Several case-controlled PA studies have examined the independent relation between common physical illnesses and suicide in older people. A study conducted in Sweden (Waern et al., 2002b) revealed that visual impairment, neurological disorders, and malignant disease were associated with elevated risk for suicide. A Canadian study also reported that chronic obstructive pulmonary disease (COPD), congestive heart failure, and seizure disorder were significantly associated with suicide in older people, and that their effect was cumulative (Juurlink et al., 2004). Studies conducted in Hong Kong (Chiu et al., 2004; Tsoh et al., 2005) found that COPD, arthritis, bone fracture, and malignancy were associated with completed suicide, and that stroke, bone fracture, arthritis, and malignancy were associated with attempted suicide. A population-based case-control study in the US found malignancy was independently predictive of completed suicide, especially in men (Cole et al., 2014). A ten-year prospective multisite study conducted in the US found that bone fractures were associated with suicide in older people (Turvey et al., 2002). Another 16-year longitudinal study performed in Australia showed that the predictive effects of major physical disorders were cumulative (Almeida et al., 2016). However, with the base rates of physical illnesses being very high in the older population, the usefulness

Suicide and attempted suicide in older people

in identifying individual older people who need intervention might be compromised (Conwell et al., 2011), with the possible exception of malignancies.

Conwell and colleagues (2010) also suggested that beyond individual physical illness, the perceived meaning of the illness burden and its impact on function, and limitations on autonomy and personal integrity, should not be overlooked. This is supported by case-controlled PA studies that showed that the presence of any impairment in instrumental activities of daily living (IADLs) was significantly associated with suicide case status (Conwell et al., 2010) and attempted suicide status (Tsoh et al., 2005) independent of the effects of physical and mental health disorders. Furthermore, a recent review of 45 studies from different nations that examined the relation between suicidal behaviours and functional impairment in middle-aged and older adults also confirmed the strong mutual associations (Lutz and Fiske, 2018).

Social factors

Social factors related to suicide in older people can be broadly classified into stressful life events, erosion of social support and connectedness (Conwell et al., 2011), perceived financial difficulties, and religious/spiritual factors.

Life events are often implicated as antecedents to suicide attempts and completed suicide in older people. Events related to physical illness, hospitalization, familial discord, interpersonal problems, retirement, bereavement, and social isolation are more typically associated with suicidal behaviour in later life (Heikkinen et al., 1995; Harwood et al., 2006). The association between stressful life events and completed suicide might be mediated through other risk factors for suicide, particularly depression. A case-control PA study in New Zealand (Beautrais, 2002) found that serious relationship and financial problems distinguished older people completing or attempting suicide from controls. The finding of a particular potency of familial discord has been replicated by other case-control PA studies in Sweden (Rubenowitz et al., 2001), the US (Conwell et al., 2010), and Hong Kong (Chiu et al., 2004; Tsoh et al., 2005).

Bereavement from the death of a spouse is a relatively common stressor in late life and is associated with elevated suicide risks after the acute event (e.g. Harwood et al., 2006; Ajdacic-Gross et al., 2008). On the other hand, widowhood per se is not uniformly identified to be a risk factor. A number of studies in Europe and Australia have found an increased suicide risk in widowers (Yip, 1998; De Leo et al., 2001; Corcoran et al., 2009); however, the reverse is true for older Chinese women in Hong Kong and Taiwan (Yip, 1998; Yip et al., 1998; Yeh et al., 2008). Furthermore, a study on all older suicide events between 1987 and 2005 in Switzerland found that, for both genders, the risk of suicide is elevated in the first week after bereavement; the risk then remains elevated for

Suicide and attempted suicide in older people

men but virtually vanishes after the first week for women (Ajdacic-Gross et al., 2008). These intriguing findings deserve further study. Stress arising from care given to a spouse with chronic illness has been consistently identified in studies from the US (Cohen et al., 1998; Karch and Nunn, 2011) and Australia (Milroy et al., 1997) in homicide-suicide cases. This is alarming, given the rapid rise of numbers of people with dementia due to population ageing.

Concerning social support, a case-control PA study conducted in New Zealand found that a low level of social interaction was an independent risk factor for suicide, after adjusting for physical and mental health variables (Beautrais, 2002). Similarly, a more recent case-control PA study in Australia reaffirmed that living alone was an important predictor of suicide in older adults (De Leo, et al., 2013). Furthermore, Turvey and colleagues (2002) found that an increase in the number of confidants was associated with a significantly reduced suicide risk in older adults.

The role of financial difficulties in older people's suicide is relatively under-researched. In PAs that have explored this factor, financial problems were present in around 13-19% of the suicide decedents (Heikkinen et al., 1994; Rubenowitz et al., 2001; Beautrais, 2002; Chiu et al., 2004; Tsoh et al., 2005). The results in controlled studies have been divergent. In the studies by Rubenowitz and colleagues (2001) and Beautrais (2002), monetary problems distinguished older people completing suicide from community controls, and Conwell and colleagues (2010) also found lower annual income (less than US \$35,000) distinguished the groups. However, such findings were not replicated in the controlled studies in Hong Kong (Chiu et al., 2004; Tsoh et al., 2005). Furthermore, in multivariate analyses, financial factors exerted no independent effect in the aforementioned studies by Rubenowitz and colleagues (2001) and Beautrais (2002), or in that of Conwell and colleagues (2010). It is therefore likely that the influence of this stressor is mediated through independent factors such as depression. However, generalization from these studies is limited by the particular socioeconomic contexts in which they were conducted (e.g. the variable extent of welfare provisions for retired individuals). Financial factors may also act at the societal level for instance, a study by Shah and colleagues (2008), found that among the 87 global nations studied, elderly dependency ratios (EDR) were positively correlated with older suicide rates. This is of concern, given the fast pace of worldwide population ageing, especially in developing countries where income protection for senior citizens is more likely to be limited.

Research studies examining the possible influence of religious and spiritual factors on suicide in older people are also sparse, despite their potentially profound roles in the maintenance of emotional health and coping with stress. In this domain, we should differentiate between studies that examine the salience of religion towards an individual (or 'religiousness') and those that have looked at the effect of affiliation to a specific religious denomination or particular set of spiritual beliefs. For

Suicide and attempted suicide in older people

the former, in a controlled study on persons aged 50 or over in the US, Nisbet and colleagues (2000) found that among 584 suicide cases, participation in religious activities was probably associated with a lower risk of completed suicide. The odds for having never participated in religious activities were greater among people dying by suicide compared with those dying from natural causes, even after adjustment for sex, race, marital status, age, and frequency of social contacts. In a controlled PA study and a controlled study on older suicide decedents and people attempting suicide in Hong Kong (Chiu et al., 2004; Tsoh et al., 2005), both studies found that those who considered religion as salient in their life had a fivefold reduction in the odds for suicidal behaviours. Pargament and colleagues (2001), Van Ness and Larson (2002), and June and colleagues (2009) have reported a generally protective effect of religiousness on mental health in older Americans, possibly by way of conferring stronger reasons for living, which generally help to counter suicidal behaviours. Furthermore, a recent meta-analysis of studies around the world concluded that the protective effect of religiosity against completed suicide is stronger in older populations (OR = 0.42, 95% CI: 0.21–0.84) (Wu et al., 2015).

Conwell and colleagues (2011) have postulated in a review article that religious and spiritual factors may be an important intrinsic constituent to the construct of social connectedness, and persons with low social connectedness are exposed to higher risk of self-destructive behaviours. However, there is also new evidence that religiousness might impart independent protective effects beyond general social connectedness (Rasic et al., 2009). Moral and religious objections to suicide are reported to be associated with less suicidal behaviour in people with depression, and are proposed to act as a protective factor against suicidal behaviour (Lizardi et al., 2008). This has been described specifically for populations with predominantly Islamic faith (e.g. Kok, 1988), so it is a surprising finding that, cross-nationally, there are significantly higher suicide rates in older men in Catholic countries compared to rates in other countries, with a trend for similar findings among women, despite the condemnation of suicidal acts attributed to Catholicism (Pritchard and Baldwin, 2000). Studies on negative religious coping or 'religious struggles' in older persons (e.g. those with thoughts of illnesses being signs of abandonment or punishment from God) might potentially illuminate this apparently paradoxical finding (e.g. Pargament et al., 2001).

On the other hand, in Oriental belief systems, delineation of religious denominations is much less clear-cut than the West. For instance, traditional Chinese religious beliefs have blended in heritages from Buddhism, Taoism, doctrines of Confucianism, regional folk religions, and ancestor worshipping (Cohen, 1992; Goossaert, 2005; Chamberlain, 2010). Moreover, collectively in traditional Chinese beliefs, ancestral spirits are commonly thought to dwell in a different world and as potentially imparting positive influences on filial descendants. Thus, during a perceived crisis, death may merely mean a different form of

Suicide and attempted suicide in older people

existence, or even an avenue to solve the many impasses in this life through reincarnation (Goodrich, 1991; Phillips et al., 1999). This could be a reason underlying the apparent weaker protective effect of religion against suicide in the Orient as compared to the West from the above-mentioned meta-analysis (Wu et al., 2015). Further studies in this area are obviously important, and hopefully methodological advances will help to disentangle these complex factors, leading to better interpretation of the data and application of the findings in evidence-based prevention programmes.

Other possible factors

Access to lethal means

Older adults are generally more ready to use more violent and potentially lethal methods for suicide attempts than younger age groups (Conwell et al., 2011). The prevalence of different methods of suicide varies with the availability of lethal means across different sociocultural contexts. For instance, the use of a firearm is the commonest method of suicide by older men in the US (Conwell and Thompson, 2008); in the UK, suicidal older men mostly die by hanging and women by drug poisoning (Cattell, 2000); in Hong Kong, the most common methods of suicide in older people are jumping from a height or hanging, while less violent methods (e.g. asphyxia from charcoal burning, an increasingly common method in Asian Pacific cities) are infrequent among older people (Chiu et al., 2004; Chan et al., 2009). In rural China, the commonest method in older people is ingestion of organophosphate pesticides or rat poisons, followed by hanging (Li et al., 2009).

Conwell and colleagues (2002b) found in a controlled PA study in the US that the presence of a firearm in the home was associated with a twofold increased risk for suicide, even after controlling for psychiatric illness. Measures to restrict access to lethal means have been demonstrated to have potential to lower overall suicide rates, especially where the method in question is readily available, with examples of success reported following coal gas detoxification in Switzerland and the UK, firearm restriction in Canada and Washington, DC, in the US (Mann et al., 2005), and legislations that limited the pack size of paracetamol and salicylates sold over the counter in the UK (Hawton et al., 2001).

In rural China, given the high rate of self-poisoning because of the easy availability of toxic substances (Li et al., 2009), the WHO has worked in recent years with Chinese governmental agencies to promote the use of safer products, as well as safer methods of storage (Chiu et al., 2012). There are now some pilot data showing that the use of 'boxes with a lock' for safe storage of pesticides in rural households is acceptable to the community in low-income countries (Konradsen et al., 2007), although further studies are necessary to examine the effectiveness of safe storage of pesticides in preventing suicide.

