predictors of poor outcome (Licht-Strunk et al., 2009), as was also reported by a longitudinal study in the Netherlands (Comijs et al., 2015). Bleak conclusions were also reached in another meta-analysis of elderly medical inpatients with depression (Cole and Bellavance, 1997a). At three months only 18% were rated as well, 43% were still depressed, and 22% were dead; by 12 months only 1% were well, 29% still depressed, and 53% had died. However, there are clearly difficulties in interpreting such data and distinguishing physical illness causes from any additional depression effect. A detailed analysis controlling for physical illness, comorbidity, and previous history of depression found no increase in mortality for those diagnosed as depressed during their hospital admission; this study also found that after taking these factors into account, pre-existing depression was associated with a reduced mortality (McCusker et al., 2006). For psychiatrists there is some encouragement from a third analysis by these authors reporting better outcomes in people with late-life depression who were seen by hospital psychiatric services (Cole and Bellavance, 1997b). This analysis of 1,487 patients in 16 studies followed for at least a year found 60% were either well or had relapses with good recovery, 14–22% were continuously ill, with the remainder again having poor outcomes such as death (ranging from 3% to 19% dead by twelve months) or developing dementia. Again, although many of the studies had weaknesses, the overall findings are similar to those in the larger and better executed studies in the analysis (Baldwin et al., 1993; Baldwin and Jolley, 1986; Burvill et al., 1991). While the mortality in medical inpatients is unsurprising (and is not clearly directly related to depression in any case) the poor outcome in community psychiatric patients compared with

Depression in older people

psychiatric secondary care patients is counter-intuitive as the former are expected to have milder forms of depression and thus better outcomes than patients referred to psychiatric services. This may reflect under detection and under treatment in the community with reports indicating only 20% (Cole et al., 1999) and 10% (Sharma et al., 1998) of depressed older people in the community receiving adequate treatment.

Subsyndromal forms of depression have a high conversion rate to major depression in older people—about 8% per year—and while having better overall outcomes than major depression, such conditions still remit by one year in only about 27% (Meeks et al., 2011).

That depression in older people is associated with an increased mortality has been long recognized, e.g. a threefold increase (Murphy et al., 1988), but is depression itself the cause of this? Several studies have investigated this question by following depressed older patients over several years and controlling for other risk factors. A Finnish study examined 813 subjects over five years and found 48% of those depressed at the beginning and end of the study had died, compared to only 26% who were never depressed, but those who were only depressed at baseline did not differ significantly (31% mortality) (Pulska et al., 1999). A four-year study from the Netherlands found those with major depression had a significant 1.83-fold increase in mortality, while only men with minor depression had a significant increase (1.80-fold) (Penninx et al., 1999). The same group reported similar findings in another cohort of 4,051 community-dwelling older people who were followed over six years (Schoevers et al., 2000). Survival analysis showed only men with 'neurotic' depression had a significant increase in mortality of 1.67-fold while both men and women with 'psychotic' depression (approximately major depression) had significant increases in mortality of about twofold. A US study following older people with broadly defined depression (20% had depression) over six years found a 24% increase in all-cause mortality in this depressed group after controlling extensively for other risk factors for mortality (Schulz et al., 2000). A ten-year prospective study in the Netherlands of 3,746 community-dwelling subjects with depression confirmed the increased mortality and reported a dose-response relationship, whereby more severe and more chronic depression was positively correlated with this increased risk (Schoevers et al., 2009).

Such studies uniformly confirm the high mortality associated with late-life depression, whether major or minor depression, and suggest men may have a higher risk; this increase seems to be due to depression itself, rather than confounding factors associated with depression. The strong relationship of depression to cardiovascular and cerebrovascular disease is likely to be an important factor in this relationship.

These findings would suggest that depression in older people has a poorer response to treatment than depression in younger adults and makes the findings from a review of this issue somewhat surprising. Reviewing 24 publications between 1996 and 2004 Mitchell and Subramaniam (2005) reported that depression remitted as frequently in

Depression in older people

later life but was associated with a higher relapse rate. This increased risk of relapse was linked to age at onset of depression, with EOD having a poorer outcome because of multiple episodes in earlier life, and medical comorbidity, which worsened prognosis and was linked to a later onset).