Suicide and attempted suicide in older people

Neurobiological theories

Several studies have reported that older people with depression who attempt suicide can be distinguished from controls without depression by their poorer executive functioning on neuropsychological profiling (King et al., 2000; Keilp et al., 2001; Dombrovski et al., 2008a,b). This could possibly translate into poorer problem-solving capabilities or a higher propensity for impulsive reactions in times of stress. In a community case-control study of adults aged 50 and over, clinical cerebrovascular risk factors were significantly higher among suicide decedents than among community-dwelling age- and gender-matched comparison participants, after adjusting for age, sex, depression diagnosis, and functional status (Chan et al., 2007). Similar findings were reported for older women attempting suicide in a controlled study in Hong Kong (Chan et al., 2014).

Reviews of neurotransmitter disturbances mostly point to possible age-related roles of the serotonergic, noradrenergic, and dopaminergic systems. For instance, in older people with depression, lower CSF levels of 5-HIAA were found in those who attempted suicide compared to those who had not (Conwell and Thompson, 2008).

To sum up, there are preliminary findings that late-life suicide is associated with disrupted neural substrates that might play crucial roles in impulse control, mood regulation, and cognition, and might represent important avenues for further understanding and prevention of self-harm behaviours in older people.

Protective factors

In contrast to the numerous studies on risk factors of suicide in older people, there is a relative paucity of studies on protective factors. The role of religious factors on suicide in older people has been examined earlier (see Social factors). Improving the social support to older people may be protective, as concluded in one study that found increased number of confidants associated with lower suicide risk in older people (Turvey et al., 2002). Two studies have attempted to improve resilience to modify suicidal behaviour risk. Lapierre and colleagues (2007) designed a programme for retired seniors based on a cognitive-behavioural approach. It consisted of an 11-week workshop and aimed to enhance meaning in the life of participants, and levels of depression, as well as suicidal ideas, were lower in the intervention group compared with the control group. The other study by Heisel and colleagues (2009) consisted of a 16-week interpersonal psychotherapy programme for older adults at increased risk of suicide to improve their social functioning so as to increase social support and satisfaction. There was a reduction of depressive symptoms and lower scores on the Geriatric Suicide Ideation Scale (Heisel and Flett, 2006) in the intervention group compared with the control group. Both of these studies are preliminary studies, but the results are encouraging.

Suicide and attempted suicide in older people

Prevention and intervention ('postvention')

Suicide prevention interventions are usually classified as: universal (targeting the entire population), selective (targeting symptomatic or pre-symptomatic individuals or subgroups who have distal risk factors for suicide, or who have a higher-than-average risk for developing mental disorders), or indicated (targeting individuals who have detectable symptoms or other proximal risk factors for suicide) (Conwell and Thompson, 2008). Examples of universal measures include restriction to the means for self-harm, promotion of healthy ageing, and de-stigmatization of mental illness. Improved access to rehabilitative care to promote functional independence in individuals with chronic medical conditions could be a selective measure for suicide prevention. Enhanced screening for depression, availability of effective treatment of this condition, and adequate follow-up of people attempting suicide ('postventions') are examples of indicated measures (Conwell and Thompson, 2008). A systematic review of suicide prevention strategies has found that the most promising interventions are physician education, means restriction, and gatekeeper education, while other methods (including public education, screening programmes, and media education) need more research (Mann et al., 2005).

To be effective, suicide prevention programmes must take into account the known barriers to suicide prevention, which include the following:

Older people completing suicide are more determined in their acts, plan their attempt with greater resolve, and display fewer external warnings of their intent compared to other age groups (Conwell and Thompson, 2008).

Older adults are less willing to communicate their suicidal intent compared with younger people (Scocco and De Leo, 2002).

The difficulty of timely identification of affective disturbances by non-psychiatrist physicians when older people present with multiple somatic complaints (e.g. Heikkinen and Lonnqvist, 1995).

The unwillingness of older people to seek specialist psychiatric care (and limited accessibility to such care in some nations), especially in the oldest-old population (aged 75 or over), despite the high rate of psychiatric morbidities in people who complete suicide. However, it should be borne in mind that most have seen a general practitioner in the month before their suicide act (e.g. Chiu et al., 2004; Conwell et al., 2011; Cheung et al., 2017; Szanto et al., 2001).

The therapeutic nihilism of some doctors towards older patients with depression (e.g. Uncapher and Arean, 2000).

Therefore, it has been recommended that effective and comprehensive prevention programmes should adopt a multicomponent approach, with a combination of universal, selective, and indicated interventions (Mann et al., 2005; Erlangsen et al., 2011).

Suicide and attempted suicide in older people

Recent large-scale suicide prevention strategies in older people have adopted multifaceted or multi-layered approaches, with particular attention to mental health. The Telehelp/Telecheck service operated in Padua, Italy, and provided telephone-based outreach, evaluation, and support services to older people who were isolated and functionally incapacitated. When assessed by De Leo and colleagues (2002) over a decade later, a reduction of suicide rates among women was identified. Oyama and colleagues reported that five to ten years after the launching of a programme in rural Japan that combined universal, selective, and indicated preventive interventions, the relative risk for suicide in older adults had dropped, with an especially significant reduction (64–76%) in the risk for suicide in older women (Oyama et al., 2005, 2006). Furthermore, in Hong Kong, the Elderly Suicide Prevention Programme (ESPP) was launched territory-wide in 2002. The initiative adopted a two-tiered, multifaceted, case-management model that offered prioritized and intensive treatment of depressed or suicidal older people referred from primary care providers or other medical disciplines over a period of at least six months. An evaluation study suggested that the programme was associated with a reduced suicide rate in women aged 85 and over in the population, relative to the pre-intervention period (Chan et al., 2011).

A systematic analysis of suicide prevention studies in older adults found that most of the described interventions aimed to reduce suicide risk factors, such as depression screening and treatment (Lapierre et al., 2011). Most studies found an effect on reducing suicidal thinking and the suicide rate in older adults, but the programmes showed most benefits in women. The authors suggested that strategies should aim to improve resilience, involve community gatekeepers, use telecommunications to contact vulnerable older adults, and evaluate the effects of means restriction and physician education on suicide in older people (Lapierre et al., 2011). A more recent systematic review of 21 available controlled intervention programmes around the globe to prevent suicidal behaviours and reduce suicidal ideation in older people revealed that there was supportive evidence for the effectiveness of multifaceted, collaborative primary care based depression screening and management programmes, treatment interventions with pharmacotherapy, telephone counselling for vulnerable older adults, and multi-levelled community-based programmes incorporating education, gatekeeper training, depression screening, group activities, and referral for treatment. Of these, findings were most robust for the collaborative primary care based program on reduction of suicide ideation in older adults. On the contrary, the evidences for programmes solely based on psychotherapies using cognitive behavioural therapies (CBT) were deemed inconclusive. A multi-level community intervention addressed known suicide risk factors in older persons and while the results on reduction of rates of completed suicides were favourable, all of these were hitherto conducted in the Far East and their generalizability would be limited by differences in cultures and healthcare systems (Okolie et al., 2017).

Suicide and attempted suicide in older people

Given the important contributory roles of physical illnesses and functional impairments towards suicide risk in older people, models that better integrate mental health care into the care pathways for general medical conditions should be further explored (Szanto et al., 2013; Okolie et al., 2017; Lutz and Fiske, 2018). Likewise, future suicide prevention programmes should also better address adequate social supports for older persons in need, considering the high rates of social disconnectedness among suicide decedents (Conwell, 2014; De Leo et al., 2013).

Conclusions

Suicide prevention initiatives in older people have taken a great stride forward in the past decade based on better understanding of the risk and protective factors pertaining to this great public health challenge. For further improvements to take place, sustained and determined collaborations across clinicians, researchers, health administrators, and policymakers are needed, given the complex, multi-determined nature of suicidal behaviours, a daunting task in many nations for various reasons (De Leo, 2002).

Moreover, it is important to note that older men are generally at higher risk of suicide than women: in many countries, they use more lethal means in their suicide acts, they are more susceptible to the effects of bereavement and widowhood, and they have responded less favourably to the most recent comprehensive suicide prevention programmes. Further research on the gender differences of suicidal behaviours is urgently needed, to understand the different underlying psychopathological mechanisms, and to adequately address the healthcare needs of older men, the largest contributing group to completed suicide instances across the world.

Manic syndromes in old age

Chapter: Manic syndromes in old age

Author(s): Lauren Mussen and Akshya Vasudev

DOI: 10.1093/med/9780198807292.003.0041

Classification issues

Bipolar disorder (BD) is a chronic disease of abnormal mood and is characterized by episodes of either elevated mood or depression or, much less frequently, a mixed affective presentation of both elevated mood and depression. To satisfy a clinical diagnosis of BD there should be at least one hypomanic or manic episode, and the abnormal mood episodes (hypomanic/manic or depressed) should have a detrimental effect on the social and occupational functioning of the individual. Though the diagnostic criteria of this disorder are well demarcated in the younger adult population in both the ICD-10 and DSM-5 (WHO, 1992, American Psychiatric Association, 2013), the same cannot be said for BD in older people. The DSM-5 does not address age-related differences in presentation of BD. This may be because BD in older people is probably a heterogeneous illness, hence attempts to classify it remain controversial. In deference to this controversy, we choose the broader term of 'manic syndromes' in old age as the title of our chapter. We recognize that

Manic syndromes in old age

recently there are reasons to believe that it can be broadly divided into two main groups: the patients with late-onset bipolar disorder (LOB) and those with early-onset bipolar disorder (EOB), and we describe these in more detail later. Perhaps the most important evidence concerning differences between younger adult and older bipolar patients comes from genetic studies. Although bipolarity is strongly influenced by genetic factors in the younger adult population (Goodwin, 1990), there is less evidence of such a relationship in the geriatric population. In this chapter, we elaborate on differences between mania in younger adults and older people, between LOB and EOB, discuss aetiopathological findings, and offer suggestions for management.

Shakespeare (through Juliet) asks 'What's in a name? That which we call a rose by any other name would smell as sweet'. While it is true that reality matters, not the name used to denote it, the opposite is not the case; using the same name for different things does matter (Vasudev and Thomas, 2010). Since older people with LOB disorder seem to have a different symptom profile with a different epidemiology and different aetiologies compared with younger people, it appears 'bipolar disorder' may not be an appropriate name for this symptom constellation in older people.

Epidemiology and clinical presentation

There is evidence suggesting that the age of the patient as well as the age of onset of the disorder are two different variables that require consideration for a better understanding of the epidemiology of the illness.

Prevalence

Bipolar illness usually affects people by the age of 30 and it has been estimated that 90% of cases are younger than 50 years of age when they have their first episode (Hirschfeld et al., 2003). This implies that 10% of bipolar patients will develop their illness after the age of 50, and a study by Kennedy and colleagues (2005) did find that around 10% of a population sample had a first incidence of mania after the age of 60. In a more recent review of the literature, Dols and colleagues (2014) estimated that six patients out of every 100 admitted to a psychogeriatric unit were manic, and of those six, two to three were likely experiencing their first manic episode, irrespective of previous depressive episodes.

Data from epidemiological studies suggest that BD in the general adult population has a prevalence rate of around 1% in the community (Regier et al., 1993). This may be an underestimate. Evidence is accumulating that BD and schizophrenia illnesses are two ends of a spectrum and often there is an overlap of symptoms and progression (Laursen et al., 2009). Indeed, if screening tools like the Mood Disorder Questionnaire (MDQ) are used for estimation of prevalence, 4% of the population might be

Manic syndromes in old age

considered to have had a lifetime episode of hypomanic or manic symptoms (Hirschfeld et al., 2003).

In contrast, the prevalence and incidence rate of mania in old age in the community is not very well established. This is because methodological factors confound the data. Some of the concerns are inherent in identifying individuals with mania in the community as they are not readily amenable to interview or cooperation with surveys. Furthermore, the literature is limited by data drawing upon cross-sectional retrospective analyses, under-representing secondary mania due to somatic illness or medications, and deriving primarily from specialist centres, thus limiting generalizability to the community (Dols et al., 2014).

Epidemiological studies conducted in the older population in the community using strict diagnostic criteria have found prevalence rates varying from 0.08% to 0.25%. Other prevalence studies also suggest that the figure for lifetime prevalence of BD in older people in the community is around 0.1% (Weissman et al., 1988; Unutzer et al., 1998; Hirschfeld et al., 2003). The reasons for differences in prevalence rate between the general adult population (around 1%) and that in older people (as low as 0.1%) remains a matter of controversy and no epidemiological factors are obvious for the discrepancy. Some suggest the influence of a relatively high mortality rate from natural causes and from suicide, as well as evidence for 'burn out' of the disorder over a long-term course (Winokur, 1975; Snowden, 1991). These studies were, though retrospective in nature, reflecting the difficulty in following up patients with BD over their lifespan. More recent expert consensus, however, suggests a prevalence (conservatively estimated at 0.5–1% of older adults) approaching that observed in the younger population, as reported by the International Society for Bipolar Disorder (ISBD) Task Force on Older-Age Bipolar Disorder (OABD) (Sajatovic et al., 2015b).

In selected populations such as nursing homes (9.7%; Koenig and Blazer, 1992) and inpatients (varying from 8 to 10%; Depp and Jeste, 2004; a prevalence of 6% was found in a more recent review including 1,519 inpatients older than 50; Dols et al., 2014), there are significantly higher prevalence rates. The higher prevalence in such populations perhaps is a reflection of the course of the illness; when older individuals suffering from BD have an affective relapse they need higher levels of care and cannot be managed in the community.

Also, until recently, it was believed that BD had a bimodal frequency distribution with a peak of episodes in early adulthood and another peak in late life (Cassidy and Carroll, 2002; Kessing, 2006). However, this view has been challenged as data also suggest a unimodal frequency distribution with no such peak later in life (Almeida and Fenner, 2002; Kennedy et al., 2005).

Manic syndromes in old age

Age at onset

Epidemiological data are better defined in late-life BD with regards to the age of onset of the illness. It is thought that this variable helps distinguish the subtypes of mania and hence lead to an improved understanding of pathogenesis and aetiology (Young and Klerman, 1992; Leboyer et al., 2005). The older person with BD may be considered to be of two types (see Fig. 41.1). The first group may be referred to as LOB, with the first episode of the affective disorder occurring late in their life; most studies consider this to be greater than 50 years of age. The other group is EOB, who when older are 'graduates' with the disorder, having had the onset of the illness at a younger age (less than 50 years of age). The demarcation is useful as clinically these two groups are different.

Fig. 41.1

Conceptual framework for differentiating manic syndromes in old age based on age of onset of bipolar disorder.

It should be noted that, while the traditional consensus cut off age for LOB has been 50 years or greater, the first report of the ISBD Task Force on OABD proposes that some consideration be given to reducing the cut-off age to 40 years in order to provide a broader lifespan perspective (Sajatovic et al., 2015b).

It has been argued that EOBs have a high familial rate of BD, while LOBs do not show this pattern consistently (Depp and Jeste, 2004). Others find a similar rate of family history between LOB and EOB (Motes et al., 2013). The estimated rates of familial penetrance in the older group per se vary between 24% and 88% (Glasser and Rabins, 1984; Shulman et al., 1992; Hays et al., 1998). The reason for this variation could be related to methodological issues such as the rigor of investigation and the criteria used for a positive family history of BD (e.g. whether only first-degree relatives are considered). Within the older group, it has been estimated that there is twice the familial penetrance rate in the EOB group compared to the LOB group (Stone, 1989; Hays et al., 1998). In an elegant review of the literature, Azorin and colleagues (2012) summarize the diverse conceptualizations of LOB, including LOB as a 'secondary' disorder to organic illness (especially right hemisphere lesions), as an expression of attenuated genetic vulnerability, and as 'Bipolar Type VI', the last of which follows Akiskal's spectrum concept of bipolar illness, with type VI representing a syndrome of mixed-labile-agitated episodes in

Manic syndromes in old age

the setting of dementia. It may be that a family history of any psychiatric illness is more prevalent in EOB, such as affective disorders, psychotic disorder, or substance abuse (Leboyer et al., 2005). In such cases and in addition to the genetic loading that comes with a family history of illness, the emotional distress of having an affected parent or other close family member could contribute to the triggering of an earlier onset (Thesing et al., 2015).

Clinical presentation and age of onset

There are no consistent differences between the clinical presentation in the young patient with BD versus the older patient, or between older patients with EOB versus LOB (Sajatovic et al., 2015b; Depp et al., 2004). This is not to say that differences in phenomenology have not been found, but findings across studies are not reliably present. For instance, using a cut-off point of 49 years, one study found the LOB group of older patients to have more psychotic features and more cerebrovascular risk factors (Wylie et al., 1999), whereas another study described more nuance in older patients, noting that the older cohort was more likely to have psychotic features as part of a depressive, as opposed to a manic, episode (Kessing, 2006). LOB patients have also been described to have fewer and milder manic symptoms compared to the EOB or the young manic patient and a tendency to have irritable mood rather than elated mood (Sajatovic, 2002). Further support for the idea of milder symptomatology comes from The National Network of Depression Centres Clinical Care Registry, in which later-life bipolar patients were found to have fewer and less severe depressive symptoms (Forester et al., 2015). In a recent longitudinal study comparing the outcome of LOB and EOB patients followed up after a manic or a mixed affective relapse, it was reported that LOB patients had a quicker remission of their illness and a greater proportion were discharged from an inpatient facility (Oostervink et al., 2009).

In terms of disease characteristics, older bipolar patients (EOB and LOB considered together) seem to have a larger time gap between a depressive episode and a manic one. In a prospective study (Jeremy and Robin, 1990), the mean time between the first episode of depression and the onset of mania was 17 years in the older group versus three years in the younger group. This study also found that, compared to their younger peers, older patients were more likely to have suffered three or more depressive episodes before their first manic episode. This result is not entirely concordant with the finding in another study, in which patients with LOB had significantly less of a delay from the time of symptom onset to a BD diagnosis (3.3 years) than patients who present earlier in age (18.6 years) (Montes et al., 2013), possibly due to a shorter time period from depression to onset of mania.

Interestingly, the older manic patient appears to be more likely to relapse into depression after mania. The older bipolar patients (>60, irrespective of age of onset) in the 24-month follow up of the large, prospective observational study, European Mania in Bipolar Longitudinal Evaluation

Manic syndromes in old age

of Medication (EMBLEM), also were significantly more depressed than the younger (<50) cohort, as measured by the Clinical Global Impression-Bipolar (CGI-BP) scale (Oostervink et al., 2015). The EMBLEM group also reported a greater proportion (40%) of older patients had a recurrence of an acute mood episode relative to the younger group (23%) over the course of the study. Furthermore, the older patients had a shorter time to recurrence (544.6 days versus 593.5 days), with recurrence defined as a relapse following remission. These results suggested to the EMBLEM group that, while remission may be easier to achieve in older patients, recovery is harder to maintain, possibly reflecting a higher cycle frequency in older patients. However, the two age groups did not differ significantly with respect to rates or time to remission and recovery. No difference was found between older EOB (first manic episode at age younger than 50 years) and LOB patients on any measure of recurrence or relapse, although a greater number of older LOB patients tended to achieve recovery (defined as functional recovery) than their peers of the same age group but with an early onset pattern of illness.

Some of these findings indicate that older people with BD have a different clinical pattern, involving more depression and possibly milder manic symptomatology, especially in the LOB group. This could be a reflection of differences in comorbidity, which we discuss next.

Comorbidities

Comorbidities may include psychiatric and physical disorders. BD in adult outpatients is often comorbid with various psychiatric conditions, formerly identified as axis I conditions, including lifetime and current substance use, anxiety, and eating disorders (McElroy et al., 2001). However, large-scale epidemiological studies such as this have tended to include younger adults as well as older people in the same group; in only *some* studies has subgroup analysis been attempted (for example, Kodesh et al., 2012). In a review of the literature, Lala and Sajatovic (2012) identified seven small cross-sectional or retrospective studies with bipolar patients older than 50, and found the most common concurrent diagnoses were anxiety and substance use disorders, albeit at a lower rate and with lower severity than in the younger cohort. Cassidy and colleagues (2001) found a lifetime substance abuse rate of around 29% in a subgroup of older bipolar patients. This contrasted with a substance abuse rate of around 48% in the younger adult bipolar population. Interestingly, the older bipolar patient tended to have more hospital admissions compared to the younger bipolar patient. In a more recent study, Goldstein and colleagues (2006) found the one-year prevalence rate in late-life BD highest for alcohol abuse (38.1%), followed by panic attack (11.9%), generalized anxiety disorder (9.5%), and dysthymia (7.1%). In a Spanish multicentre study of elderly outpatients with BD, Montes and colleagues (2013) reported current alcohol use disorder and tobacco use disorder as 15.9% and 11.6%, respectively.

Manic syndromes in old age

There are fewer data on the prevalence of personality disorders (formerly axis II conditions) in late-life BD. In a study on outpatients as well as inpatient populations of late-life affective disorders, 63% had a personality disorder based on their responses to a structured interview for personality. There was no difference in the prevalence rate between the depressed and the bipolar group (Molinari and Marmion, 1995). This is similar to a lifetime odds ratio of having an axis II diagnosis of 10.6 (95% CI 9.2–12.3) (equivalent to a percentage prevalence of 53% by imputation assuming 5% prevalence in the adult population) in the general adult bipolar population in a large community survey (Grant et al., 2005).