Prognostic factors

Box 39.4 summarizes several poor prognostic indicators recognized in late-life depression. The presence of such factors should not lead to under-treatment or pessimism, but rather should encourage a more vigorous approach to treatment. Unsurprisingly, physical illness burden (Azar et al., 2011; Reynolds et al., 2006; Baldwin and Jolley, 1986; Burvill et al., 1991; Murphy, 1983; Licht-Strunk et al., 2009), depression severity (Licht-Strunk et al., 2009; Azar et al., 2011; Reynolds et al., 2006), comorbid anxiety (Azar et al., 2011; Reynolds et al., 2006), and cognitive impairment (Cole and Bellavance, 1997b; Nelson et al., 2008) have been associated with a worse outcome in late-life depression and clinically significant cognitive impairment is strongly associated with an increased risk over the following few years of dementia (Alexopoulos et al., 1993a). The only other consistent predictors of outcome have been discussed earlier, namely ischaemic WMHs and executive dysfunction. WMHs and related white matter changes leading to increased diffusion are associated with a poorer response to antidepressants (Alexopoulos et al., 2002; Alexopoulos et al., 2008), poorer longer-term outcome and increased relapse rates (Hickie et al., 1996; O'Brien et al., 1998), and persistent cognitive impairment up to four years (Kohler et al., 2010b). Executive dysfunction predicts poorer response to antidepressants and increased relapse rates (Alexopoulos et al., 2000; Kalayam and Alexopoulos, 1999; Sneed et al., 2010).

Box 39.4 Poor outcome predictors

- Physical ill health
- Depression severity
- Chronicity of depression
- Presence of white matter hyperintensities
- Cognitive impairment (especially executive dysfunction)

Other factors examined do not seem to predict outcome. Once confounding factors have been accounted for, there appear to be no consistent differences due to sex or age. Depression severity and duration were reported in one study to predict poorer outcome (Murphy, 1983) but other studies have not replicated this (e.g. Baldwin and Jolley, 1986; Burvill et al., 1991). Murphy (1983) reported that adverse life events after

Depression in older people

the onset of depression predicted poor outcome, but Burvill and colleagues (1991) assessing this did not show the same results. Again, Murphy (1983) found the occurrence of adverse life events following the onset of depression had a particularly adverse effect on outcome, where Burvill and colleagues (1991) found no such relationship.

Conclusion

Depression in late life remains common and has a similar symptom profile to that in younger adults, but the elderly tend to have more psychosis and cognitive impairments. The relative contributions of the proposed aetiologies need to be more precisely defined. Although factors such as adverse life events and social isolation remain important, physical illness, vascular brain disease, and other subtle organic factors become important, too, especially for those with LOD. Antidepressants are as effective in the 'younger-old' (those without clinically significant cognitive impairments or physical illness) as in younger adults, but probably less so for those afflicted by such comorbidities. ECT remains an effective and safe treatment in the elderly. The evidence supporting benefits from specific psychotherapies is limited, though for the 'younger-old' they probably remain as useful as in younger adults and multifaceted interventions involving care management applications of several interventions appear highly effective. Continuation and maintenance use of antidepressants is effective in reducing relapse and should probably be used in all late-life major depression. Longer-term outcome is poor in naturalistic studies but much improved in treated patients. A high (two- to threefold increase) mortality is evident and depression is an important risk factor for subsequent dementia. All this highlights the need for careful detection and thorough assessment of depression in later life, combined with vigorous treatment and regular follow-up to monitor maintenance treatment.

Suicide and attempted suicide in older people

Chapter: Suicide and attempted suicide in older people

Author(s): Helen F.K Chiu, Baoliang Zhong, and Joshua Tsoh

DOI: 10.1093/med/9780198807292.003.0040

Introduction

Suicide rates vary considerably across age groups, genders, races/ethnicities, socioeconomic groups, residences (urban/rural), countries, regions, and over time (Chang et al., 2014; Ivey-Stephenson et al., 2017; Snowden et al., 2017; Värnik, 2012; World Health Organization, 2014). In most nations of the world, the risk of suicide increases with age, particularly for older men (WHO, 2014). The magnitude of this global public health challenge will escalate rapidly with the anticipated worldwide burgeoning of the older population. Another factor highlighted by some researchers is the cohort effect from baby boomers, who may have a higher rate of suicide than their predecessors entering old age after the first decade of the millennium (Conwell et al., 2002a; Phillips et al., 2010). This chapter first examines the scope of the problem and, from a public health perspective, addresses the risk and protective factors related to suicidal behaviours in late life, upon which evidence-based prevention and intervention ('postvention') measures might be mounted

Suicide and attempted suicide in older people

at accessible points along the suicide trajectory (Conwell et al., 2011). It reviews the available studies that have looked at possibilities for prevention of suicide in older people around the world.