There are few large prospective and case-controlled investigations into medical comorbidities across the lifespan of bipolar patients. Data from the younger adult demographic suggests that, relative to healthy controls, bipolar adults have an increased risk of the following: early onset of cardiovascular disease (Goldstein et al., 2015; Hays et al., 1998); cerebrovascular disease (Subramaniam et al., 2007); diabetes mellitus, hypertension, cancer (Kodesh et al., 2012); neurological conditions (Shulman et al., 1992); overall burden of medical illness (Soreca et al., 2008); obesity (Goldstein et al., 2013); and premature mortality from general medical conditions (Roshanaei-Moghaddam and Katon, 2009). Whether this extends into old age is not firmly established, although some data appears to suggest that elderly bipolar patients are no more afflicted with illness than the general elderly population (Tsai et al., 2009; Gildengers et al., 2008a). This may reflect a ‘survivor effect’ in which EOB patients who graduate into old age represent a healthier subgroup relative to their cohort of a similar age of onset who may have died prior to reaching a geriatric age (Leboyer et al., 2012). An alternative explanation may include the bipolar elderly receiving more fragmented or inconsistent primary care, leading them to be potentially underrepresented in these studies (Rise et al., 2016).

One small Taiwanese study compared 59 euthymic bipolar I patients sixty years or older with age and education matched healthy individuals, and found that bipolar patients in their study had significantly *less* hypertension and lower mean systolic blood pressures than their non-bipolar counterparts (Tsai et al., 2009). Furthermore, the Taiwanese bipolar sample did not have greater estimates of cardiovascular morbidity relative to the general elderly population, despite having higher rates of diabetes. On average, elderly bipolar patients were found to have three to four comorbid medical conditions (Lala and Sajatovich, 2012). Research from the Bipolar Disorder Centre for Pennsylvanians Study has attempted to estimate other medical illness burden in patients with late-life BD (Gildengers et al., 2008). They found that patients 60 years of age or older with late-life bipolar had similar total medical morbidity, as measured by the Cumulative Illness Rating Scale-Geriatrics (CIRS-G), as age-matched unipolar depressed patients. Those with BD had a higher BMI and increased burden of endocrine/metabolic and respiratory disease

Manic syndromes in old age

as measured by the CIRS-G sub-scores. Because CIRS-G scores in late-life depression are increased compared with non-psychiatric controls, this study suggests the same is true for late-life BD, although direct comparisons are needed (Baldwin, 2008).

In a cross-sectional study of chronic non-cancer pain (for example: back pain, arthritis, chronic pain, migraines, neuropathic pain) in American veterans, bipolar patients, including over 58,200 aged 50 or above, were found to have a significantly greater likelihood of having any pain condition (OR = 1.85) than patients with schizophrenia (OR = 0.91), but significant less likelihood than patients with major depression (OR=2.3) (Birgenheir et al., 2013), which is an interesting finding that parallels the view that BD exists in the middle on a continuum between schizophrenia and unipolar depression.

Inflammation may be the mechanism by which the bidirectional relationship between psychiatric and medical illness is explained, and understanding BD as a multi-system inflammatory disease is gaining momentum as an explanatory model (see Leboyer et al., 2012; Sajatovic et al., 2013). Alternatively, longstanding lifestyle variables such as sedentary lifestyle, tobacco use, poor diet high in saturated fats, and obesity undoubtedly contribute to medical comorbidity in BD, as they do in any serious and persistent mental illness (Compton et al., 2006; Ward et al., 2015; Scott and Happell, 2011). To address whether medication use may be a factor in medical comorbidity as measured by rates of medical hospitalization, a large Canadian cohort study compared acute medical or surgical admissions to hospitals in late-life bipolar patients receiving lithium only, valproate only, or neither lithium nor valproate over one year following psychiatric hospitalization. (Rej et al., 2015). Interestingly, there was no significant difference between any of the groups in terms of time to medical hospitalization, reasons for acute medical hospitalization, medical outcomes, or medical comorbidity rates.

With regards to physical illness, a number of studies have shown an increased prevalence of neurological illnesses, as defined variously, but especially including dementia and cerebrovascular disease in patients with LOB (Depp and Jeste, 2004, Subramaniam et al., 2007, Shulman et al., 1992). A large longitudinal study confirmed that the elderly bipolar patient has double the odds of developing stroke compared to age matched controls over a period of six years (Lin et al., 2007), which appeared similar to findings in unipolar disorder (Thomas et al., 2004), although once cardiovascular risk factors were controlled for, this increased risk in BD became negligible in a study involving younger adult bipolar patients (Prieto et al., 2016).

In a similar vein, the context of poststroke mania, or 'secondary mania' as described in psychiatric literature, tends to be like the concept of 'disinhibition syndrome' as preferred by neurologists. Perhaps this reflects the same pathology but is labelled differently by different group of clinicians. It is now relatively well established that normal mood is

Manic syndromes in old age

dependent on the integrity of the frontal, limbic, and basal ganglia circuitry. To understand the pathology observed in secondary mania, the relevant neuroanatomical domains are as follows: frontal lobes modulate motivational and psychomotor behaviour; limbic connections modulate emotions; while the biogenic amine nuclei in the hypothalamus, amygdala, and brainstem modulate instinctive behaviours. It is therefore understandable that any loss in these neural circuits can lead to mania (Starkstein and Robinson, 1997). In addition, several case reports suggest that the right part of the cerebral cortex seems to be more affected in patients with secondary mania (Braun et al., 1999). Other authors also consistently argue that right-sided cerebral lesions subsequent to head injuries or other causes of organic brain damage lead to a 'disinhibition syndrome', similar to what is found in 'secondary mania' (Starkstein et al., 1990; Strakowski et al., 1994; Verdoux and Bourgeois, 1995; Steffens and Krishnan, 1998). The role of the cerebellum as an important structure in post-stroke mania is also evident from cases of posterior circulation infarction (Das et al., 2015).

Cognitive impairment is often found in younger patients with BD even in the euthymic stage (Martinez-Aran et al., 2004). Years of education and age at last manic/hypomanic episode were shown in one study to be important predictors of cognitive impairment, followed by age at first depressive episode and presence of a manic episode prior to the age of 40 (Tsai et al., 2007). This impairment continues into older age (Dhingra and Rabins, 1991), and seems to cause global, generalized deficits (Mann-Wrobel et al., 2011; Gildengers et al., 2013; Aprahamian et al., 2014), as highlighted by one study in which more than half of euthymic older bipolar patients scored one or more standard deviations below the mean of age- and education-matched comparison subjects on cognitive screening instruments, the MMSE, and the Mattis Dementia Rating Scale (Gildengers et al., 2004). Some researchers have found that particular cognitive domains are preferentially affected, although findings are not consistent between studies (for example, verbal learning and memory, Kurtz and Gerraty, 2009; processing speed and episodic memory, Delaloye et al., 2011; executive function and verbal memory, Robinson et al., 2006). In a study of a middle-aged and older population, bipolar patients underperformed comparably to patients with schizophrenia in tests involving reasoning/problem solving, and visual memory/learning, but performed marginally but significantly better on tasks involving other skills. These same BD patients had worse performance across domains with a much larger effect size compared to mentally healthy subjects, leading to a tentative conclusion that the neurocognitive impairments in BD more closely approximate those in schizophrenia, albeit with subtle and small differences (Depp et al., 2004). In comparing deficits between bipolar I, bipolar II, and unipolar patients in the acutely depressed phase, one group of researchers observed impairment in the same four domains (processing speed, memory, verbal fluency and executive function), albeit with greater severity in the bipolar I group (Xu et al., 2012).

Manic syndromes in old age

Whether there is a progressive component to the cognitive impairment seen in BD is still a matter of debate. Some studies (see, for example, Sanamé et al., 2013; Robinson and Ferrier, 2006) find stability over time with older bipolar patients having an equivalently impaired neurocognitive profile relative to the younger patients, suggesting that impairment occurs early but is stable over time, or at most parallels the cognitive changes that occur in normal ageing, as suggested by the findings in one five year follow-up study (Schouws et al., 2016). The findings from other studies, however, observed more pronounced deficits in the older group (Depp et al., 2007), out of keeping with age and education (Gildengers et al., 2009). In support of the latter view, two separate 24-month prospective studies did not find an accelerated course of cognitive decline between euthymic bipolar patients and normal cognitive subjects (Gildengers et al., 2013; Delaloye et al., 2011). This fits in with theory of 'neuroprogression', which posits that impairments are illness- and not age-dependent (Goodwin et al., 2008; Cardoso et al., 2015), implying that structural rewiring of brain networks occurs as a result of repeated mood episodes. This observation aligns itself well with findings in the unipolar depression literature in which late life depression is associated with more cognitive impairment than that observed earlier in the course of illness, and which continues even when controlling for the effect of ageing (Thomas et al., 2009). Certainly, one study has found more severe cognitive impairment in LOB patients compared to elderly EOB, although the confounder in this study is that the EOB group was on average four years younger than the LOB group (Schouws et al., 2009),

Taken together, this might suggest that several older bipolar patients have cognitive deficits similar to and in the range of mild cognitive impairment (MCI), the latter often being regarded as the precursor state to dementia. This hypothesis has not been well investigated, as most studies compare cognition in bipolar patients to control subjects judged to have 'normal' cognition. In fact, it is possible the cognitive deficits in patients with BD are different from those who have MCI, as suggested by a recent study in which the cognitive deficits in older adults with Bd (mean age 63 years) were compared to those with MCI and no history of affective disorder. Patients with MCI were more impaired in verbal memory, whereas BD patients showed more deficits in attention, calculation, and verbal abstraction (Silva et al., 2009).

Whether there is a link between dementia and BD as exists between the former and late-life depression (Ownby et al., 2006; Gualtieri and Johnson, 2008; Brommelhoff et al., 2009; Himmelhoch et al., 1980) does not appear to have been settled. Some authors have commented on the difficulty in differentiating between behavioural symptoms associated with Alzheimer's disease (AD) and LOB (example, Depp and Jeste, 2004; Ng et al., 2008), and in recognition of that, one group has attempted to develop a computer-aided diagnosis system using clinical observation, neuropsychological testing, and inflammatory and neurotrophic biomarkers to discriminate between the two disease entities (Besga et al.,

Manic syndromes in old age

2015). Further evidence that BD and AD can be distinguished biochemically came from a study in which the signature AD CSF profile of low amyloid-beta peptide levels and high concentration of hyperphosphorylated tau protein was not found in patients with late-life BD (Forlenza et al, 2016), suggesting that cognitive impairment in LOB is not via the pathological mechanisms present in AD. In a small neuroimaging study, this lack of common pathophysiology is indirectly supported by the finding that late-life bipolar patients had a smaller burden of white matter hyperintensities (WMH) than healthy comparators, despite having more cognitive impairment (Rej et al., 2014a), which is not in keeping with emerging consensus that WMH is a preclinical and independent biomarker for AD (Lee et al., 2016; Mortamais et al., 2014).