Epidemiology and trends

Completed suicide

Geographical and demographic variations in suicide

In 2015, around 26% of the 0.8 million completed suicides in the world occurred in adults aged 60 years and above, with males being predominant (62.2%) (World Health Organization, 2016). Of those elderly suicide events, 45.3% and 15.9% took place in the WHO Western Pacific Region and South-East Asia Region, respectively. Considering nation states, China (34.9%), India (10.6%), United States (5.8%), Japan (5.0%), Russia (3.0%), and South Korea (3.0%) were the top six contributors to the total number of elderly suicide deaths worldwide (World Health Organization, 2016). According to the 2016 Global Burden of Disease Study (GBD) (Global Burden of Disease Collaborative Network, 2017), suicide rates in people 70 and over were generally lowest in North Africa and Middle East and Central and Andean Latin America, and highest in East Asia, the Asia Pacific region, and Sub-Saharan Africa.

In 2000–2015, the total number of global elderly suicides increased by 26.9%, which was mostly due to the substantial increase in the WHO Western Pacific Region and South-East Asia Region (Fig. 40.1). (World Health Organization, 2016).

Fig. 40.1

Total number of 60+ elderly suicide instances in the world, 2000–2015.

Source: data from World Health Organization, mortality estimates by cause, age and sex, globally and by region, 2000–2015, http://www.who.int/healthinfo/global_burden_disease/estimates/en/index1.html.

Suicide and attempted suicide in older people

Considering individual countries and regions, in 2013–2014, the suicide rate in adults aged 65+ was estimated to be 34.5 per 100,000 in mainland China, which was lower than South Korea (58.7) but higher than Taiwan (30.7), Japan (24.4), Hong Kong (21.0), Singapore (21.1), United States (17.2), Australia (12.0), United Kingdom (8.5), and Germany (21.4), when rates in these jurisdictions were standardized to the 2014 Chinese population (Zhong et al., 2016b).

Globally, rates of suicide for both men and women are generally higher in older than younger age-groups, and this is particularly evident in males (Fig. 40.2) (Global Burden of Disease Collaborative Network, 2017; Sachs-Ericsson et al., 2016; Zhong et al., 2016b). However, the pattern varies across countries. For example, in 2015, in the United States (US), Canada, and Australia, suicide rates peaked in mid-life for females and declined slightly thereafter (Global Burden of Disease Collaborative Network, 2017); or, in 2010, among Indian men in the US, suicide rates peaked in young adulthood, then declined progressively with age (Conwell, 2014).

Fig. 40.2

Rates of suicide in older people by quinquennial age-group and gender in the world, 2015.

Source: data from Institute for Health Metrics and Evaluation (IHME), Global Burden of Disease Study 2016 (GBD 2016) Results, 2017, <http://ghdx.healthdata.org/gbd-results-tool>.

Based on the suicide mortality data provided by the GBD 2016 and world population data provided by the United Nations (Global Burden of Disease Collaborative Network, 2017; United Nations, 2015a), the global suicide rate in people 60 years or older was estimated to be 22.2 per 100,000 in 2015, 32.1 in men and 13.7 in women, with a 2.3 male-to-female ratio. Worldwide, older men have a higher of suicide mortality rate than older women, but there are wide variations in the male-to-female ratios between countries (Alves et al., 2014; Shah, 2007): for example, 5.8 in the US compared to 1.4 in China (Zhong et al., 2016b).

Suicide and attempted suicide in older people

Time-trends

Adults aged 60 or above comprised 12% of the world's population in 2015 (United Nations, 2015b) but they accounted for 26% of the total suicide deaths, showing that suicides are over-represented in older adults. Furthermore, the proportions of elderly suicides within all suicide events increased from 22% in 2000 to 26% in 2015. In contrast, the proportions of suicide deaths occurring in young people (15–29 years of age) had decreased from 32% to 28% during the same period (World Health Organization, 2016). In some countries like China, the proportion of all suicide deaths occurring in people aged 65 or above had greatly risen from 17% in 1987 to 41% in 2014 (Zhong et al., 2016a).

Worldwide, the overall time-trend in elderly suicide rates is downward from 2000 to 2015 (Fig. 40.3) (Global Burden of Disease Collaborative Network, 2017).

Fig. 40.3

Rates of suicide in older people by quinquennial age-groups in the world, 1990–2015.

Source: data from Institute for Health Metrics and Evaluation (IHME), Global Burden of Disease Study 2016 (GBD 2016) Results, 2017, <http://ghdx.healthdata.org/gbd-results-tool>) +H86:K86.

Similar time trends have been ascertained in individual regions such as mainland China and Cuba (Corona-Miranda et al, 2016; Zhong et al., 2016a), but the changing patterns vary between countries, for example, the elderly suicide rates in Cuba increased with time before 1993 and declined thereafter while the rates in China remained stable before 1998 and dramatically decreased thereafter. In contrast, in South Korea suicide rates in people 70 or over significantly increased from 29.9 per 100,000 in 1990 to 99.5 in 2010 followed by a decrease to 89.0 in 2015. It is noteworthy that some major social changes can influence the time-trend in elderly suicide rates, for example, in Sri Lanka, the restrictions on the import and sales of WHO Class I toxicity pesticides in 1995 and endosulfan in 1998, are believed to have successfully reversed the upward trend before 1995 to a downward trend thereafter in elderly suicide rates (Gunnell et al., 2007). On the other hand, in 45 European and American countries, suicide rates in male older adults significantly

Suicide and attempted suicide in older people

increased in 2009 after the 2008 global economic crisis (Chang et al., 2013).

However, caution is necessary when comparing suicide statistics across countries. First, there is a lack of reliable surveillance systems in some low- and middle-income countries. Even for the WHO databank on mortality, there is scarce information on suicide data from some regions of the world (Beautrais, 2006). Second, for some countries like India, suicide statistics are collected from a small percentage of the population, which may influence the accuracy of the data. Third, there are variations in the practice of ascertaining a death as suicide in different countries. In countries with a coroner system, the extent of the use of 'open verdicts' and 'narrative verdicts' are likely to influence the number of deaths recorded as suicide. For instance, a narrative verdict may describe the circumstances of the death briefly without attributing the death to a category such as suicide (Carroll et al., 2012).

Cohort and period effects

Some authors have speculated that cohort effects (the ensemble of environmental factors that connote a certain generation and its relative size; see De Leo, 2002) may further accentuate suicide rates for older age groups in the foreseeable future (Conwell et al., 2002a). Higher suicide rates have been identified in the generations born in the fertile post-war decades in the US (Conwell et al., 2010) and in 18 European nations (Pampel, 1996), especially among men. Suicide rates tend to be higher in those age groups that comprise larger proportions of the total population, perhaps because of increased competition for scarce societal resources (Lindesay, 1991). However, because of different cultural influences, this cohort effect is unlikely to be universally applicable across countries (De Leo, 2002), and further studies are needed to examine the impact on trends in suicide rates at older age ranges. Period effects (e.g. from wars or major catastrophes experienced by the whole population at the same time) on suicide rates among older people are even less well understood. In Hong Kong, during the community outbreak of severe acute respiratory syndrome (SARS) in 2003, the older suicide rate in Hong Kong showed a sharp upturn from a previous downward trend, particularly in older women. It was postulated that factors such as the breakdown of social networks and limited access to healthcare might account for the findings: older women, because of their previous readiness to utilize social and health services instituted in the past decade, might have been more susceptible to the effects of temporary suspension of these socially supportive services during the epidemic (Chan et al., 2006).