There is interest in the use of lithium to potentially preserve cognitive function in BD. Rybakowski and colleagues (2009) found a beneficial effect of lithium prophylaxis on executive cognitive function. There have also been interesting results from a large ten-year follow-up study (1995–2005) conducted in Denmark (Kessing et al., 2008). Two groups were compared: 16,238 persons who had purchased lithium at least once in the community (implying a possible diagnosis of BD) and 1,487,177 persons from the general population who had not purchased lithium. Patients who purchased lithium at least once had an increased rate of dementia compared with persons not exposed to lithium (relative risk, 1.47; 95% CI, 1.22–1.76), providing further evidence that BD increases the risk of dementia. For persons who continued to take lithium, the rate of dementia decreased to the same level as the rate for the general population, suggesting a protective effect of lithium. More disappointing is that another small study (Gildengers et al., 2008b) found that twelve older adults with BD who were prescribed donepezil for 12 weeks showed no improvement in either ADL score or cognitive test scores at the time of completion of the study.

These findings suggest that late-life BD patients are, at minimum, at increased risk of cognitive impairment, and possibly dementia. There are some data on a possible protective effect of lithium for preventing dementia, but good-quality intervention studies are needed to investigate this and to determine if better control of vascular risk factors improves outcome.

Prognosis

Suicide has been consistently shown to be one of the important causes of mortality in patients with affective disorders, especially in patients younger than age 35 after an interval of seven to 12 years of illness (Tsai et al, 2002). Whether this risk continues into older age, irrespective of early or late onset, is unclear. In their comprehensive review of the literature, Depp and Jeste (2004) did not find increased rates of suicide in elderly patients with BD, offering the possible interpretation that, in the case of EOB, elderly patients represented a ‘survivor cohort’. In a large

Manic syndromes in old age

longitudinal study of patients suffering from affective disorder admitted to an inpatient unit who were followed up for more than 34 years, it was observed that those patients who were on psychotropics (including antidepressants, neuroleptics, and lithium) had significantly reduced completed suicide rates compared to those not treated (Angst et al., 2002). Indeed, in a retrospective analysis of cases of older bipolar patients who had a suicide attempt, usage of antidepressants and mood stabilizers was noted to have reduced suicide attempt rates compared to age- and sex-matched controls (Aizenberg et al., 2006).

There is a relative paucity of research in how older patients with BD fare in terms of psychosocial functioning. There appears to be an additive effect of ageing and disease on older patients with BD manifesting in reduced quality of life, impacted cognitive skills, and ability to perform physical tasks (Weisenbach et al., 2014). Extrapolation from prospective data in the younger population in which one year psychosocial functioning in patients with multiple mood episodes is found to be significantly lower than in those with a history of only a single episode (Rosa et al., 2012) supports the concept of sustained impairment, possibly due to the progressive neurotoxicity of repeated episodes (Gildengers et al., 2013). In the Taiwanese study cited earlier, elderly patients with BD had a mean General Assessment of Functioning (GAF) score and Community Psychiatrist Rating Scale (CPRS) score significantly below their non-bipolar counterparts (Tsai et al., 2009). In a study of middle-aged and elderly adults with BD (ages 45–85 years), bipolar patients were found to have comparable scores on Quality of Well-Being scale and Medical Outcome Study-Short Form Health Survey (SF-36) relative to age-matched schizophrenia patients, and substantially lower scores relative to older healthy comparators (Depp et al., 2006).

Aetiopathology

Analogous to the vascular depression hypothesis in late life, the hypothesis that mania in late life may have a vascular cause has generated much interest (Wijeratne and Malhi, 2007). In a study of patients with late-life BD, a higher Framingham Stroke Risk Score was found in LOB versus EOB (Subramaniam et al., 2007). Huang and colleagues (2012) found imaging evidence of silent cerebral infarctions in over half of elderly bipolar patients irrespective of age of onset. Also, in a sample of older bipolar patients (n=119), more vascular risk factors predicted poorer cognitive performance (Schouws et al., 2010). Cerebrovascular disease is also reflected in the extent of brain WMHs as revealed by neuroimaging. The seminal paper proposing the relationship between LOB and cerebrovascular illness was described over twenty years ago with the description of a significantly higher incidence of silent cerebral infarcts in late onset mania relative to earlier onset as demonstrated by WMH on magnetic resonance imaging (MRI; Fujikawa et al., 1995). There are consistent findings of an increase in WMH in patients with BD (Lloyd et al., 2009) and even more so in LOB (Tamashiro et al., 2008); the latter of these found that there were more WMH in the

Manic syndromes in old age

deep frontal and parietal lobes and the putamen in LOB patients compared to age-matched older people with EOB, findings that correlated well with a similar study of mood disorders more broadly in which late-onset patients with an affective disorder had more deep WMH than age-matched early onset subjects (Takahashi et al., 2008). There is evidence that in unipolar disorder in older people, WMH are due to hypoxia-ischaemia (Thomas et al., 2002), but there have been no studies in BD. The aetiology of WMH may be a result of deficits in vascular perfusion (Thomas et al., 2002).

Though it is relatively well established that traumatic brain injury in the younger adult population can cause secondary mania as a neuropsychiatric sequel, the evidence for this association in older people is much weaker. There are only a few case reports of secondary mania in this population because of either anoxic encephalopathy (Ku et al., 2006) or thalamic damage (Lopez et al., 2009). Although it seems reasonable that brain injury would have similar or worse effects in older people, good studies are needed to demonstrate this.

Brain volume changes

There is increasing characterization of the neural substrates of late-life BD, made possible with advances in neuroimaging techniques such as structural MRI to estimate brain volume. There are contradictory reports of the extent of brain volume changes in late-life BD, with some research indicating no difference in gray matter and white matter volumes between euthymic older adults and healthy comparators (Delaloye et al., 2011; Sarnicola et al., 2009) whereas other researchers have found a significant volumetric difference between euthymic BD patients age-matched and gender-matched controls. This has obvious implications for the question of whether there is an active neurodegenerative process at play in BD, and certainly progressive gray matter loss has been documented in the longitudinal studies of the non-geriatric bipolar population (Moorhead et al., 2007). On balance, it appears that evidence is accumulating for there being focal areas of more specific atrophy in later age BD (Brambilla et al., 2001), where smaller gray matter volumes have been shown bilaterally in the inferior frontal areas (Beyer et al., 2009), along with decreased right caudate volume (Beyer et al., 2004a), smaller left hippocampal (Beyer et al., 2004b), and right posterior cingulate gyrus (Huang et al., 2011) volumes, and age-related reduction of amygdala volume (Doty et al., 2008). Interestingly, there is some evidence of an *increase* of volume in specific areas in middle-aged patients with BD (Jones et al., 2009), which may reflect compensatory neuroplasticity and is of particular importance given its cortical and subcortical connections with other brain areas controlling emotions and mood, as well as its role in regulating memory.

Unfortunately, there is little research on whether LOB has a different neuroimaging pattern from EOB (Hahn et al., 2014). One study has found *smaller* posterior cingulate gyri and *larger* left caudate nuclei and left

Manic syndromes in old age

middle frontal gyri in late-onset mania patients relative to the age-matched early-onset mania group (Huang et al., 2011). These authors hypothesized that the smaller cingulate gyrus may be due to the protective effect of medications taken earlier in life or could reflect the higher burden of cerebrovascular disease in the late-onset mania group. They further ventured that the left caudate nucleus and middle frontal gyrus may be relevant to the pathophysiology of early onset mania, with the implication being that these structures in the late-onset mania group were in fact more representative of normal.

Recent findings of reduced brain derived neurotrophic factor (BDNF) in older patients with BD (Soares et al., 2016) is particularly compelling in the context of this evidence of selectively reduced brain volumes in BD as BDNF is known to be critical for neurogenesis and neuroplasticity, raising the question of whether BDNF may be a mechanism between prolonged affective illness and dementia, as has been proposed in major depressive disorder (Kim et al., 2016).

Brain connectivity

It is recognized that bipolar patients have impaired connectivity between different areas of the brain because of disruption to the connecting white matter tracts (Benedetti and Bollettini, 2014; Bellani and Brambilla, 2011). Diffusion tensor imaging (DTI) is a relatively new neuroimaging technique that allows measurement of water diffusion within the neural tissue, which in turn provides information about white matter integrity. Abnormal DTI is thought to indicate damage to axonal membranes, demyelination, or reduced axonal density and thickness. Interest in the use of DTI as a means of exploring functional differences between healthy brains and those of bipolar patients is gaining momentum, as reflected by the number of papers published over the past decade. However, as noted by Nortje and colleagues (2013), the attempts to summarise the literature are inconsistent. For example, one meta-analysis of ten studies of DTI in BD suggested two significant clusters of decreased connectivity in right subcortical regions (areas close to the posterior parahippocampal gyrus, to the right anterior and subgenual cingulate cortex, respectively) (Vederine et al., 2011), whereas another review identified more evidence for loss of white matter network connectivity involving the prefrontal and frontal regions with less consistent and robust evidence for subcortical and non-frontal lobe areas (Heng, Song, and Sim, 2010). Yet another meta-analysis identified a right posterior temporoparietal and two left cingulate area as significant clusters of white matter alterations (Nortje et al., 2013).

Further complicating the application of the literature to late-life BD is the fact that the current research focus is primarily on the adult populations and information on microstructural white matter changes in late-life BD may have to be extrapolated from the adult data. In the only published study (Haller et al., 2011) in older bipolar (LOB and EOB together) patients conducted on only 19 patients, there was significantly decreased

Manic syndromes in old age

connectivity in the ventral part of the corpus callosum. This was supported by a report by Sexton and colleagues (2012) that there was abnormal connectivity as measured by DTI within the corpus callosum of 10 LOB patients compared to unipolar patients and healthy volunteers, supporting the hypothesis that abnormal interhemispheric connectivity is a feature of the disorder. It is still unclear to what end the use of DTI in the study of late life BD will be helpful, but it may ultimately be shown to be a neurobiological marker to help distinguish late life bipolar from other nosological entities, such as unipolar depression and AD (Teipel et al, 2014; Besga et al, 2016).

Inflammation/oxidative stress

An exciting development in our understanding of the aetiopathology of BD generally is the mounting evidence that chronic inflammation may be present in even the earliest stages of disease (Goldstein et al., 2009). Whether inflammation plays a distinct role in late-life BD is understudied, but interestingly the interleukin-1 (IL-1) family of cytokines, but not other inflammatory cytokines, were found to be elevated in euthymic bipolar older patients with cognitive impairment, increasing the speculation that IL-1 may be involved in impaired cognitive functioning in BD (Lotrich et al, 2014). Increases in the acute-phase reactant C-reactive protein also appears to be associated with BD, and independent of medication use (Dargel et al., 2015). Inflammation may play a role in the induction of increased markers of oxidative stress that have been found in older BP patients. For example, higher peripheral levels of lipid hydroperoxide, a surrogate measure of oxidative damage, were found in 110 euthymic patients older than 50 compared them to 75 age-matched healthy comparators (Andreazza et al., 2015). These findings supported a previous study from the same group in which elevated LPH levels were associated with WM abnormalities in the prefrontal cortex in euthymic adult bipolar patients, with the inference being that lipid peroxidases target the axonal membranes and myelin sheaths of WM tracts (Versace et al, 2014).