Attempted suicide

There is very limited epidemiologic data on attempted suicide in old age, as, unlike completed suicide, there is usually no systematic registry for such events, even in the most developed countries. Attempted suicide is

Suicide and attempted suicide in older people

far less frequent in later life than among younger age groups (Mościcki, 1997, 2001). In adolescents, the ratio of attempted to completed suicide has been estimated to be 200:1. In contrast, there are estimated to be approximately four attempts for each completed suicide in later life (Conwell, et al., 2002a). Contributory factors to the increased lethality of self-harm behaviours in older people include higher levels of planning and resolve, the violence of methods used, diminished physical resilience, and greater social isolation (thus lower chance of timely availability of medical interventions), as well as potentially a reluctance to express or endorse suicide ideations (Conwell et al., 2002a). In a controlled retrospective study of older people completing suicide, those attempting suicide, and community controls, it was further shown that those completing suicide and hospital-treated attempters were largely overlapping populations and their acts were driven by very similar spectra of risk factors. This is different from the situation in younger counterparts, where major disparities have been found in sociodemographic factors and diagnoses (Tsoh et al., 2005). Furthermore, it adds to the evidence that in late life, preceding suicide attempt is among the strongest predictors for subsequent suicide (Beautrais, 2002; Waern et al., 2002a; Chiu et al., 2004; Conwell et al., 2010). Both findings show the need for high vigilance in the management of all cases of deliberate self-harm in older people.

Risk and protective factors for suicide in older adults

To understand and prevent suicide in older people, it is important to explore the related risk and protective factors from a public health perspective. Such factors are often identified through retrospective case-controlled 'psychological autopsy' (PA) studies. In PA research, information about suicide decedents is gathered retrospectively from relatives and other informants familiar with the decedents, as well as perusal of medical records (Hawton et al., 1998). Despite its limitations, such as its retrospective nature and the potential for reporting bias, case-controlled PA studies around the globe in the past 15 years have been striking in the consistency of the array of factors associated with suicide in older people (Harwood et al., 2001; Beautrais, 2002; Waern, et al., 2002a; Chiu et al., 2004; Conwell et al., 2010; De Leo et al., 2013) (see Table 40.1 for details).

Suicide and attempted suicide in older people

Table 40.1 Odds ratios (OR) for suicide for risk and protective factors in different domains that are statistically significant in case-controlled psychological autopsy (PA) studies of older adults.

IADL, instrumental activities of daily living (in the adapted version in Hong Kong, a lower score indicates worse functional level); LSNS, Lubben Social Network Scale; ns, not statistically significant; OTE, openness to experience.

Suicide and attempted suicide in older people

Other methods for ascertaining risk and protective factors of suicide include prospective follow-up studies of high-risk subjects (e.g. individuals with depression and those attempting suicide) and case-control studies of older people attempting suicide (as their profiles resemble those whose acts are fatal). The former are often limited by a low base rate of suicide and lack of statistical power to quantify the effect size of the putative risk factors. The latter are limited generally by the lack of systematic registries for suicide attempts. Nonetheless, these observational studies have indicated that suicidal behaviours in seniors are multi-determined. The following domains of risk and protective factors have been consistently identified: mental health, personality, physical diseases, social factors (e.g. network and support, life events), functional levels, and a range of miscellaneous others, including access to lethal means and neurobiological factors (Conwell and Thompson, 2008; Conwell, et al., 2011; Van Orden and Conwell, 2011; Conwell, 2014).

Mental health

In a systematic review of global data from controlled PA studies on suicide in older people, Conwell et al., (2011) reported that of all factors examined, psychiatric illness was consistently found to be most prominent: it is present in 71–97% of suicide cases, with affective disorder being the most common (with odds ratio (OR) of 48–185 in relation to community controls) and with major depressive disorders particularly implicated. However, in a controlled PA study, hopelessness, a pertinent depressive symptom, also stood out as a predictive factor (De Leo et al., 2013).

Psychotic disorders, including schizophrenia, schizoaffective disorder, and delusional disorder, as well as anxiety disorder, tend to be present in lower proportions of cases, unlike suicide investigations among younger populations. Furthermore, the prevalence of comorbid substance use disorder has been highly variable in these studies, although this might be related to the different rates of problem drinking in Oriental and western populations (Chiu, et al., 2004; Waern et al., 2002a; Conwell, et al., 2010, 2011).