These findings show that our knowledge of the aetiopathology of late-life BD is limited, but the best evidence so far supports a role of cerebrovascular disease.

Management

This section focuses on those features of the management of BD that are distinct for older people. Most fundamental, given the high prevalence of neurological morbidity in late-life BD, is the need to search assiduously for localizing neurological signs and symptoms. A careful history, being alert to evidence of head injury, cerebrovascular disease, and related risk factors, is essential in light of our current understanding of the illness. Indeed, neuroimaging may be considered as an important component of the investigation of the older manic patient, especially LOB (van Gerpen et al., 1999). Furthermore, given our understanding of the probable role

Manic syndromes in old age

cerebrovascular risk factors play in the aetiopathology of LLB, both primary and secondary preventive strategies at the level of general medical care of these risk factors become important (Compton et al., 2006; Leboyer and Kupfer, 2010; Ward et al., 2015).

The ISBD Task Force for OABD is drawing increasing attention to the lack of specific recommendations for the management of the older individual with BD in the various international and national treatment guidelines (Dols et al., 2016). In general, combined medication treatment (for example, a mood stabilizer and an anti-psychotic) for late-life BD is the rule, rather than the exception (Oostervink et al., 2015). In a retrospective study on patterns of pharmacotherapy and treatment response following up 138 acutely unwell patients in a single centre, it was observed that mood stabilizers were the most prescribed (68%), followed by antipsychotics (54%), and antidepressants (34%). Combination therapy with these medications was more common than monotherapy (57% vs 38%). Remission was achieved in only 35% of subjects, while 32% showed no significant improvement (Beyer et al., 2008). A recent multisite, cross-sectional naturalistic study in the US found greater rates of antidepressant prescription in late-life bipolar patients, defined in this study as patients 55 years and older. These findings suggested to the authors that older adults may respond more efficaciously to antidepressants, although they cautioned that the population reported fewer and less severe depressive symptoms, suggesting that a prospective study was required to establish cause and effect (Forester et al., 2015). In a multisite cross-sectional study, elderly EOB patients were found to be receiving a higher mean number of psychotropic medications (3.3) relative to elderly LOB patients (2.3), as well as higher antidepressant use (71.7% relative to 35.3%) and higher mean daily dose of antipsychotics (257.3 mg of chlorpromazine equivalent relative to 175.54 mg) (Montes et al., 2013).

Results from the multicentre prospective EMBLEM study have been of interest. At a 12-week outcome point, a total of 2,761 patients had been treated for a manic episode, including 475 over the age of 60 (Oostervink et al., 2009). At that juncture, it was found that LOB patients (n=141) tended to be maintained on typical antipsychotics, lithium, and anticholinergics, much more than EOB patients (n=323), and that after an episode of manic or mixed affective relapse there was an increase in prescription of atypical antipsychotics and a consequent decrease in typical antipsychotic use. Rapid cycling older patients had a higher use of antidepressants (40%) compared to non-rapid cycling older patients. The EMBLEM data also suggested that, while older bipolar patients as a group differed from younger patients in terms of treatment, treatment outcomes in the short term did not differ between the age groups. A further analysis of patients over 60 did suggest that treatment outcome was more favourable for the LOB patients than for the EOB when assessing on the physician-rated CGI scale.

Manic syndromes in old age

At the 24-month follow up, greater use of antidepressants in older (relative to younger) patients was observed, as well as less frequent use of atypical antipsychotics, and greater use of other concomitant psychiatric medications, such as anticholinergics, benzodiazepines and other hypnotics. Prescribing rates of anticonvulsants and lithium did not differ relative to younger bipolar patient. No statistically significant differences in prescribing was found between older EOB or LOB patients, although the authors acknowledge that the small numbers in these subgroups could reflect a type 2 error, thus preventing the detection of a clinically relevant difference (Oostervink et al., 2015). Unlike what was found at the 12-week time point, after two years no statistically significant differences in treatment outcome could be found between EOB and LOB patients.

Of note, the evidence base for psychotherapeutic treatments in the younger bipolar patient group is relatively strong, with different approaches being effective in different phases of the illness. Family therapy, interpersonal therapy, and systematic care appear to be effective in preventing recurrences when initiated after an acute episode, whereas cognitive behavioural therapy and group psychoeducation appear to be most effective when initiated during a period of recovery (Miklowitz, 2008). However, there has been less investigation of the effectiveness of nonpharmacological treatments of late-life BD. While there are some encouraging findings from psychosocial intervention trials (Fagiolini et al., 2009), no randomized controlled trials (RCTs) have been reported hence we do not offer any specific recommendations for such treatment approaches.

As a general therapeutic approach, one needs to be aware that pharmacological treatment of any disorder in older patients is challenging because of pharmacokinetic and pharmacodynamic changes associated with ageing, as well as an increased risk of drug interactions (see Chapter 13). In view of these challenges, one needs to be cognizant of the risk of such interactions. In a ward-based study of older aged psychiatry patients found that 96% of prescriptions had a potential for drug-drug interactions, with an average of eight drugs prescribed for each patient (Vasudev and Harrison, 2008).

Mood stabilizers

Lithium

Lithium continues to be a commonly used mood stabilizer in old age. Traditionally some clinicians and patients have been reluctant to use lithium as first-line treatment because of concerns regarding frequent blood level monitoring, nephrotoxicity, and the narrow therapeutic window. A recent cross-sectional study, however, has demonstrated that patients using lithium for BD (n=46, mean age 68.7) actually report higher contentedness, somatic health, and social functioning than counterparts using anticonvulsants or other medications (n=30, mean

Manic syndromes in old age

age 68.1) (Rej et al., 2016). This attitude holds true despite higher rates of adverse effects (polyuria, thirst, tremor, and fatigue being reported in 48 lithium users). In addition, the BALANCE trial, a pragmatic RCT in working-age adults, has revisited lithium again and concluded that, for adults with bipolar I disorder for whom long-term therapy is clinically indicated, both combination therapy with lithium plus valproate and lithium monotherapy are more likely to prevent relapse than is valproate monotherapy (Geddes et al., 2010). Unfortunately, there are still no RCTs on the use of this agent in the pharmacological treatment of older bipolar patients. There are, however, several open-label trials and retrospective reports that suggest that even older, frail patients can be safely and effectively treated (Himmelhoch et al., 1980; Shulman and Post, 1980; Chen et al., 1999; Fahy and Lawlor, 2001; Gildengers et al., 2005). Furthermore, there is evidence that age is not a determinant of erratic serum lithium levels (van Melick et al., 2013).

Evidence suggests lithium may help in reducing progression to dementia in late-life BD (Nunes et al., 2007; Kessing et al., 2008; Dell'Osso et al., 2016), findings that may improve clinicians' favourability towards the use of lithium in older people. Long-term lithium may be related to better white matter integrity, as demonstrated by a small study comparing the MRI of older BD patients with a mean lithium exposure of 13.8 years to an otherwise similar group of BD patients with either no or less than one year of lithium treatment (Gildengers et al., 2015). While this preliminary study is very interesting and supports the hypothesis that lithium may be neuroprotective, this same study did not demonstrate an association between duration of lithium exposure and global cognitive functioning. Interestingly, in a cross-sectional rank order analysis of the relative neurocognitive effects of psychotropic medications, lithium ranked behind lamotrigine and oxcarbazepine in terms of cognitive favourability, but ahead of carbamazepine, valproic acid, and topiramate (Gaultieri and Johnson, 2006), which may reflect lithium's known serum anticholinergic activity (Chew et al., 2008). At this time, it is difficult to reconcile the cognitive blunting effects of which patients on lithium often complain with the concept of lithium's neuroprotective role. Another factor to consider is the increase in sensitivity to lithium by age. Adverse reactions and toxicity levels have been reported in older people even with serum levels within the 'safe' and therapeutic range (Roose et al., 1979; Murray et al., 1983). However, under well-controlled conditions in a specialized geriatric clinic, lithium is reported to be safe and well tolerated (Parker, 1994).

Lithium must be used with caution in the geriatric population as it is eliminated exclusively by the kidneys and may be excreted in older people at a rate approximately half that of younger patients (Hardy et al., 1997). This has led to the recommendation that in old age, only half the adult dose should be prescribed. Lithium use appears to be safe in geriatric patients who have normal kidney function (Rej et al., 2015); caution needs to be exercised in patients where the baseline estimated

Manic syndromes in old age

glomerular filtration rate (eGFR) is less than 60 ml/min/1.73 m² (stage three chronic kidney disease) and in such patients adverse renal outcomes are more likely (Rej et al., 2014b). Unfortunately, this applies to a large proportion of older people. The traditional wisdom about the inexorable nephrotoxicity of long-term lithium therapy is being revised in light of a recent large population-based cohort study in which the rate of change in eGFR over 12 years of lithium-treated adult patients was comparable to patients on quetiapine, olanzapine, and valproate (Clos et al., 2015). This should not, however, prevent a cautious prescriber from remaining alert to potential lithium nephrotoxicity, especially in an older patient with other medical comorbidities, or to seek alternative treatments in patients with baseline renal disease. Lithium has been known to cause nephrogenic diabetes insipidus through various mechanisms, including alterations in purinergic signalling (Zhang et al., 2009), disturbance in epithelial sodium channel functioning in the collecting ducts (Kortenoeven et al., 2009), and dysregulation of renal aquaporins and acid-base transporters (Nielsen et al., 2008). Perhaps in the future, newer treatments will be available to counteract the effects of lithium on the kidneys, but at the moment no specific recommendations are available for the management of lithium-induced nephrotoxicity, although amiloride has been found to be beneficial to some extent (Bedford et al., 2008). Prudence would suggest that the clinical management of such a patient should be done collaboratively with a nephrologist.

Additionally, lithium can cause a wide range of systemic adverse reactions, including those on the central nervous system. Lithium induces tremors, aggravates parkinsonian tremor, and causes spontaneous extrapyramidal symptoms. Interestingly, one Canadian study showed that chronic lithium use is associated with the prescribing of Parkinson medications such as levodopa, prompting the authors of this study to speculate that this prescribing cascade made be the inappropriate treatment of lithium-induced action tremor (Marras et al., 2016). One community study found that almost a third of older patients on lithium were on thyroid replacement or else had elevated levels of thyroid stimulating hormone (Head and Denning, 1998), and another study of 1,705 new lithium users over 65 years of age found it treated hypothyroidism in almost 6% of the sample, twice the prevalence expected among a mixed-age population (Shulman et al., 2005b). Lithium can also cause frank encephalopathy when taken as an overdose or when combined with various neuroleptics. Cautious slow withdrawal is usually found to alleviate the symptoms (Swartz and Dolinar, 1995; Boora et al., 2008).

Drug interactions continue to be an ongoing concern with lithium, particularly when thiazide diuretics are prescribed as these can significantly lower lithium clearance and thereby put the patient at risk of toxicity by increasing the serum lithium levels. Other medications of concern include the angiotensin-converting enzyme (ACE) inhibitors and

Manic syndromes in old age

non-steroidal anti-inflammatory drugs (NSAIDs) such as indomethacin. In an observational study of 10,615 older lithium users, 3.9% had been admitted to hospital for lithium toxicity. In this study, initiation of a loop diuretic like furosemide or an ACE inhibitor significantly increased the risk of lithium toxicity, while neither thiazide diuretics nor NSAIDs were independent risk factors (Juurlink et al., 2004).

Anticonvulsants

Valproic acid, lamotrigine, and carbamazepine are standard medications in the treatment of BD in the adult population. While they have proven efficacy as mood stabilizers, one must remain mindful of their exhaustive list of serious drug interactions, and concerns for their safe and well-tolerated use in an older population in whom frailty and comorbidities are more often the rule rather than the exception. Moreover, there is limited data on anticonvulsant use in older bipolar populations and a paucity of specific guidelines for their use. There are some important class effects of which to be mindful in the older population, such as sedation (Mula and Trimble, 2009), reduced bone mineral density and increased fracture risk (Lee et al., 2010), and memory impairment (Montamendi and Meador, 2004), although the latter may be more of a concern for the older generation anticonvulsants (valproic acid, carbamazepine) than lamotrigine (Mula and Trimble, 2009).

Valproic acid or its congener, divalproex, are now frequently used in the treatment of BD in the younger adult population. Some evidence suggests that valproate therapy is now used more frequently for older bipolar patients than even lithium (Shulman et al., 2003; Sajatovic et al., 2004). There are no RCT data available, but there are a number of published case reports and case series (Risinger et al., 1994; Gildengers et al., 2005). These studies indicate that valproate is an effective and well-tolerated mood stabilizer in the older population, although in this population it is important to remain mindful of the finding that valproate had the most neurocognitive effects of the anticonvulsants after carbamazepine (Gaultieri et al., 2006). Though there are recommendations that valproate should be up-titrated quickly for acute management of mania in the adult population, there are no such recommendations in the older population. This is possibly because of the higher incidence of adverse effects even at therapeutic dosages. Principal side effects include sedation and gastrointestinal disturbance, which can be modulated by dosage reduction (Shulman and Herrmann, 1999). Indeed, valproate did not fare better than lithium in a relatively large study comparing differences in hospitalization rate for delirium in 2,422 lithium users compared to 2,918 valproate users (Shulman et al., 2005a). Use of valproate is associated with a relatively high incidence of thrombocytopenia, an often under-recognized side effect of this medication, which may occur frequently in older people (Trannel et al., 2001). There are several case reports of valproic-acid induced parkinsonism (Mahmoud and Tampi, 2011) and hyperammonaemic encephalopathy (Mittal et al., 2009), which suggests caution while

Manic syndromes in old age

prescribing. There also may be merit in using valproate in the treatment of rapid cycling illness in old age (Gnam and Flint, 1993), though as there are no RCTs, one must be cautious in extrapolating results to the routine clinic.

Valproate is highly protein bound. There is a risk of higher adverse events when consumed at higher dosages, which may be related to higher total as well as unbound drug levels in the blood. This may result from complex protein binding. It has been shown that the protein binding of valproate decreases as the serum concentration increases (Felix et al., 2003). The drug is also a moderate broad spectrum inhibitor the CYP system and UGT-glucuronidation (Fenn et al., 2006), which leads to the potential for multiple drug interactions with non-psychiatric medications commonly prescribed to the older adults, such as warfarin and acetylsalicylic acid (Virani et al, 2012; Fenn et al, 2006). Furthermore, co-administration of valproic acid and psychotropic medications can be tricky; for instance, valproate has been found to inhibit the metabolism of tricyclic antidepressants and displace diazepam from protein binding sites, thus increasing their plasma concentrations (Janicak, 1993).

Carbamazepine, a mood stabilizer preferred in the past, is still recommended in various guidelines for the management of BD in younger adults. The British Association for Psychopharmacology recommends that it could be used for acute mania that is mild in severity and for prevention of relapse in bipolar I patients (Goodwin, 2009). Its clinical usage in the geriatric population is low, perhaps because of its risk of drug interactions, auto-induction, rash, and high neurotoxicity. It has the potential to cause hyponatraemia, an imbalance that is always poorly tolerated in the elderly and which can present as a confusional state (Fenn et al., 2006). Therapeutic target serum levels might be a bit lower for the geriatric population and some authors suggest keeping serum levels below 9 µg/ml (Young, 1996), although carbamazepine is notorious for its wide interindividual variation in pharmacokinetics.

Among other mood stabilizers, gabapentin has been found to be beneficial in some case reports. Two case series used gabapentin in a subsample of older patients (Ghaemi et al., 1998; Cabras et al., 1999). There is some evidence of lamotrigine's efficacy in BD in those greater than 55 years of age (Marcotte, 2004). In an open-label trial of treatment of refractory BD, a number of older patients appeared to tolerate lamotrigine (Calabrese et al., 1999). In a subanalysis of older subjects enrolled in a placebo-controlled trial of maintenance therapy for bipolar I disorder, 33 patients were treated with lamotrigine (Sajatovic et al., 2005), and it was found that lamotrigine was significantly better than placebo at delaying time to intervention for any mood disorder. The average age of these older subjects was, however, only 62. A multisite, open-label, prospective trial of lamotrigine (mean dose 150.9 mg/day) for geriatric bipolar depression found nearly 60% remission and response rate in the study population of type I and II bipolar depression (n=57, mean age 66 years) (Sajatovic et al., 2011). Dropout rates due to adverse events were modest (10.5%), and

Manic syndromes in old age

included rash (four patients), manic switch (one patient), and hyponatraemia (one patient). A number of side-effects were noted including both reduced and increased sleep, weight loss and weight gain, increased dreams, polyuria, diminished sexual desire, fatigue, and unsteady gait.

Among other anticonvulsants there was some early evidence for levetiracetam (Kyomen, 2006), although a more recent review of RCTs emphasizes that mood stabilization is not a class effect for anticonvulsants (Rosa et al., 2011), and levetiracetam specifically has no efficacy as a mood stabilizer (Dubovsky et al., 2015).

Antidepressants

Antidepressants have a role in the acute treatment of a depressive episode in unipolar depressive disorder in older people as well as prophylaxis in preventing relapse. For the treatment of BD, monotherapy with antidepressants has also been linked to an increased risk of a manic episode, also called as 'switching' (Goodwin, 2009). Additionally, a bigger concern is that antidepressants may not offer any clinical benefit per se. A recent systematic review and meta-analysis of use of antidepressants in adult BD highlighted that antidepressants do not offer clinical superiority over placebo for treatment response or remission (Sidor, 2011). Additionally, we found no good-quality studies exploring the use of antidepressants in late-life BD and hence we do not elaborate much on their usage.

Antipsychotics

Some antipsychotics have displayed efficacy in late-life BD, especially as medications useful in the management of acute mania. For instance, in a post hoc analysis of noncontrolled data, Sajatovic and colleagues (2008a) found quetiapine monotherapy to be effective for the acute treatment of bipolar mania in adults greater than 55 years of age, and in an open-label trial, this group showed evidence for efficacy of aripiprazole in a small (n=20) study of older adults in acute mania (Sajatovic et al., 2008b). Similarly, 88 depressed old age bipolar patients were randomized to lurasidone monotherapy, and after six weeks, the average improvement in Montgomery-Asberg Depression Rating scale was significantly greater for lurasidone monotherapy relative to placebo, with an impressive effect size of 0.83 (Sajatovic et al., 2016). Further work is needed on the use of this agent especially since adjunctive lurasidone therapy did not demonstrate efficacy.

Asenapine has been approved by the Federal Drug Administration for adult use in acute and mixed mania as either monotherapy or as an adjunct to lithium or valproate, and has been found to be efficacious and well tolerated. In the 2013 guideline updates for Canadian Network for Mood and Anxiety Treatments (CANMAT) for the management of BD, asenapine is included as a new first-line monotherapy option for the treatment of acute mania (Yatham et al., 2013). In a small open-label

Manic syndromes in old age

study in Tel-Aviv, 11 admitted psychogeriatric (mean age 67.7) patients with acute bipolar mania were treated with a mean daily dose of 20 mg of asenapine (Baruch et al., 2013). Treatment was discontinued in two patients, for rash and severe peripheral oedema, respectively, with complete resolution in days following medication discontinuation. Improvement in Young Mania Rating Scale (YMRS) was significant at day 28, with improvement noted in all the YMRS items. For the nine patients that remained on asenapine for four weeks, all achieved response (defined as a $\geq 50\%$ decrease in YMRS total score from baseline), and all but two attaining remission (YMRS total score ≤ 12). Overall, asenapine was well tolerated with only mild sedation reported by minority of the patients. Similar findings of tolerability and efficaciousness were found in a small (n=15, mean age 68.8) open-label trial in which community-dwelling seniors exhibiting diminished functional abilities, or lability, irritability, or agitation due to BD were tried on asenapine at an average dose of 11.2 mg daily after suboptimal control on their current medication (Sajatovic et al., 2015a). Maintenance medications for BD were continued provided no changes had been made in the previous 30 days. One patient was lost to follow-up and three dropped out prematurely because of perceived medication side effects, one of whom developed a mixed manic state. Of the 11 who completed the 12-week trial, there was significant improvement in scores for the Brief Psychiatric Rating Scale, and the CGI bipolar version scale. Tolerable side effects that did not lead to study discontinuation included gastrointestinal distress, restlessness, tremors, cognitive difficulties, and sluggishness/sedation.

Management of cognitive impairment

As for the pharmacological management of cognitive impairment in BD, the data is limited and of inferior quality (Sanches et al., 2015). Cholinesterase inhibitors have been tried but with mixed results, suggesting that the nature of cognitive impairment at the neurotransmitter level involves something other than cholinergic deficits. In a small, open label trial of donepezil 5–10 mg in older patients with late life BD and minor cognitive decrements, Gildengers and colleagues (2008b) observed no significant effects in cognitive or functional measures after three months. Overall, the research into pharmacological management of cognitive impairment of late-life BD is in its infancy.

Conclusion

Late-life BD, especially LOB disorder, appears to be a different entity from BD in the younger population. Late-life BD is frequently associated with vascular changes in the brain and these may be of aetiological significance. There is also cognitive impairment associated with late-life BD and there is some evidence that lithium might prevent further deterioration in cognition. Good quality RCTs of psychotropics in both acute and maintenance stages are needed, as currently practice is based

Manic syndromes in old age

largely on extrapolation of clinical evidence from younger bipolar patients, who may have a different kind of illness.