Despite the prevalence of dementia in old age, it is infrequently diagnosed in completed suicide using the PA method, which is likely related to intrinsic methodological limitations, as the clinical picture of dementia, particularly in the early course, is less likely to be recognized by family members and other informants (Conwell et al., 2011). There are biological (Rubio et al., 2001) and epidemiological (Erlangsen et al., 2008) data that support the notion that dementia is associated with an amplified risk of suicide in late life. A recent systematic review focusing on Alzheimer's disease also echoes this finding (Serafini et al., 2016). Furthermore, a nationwide longitudinal study in Denmark of persons aged 50 and over found that in both genders, the diagnosis of dementia upon hospitalization was associated with a significantly elevated risk of

Suicide and attempted suicide in older people

completed suicide (especially in the first few years after the diagnosis was made) in the ten-year study period (Erlangsen et al., 2008).

A history of past attempted suicide is a significant risk factor for future completed suicide (e.g. Beautrais, 2002; Hawton and Harriss, 2006; De Leo et al., 2013; Jokinen et al., 2016). Chiu and colleagues (2004) found that almost one-third of older people in a Chinese community who died from suicide had a history of a suicide attempt, and that over 30% of these attempts had occurred within one week prior to the completed suicide. On the other hand, retrospective PA studies have indicated that nearly 75% of cases died on their first attempt (Chiu et al., 2004; Conwell et al., 2010), so effective public health strategies towards suicide prevention programmes must target both high-risk groups (e.g. those attempting suicide) and the general population, in accordance with Rose's theorem (Rose, 1985).

Both studies in the West (as summarized by Conwell et al., 2008) and the Orient (Chiu et al., 2004) indicate that, although the rate of psychiatric diagnosis is high, only a minority of decedents had consulted specialist psychiatrists before their fatal act. On the other hand, up to 80% had consulted a primary care doctor in the preceding month. In old age, depressive symptoms are often attenuated or expressed as physical symptoms and thus easily overlooked (Fountoulakis et al., 2003; Conwell and Thompson, 2008). These findings underscore the importance of screening for suicidal risk and depression, at the primary care level. A number of collaborative stepped-care management programmes targeting older primary care clients with chronic physical illness using algorithm-driven treatment of depression have shown that suicide ideation is sustainably reduced among the participants after completion of the programme, in addition to effective treatment of depression, for instance, the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT) (Alexopoulos et al., 2005, 2009).

Several ecological studies have found an association between increased antidepressant prescription and fewer completed suicides based on national registry and population statistics, which points to the possibility that antidepressant use may be associated with a reduced risk for completed suicide at a population level (Henriksson and Isacson, 2006; Bramness et al., 2007). Such an association was also found in senior populations in Australia (Hall et al., 2003) and the UK (Shah and Lodhi, 2005), although causality is difficult to conclude in this type of study design.

Personality

Personality is a relatively under-researched domain in suicide studies among older people. Among the controlled studies, Harwood and colleagues (2001) reported that levels of anankastic (obsessional) and anxious traits significantly distinguished suicide from natural deaths, though personality disorder per se did not. Utilizing the NEO Personality

Suicide and attempted suicide in older people

Inventory (Costa and McCrae, 1992), Duberstein and colleagues (1994) found that of the five domains of personality measured (neuroticism, extraversion, openness to experience (OTE), agreeableness, and conscientiousness), high neuroticism and low OTE distinguished a group of individuals older than 50 years who completed suicide and an age- and gender-matched living comparison group. Low OTE was associated with reduced affective and hedonic responses, a reduced range of interests, and a strong preference for the familiar (Duberstein et al., 1994).

Both low OTE and the similar attribute of anankastic personality traits (as described by Harwood et al., 2001) might render older individuals more vulnerable to a negative impact from the challenges of ageing and thus an escalated risk for suicide when stressors arise. The findings on OTE and neuroticism were replicated in a study on Chinese older suicide attempters (Tsoh et al., 2005). In the same study, it was also found that, compared to community controls, suicide decedents were less extraverted, less agreeable, and less conscientious. Furthermore, when those completing and attempting suicide were compared, it was found that the former group was distinguished by their higher conscientiousness, agreeableness, and lower neuroticism. These attributes might contribute to a higher chance of people attempting suicide succeeding in their self-harm act, and/or might render their emotional distress less easily noticed by their relatives (Tsoh et al., 2005). Psychometric screening for early detection of impulsive behaviour and suicide proneness in susceptible groups of older people has been suggested to hold promise for shaping future prevention strategies (De Leo, 2002).

Physical health and functioning