Anxiety disorders in older people

Chapter: Anxiety disorders in older people

Author(s): Gerard Byrne

DOI: 10.1093/med/9780198807292.003.0042

Introduction

Fear and anxiety are phylogenetically ancient emotions that confer survival advantage across species (Darwin, 1872). They facilitate escape from present danger and prepare the individual to deal rapidly with future threats. In contemporary life, a moderate increase in anxiety is commonly associated with increased performance (Yerkes and Dodson, 1908). However, anxiety that is excessive or prolonged is maladaptive and may represent a mental disorder. Individual differences and contextual factors influence the final form that an anxiety disorder takes. Like many complex behaviours, anxiety disorders result from interactions between genetic and environmental factors. In older people, anxiety often complicates physical frailty and cognitive decline. From a nosological perspective, anxiety can be conceptualized as both dimensional and categorical. Both psychological and pharmacological treatments are commonly applied to anxiety disorders in older people, with moderate efficacy. This chapter deals with classification, epidemiology, scientific

Anxiety disorders in older people

underpinnings, phenomenology, and modern treatment approaches to anxiety disorders in later life.

Classification

The tenth edition of the International Classification of Diseases (ICD-10) includes anxiety disorders, including obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD) within a broad category of neurotic, stress-related, and somatoform disorders (World Health Organization, 2010). In contrast, DSM-5 has a section for anxiety disorders and separate sections for OCD and PTSD (American Psychiatric Association, 2013). Similar changes have been made in ICD-11, with data reporting from participating countries to commence in 2022 (World Health Organization, 2018). For ease of reference we retain OCD and PTSD in this chapter. Table 42.1 shows the classification of anxiety disorders under ICD-10, ICD-11, and DSM-5. There is considerable commonality between the lists of anxiety disorders under the two dominant nosologies, reflecting convergence over time. ICD-10 is currently under revision, with ICD-11 due in 2018. The most significant change to the diagnostic criteria for anxiety disorders introduced in DSM-5 was the deletion of DSM-IV PTSD criterion A2, which required the person to have experienced 'intense fear, helplessness or horror' at the time of the traumatic exposure (Friedman et al., 2011). In ICD-11 (World Health Organization, 2018), complex post-traumatic stress disorder (6B41) has been added to the nosology and acute stress disorder relegated from a disorder to a problem (acute stress reaction, QE84).

Table 42.1 Anxiety disorder classifications.

ICD-10	ICD-11	DSM-5
F40.0 Agoraphobia, unspecified	6B02 Agoraphobia	300.22 Agoraphobia
F40.01 Agoraphobia with panic disorder		
F40.02 Agoraphobia without panic disorder		
F40.10 Social phobia	6B04 Social anxiety disorder	300.23 Social anxiety disorder (social phobia)

Anxiety disorders in older people

F40.2 Specific phobia	6B03 Specific phobia	300.29 Specific phobia
F41.0 Panic disorder	6B01 Panic disorder	300.01 Panic disorder
F41.1 Generalized anxiety disorder	6B00 Generalized anxiety disorder	300.02 Generalized anxiety disorder
F41.2 Mixed anxiety and depressive disorder	6A73 Mixed depressive and anxiety disorder	<i>No corresponding disorder in DSM-5</i>
F41.3 Other mixed anxiety disorders	<i>No corresponding disorder in ICD-11</i>	<i>No corresponding disorder in DSM-5</i>
F42 Obsessive-compulsive disorder	6B20 Obsessive-compulsive disorder ^a	300.3 Obsessive-compulsive disorder ^b
F43.0 Acute stress disorder	<i>No corresponding disorder in ICD-11, but QE84 Acute stress reaction (not a disorder) can be coded</i>	308.3 Acute stress disorder ^d
F43.1 Post-traumatic stress disorder	6B40 Post-traumatic stress disorder ^c	309.81 Post-traumatic stress disorder ^d
F43.22 Adjustment disorder with anxiety	6B43 Adjustment disorder	309.24 Adjustment disorder with anxiety ^d
F43.23 Adjustment disorder with mixed anxiety and depressed mood		309.28 Adjustment disorder with mixed anxiety and depressed mood ^d
F06.4 Anxiety disorder due to a known physiological condition	6E63 Secondary anxiety syndrome	293.84 Anxiety disorder due to another medical condition

Anxiety disorders in older people

Various disorders listed under F10-F19	Various disorders listed under 6C40.71-6C4G.71	292.8 Substance/medication-induced anxiety disorder
F41.8 Other specified anxiety disorders	6B0Y Other specified or fear-related disorders	300.09 Other specified anxiety disorder
F41.9 Anxiety disorder, unspecified	6B0Z Anxiety or fear-related disorders, unspecified	300.00 Unspecified anxiety disorder

^aIn ICD-11, Obsessive-Compulsive Disorder has been moved into a separate chapter: Obsessive-Compulsive or Related Disorders.

^bIn DSM-5 Obsessive-Compulsive Disorder has been moved into a separate chapter: Obsessive-Compulsive and Related Disorders.

^cIn ICD-11 Post-traumatic Stress Disorder and Adjustment Disorder have been moved into a separate chapter: Disorders specifically associated with Stress.

^dIn DSM-5 Acute Stress Disorder, Post-Traumatic Stress Disorder, and the Adjustment Disorders have been moved into a separate chapter: Trauma- and Stressor-Related Disorders. Epidemiology

There is now a substantial literature on the prevalence of anxiety disorders in older people, although a firm consensus is yet to emerge due to unresolved substantive and methodological issues. Bryant and colleagues (2008) have reviewed anxiety disorder prevalence estimates and associated methodological issues. Most population-based surveys find that the prevalence rates for anxiety disorders fall significantly after the age of about 50 years. The reasons for this oft-repeated observation are unclear. The observation that this effect begins in middle age makes it particularly challenging to explain using conventional age-related arguments. It has been suggested that the diagnostic interviews used to detect anxiety disorders are not appropriate for use in older people (O'Connor, 2006; O'Connor and Parslow, 2010), or that the diagnostic criteria themselves have intrinsic age biases. Using data from 1,738 self-reported worriers, Hobbs and colleagues (2014) investigated whether age influences the probability of endorsing GAD criteria and thus the prevalence of GAD. They found that respondents aged 60 years and over

Anxiety disorders in older people

were less likely than younger adults to endorse most of the GAD criteria. Although non-invariance of the GAD criteria was present, this had only a small impact on the prevalence of GAD. They argued that this finding supported the validity of age-related declines in GAD prevalence. Anxiety disorder prevalence rates are higher in women than men at all ages, including later life. However, there is some evidence that the sex difference in anxiety prevalence might decline in advanced old age (Pachana et al., 2012).

Table 42.2 provides a summary of non-hierarchical 12-month population prevalence estimates for anxiety disorders according to DSM-IV and ICD-10 criteria in persons aged 65–85 years and in persons aged 16–64 years, based on the 2007 Australian National Survey of Mental Health and Wellbeing (NSMHWB) (Australian Bureau of Statistics, 2007). This population survey employed trained lay interviewers, who used the Composite International Diagnostic Interview (CIDI). The survey included 1,905 community-residing persons aged 65 years and over, but it did not sample persons residing in hospitals, nursing homes, or caravan parks. The two diagnostic systems generated somewhat different prevalence estimates for panic disorder, agoraphobia, and PTSD, with ICD-10 providing higher estimates in each case. The survey did not measure the prevalence of simple phobia. The population prevalence estimates in Table 42.2 are associated with relatively wide confidence intervals (CI), indicating the level of imprecision with which the estimates were made. The variations in prevalence estimates between the DSM-IV and ICD-10 nosological systems can be explained by differences in their diagnostic criteria. To illustrate this, let us take panic disorder as an example. Both DSM-IV and ICD-10 require a person with panic disorder to experience multiple, unexpected panic attacks, and the definitions of a panic attack are similar under each system. The main difference is that ICD-10 requires the person simply to experience recurrent panic attacks (World Health Organization, 2010), whereas DSM-IV requires the person to experience recurrent panic attacks and one or more sequelae, including a persistent concern about having another attack, worry about the implications or consequences of the attack, or a significant change in behaviour following the attack (American Psychiatric Association, 2000). Thus, in NSMHWB, similar proportions of older people reported having experienced panic attacks in the past 12 months under the DSM-IV and ICD-10 criteria, but the absence in ICD-10 of the requirement for one or more panic attack sequelae meant that the prevalence of panic disorder was much higher under this system than when the DSM-IV criteria were applied (see Table 42.2). So, these different prevalence estimates do not reflect minor methodological issues, but major differences in the way disorders are conceptualized or formalized. These differences might need to be taken into consideration when basing service development or funding decisions on epidemiological data.

Anxiety disorders in older people

Table 42.2 Twelve-month prevalence rates for DSM-V and ICD-10 anxiety disorders.

	DSM-V 12-month prevalence (95% CI)		ICD-10 12-month prevalence (95% CI)	
	65-85 years	16-64 years	65-85 years	16-64 years
Generalized Anxiety Disorder	1.4 (0.8-1.9)	4.3 (3.8-4.7)	1.5 (1.0-2.1)	3.7 (3.3-4.1)
Panic disorder	0.5 (0.2-0.9)	2.2 (1.9-2.6)	0.9 (0.5-1.4)	3.1 (2.7-3.5)
Agoraphobia (+/- panic disorder)	0.3 (0.1-0.6)	1.6 (1.3-1.9)	1.0 (0.6-1.5)	3.4 (3.0-3.9)
Social phobia	1.2 (0.7-1.7)	5.4 (4.8-5.9)	1.3 (0.8-1.8)	5.8 (5.3-6.4)
Post-traumatic stress disorder	1.6 (1.1-2.2)	5.3 (4.8-5.8)	2.5 (1.8-3.2)	7.9 (7.3-8.6)
Obsessive-compulsive disorder	0.7 (0.4-1.1)	3.1 (2.7-3.5)	0.7 (0.4-1.1)	2.4 (2.0-2.7)
Any anxiety disorder	4.3 (3.3-5.2)	14.2 (13.4-15.0)	6.0 (4.9-7.1)	17.1 (16.1-17.9)

These population-weighted estimates were calculated from the confidentialized unit record file of the National Survey of Mental Health and Wellbeing, Australian Bureau of Statistics (2007). All diagnoses are non-hierarchical. Source: data from Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, DSM-5, 2013, American Psychiatric Association; data from International statistical classification of diseases and related health problems, 10th Revision, 2010, World Health Organization.

Anxiety disorders in older people

One method of attempting to sort out the validity of competing diagnostic approaches in a clinically meaningful way is to measure the degree of distress and disability associated with a diagnosis. Using the 12-item Short Form Health Survey (SF-12) to gauge disability, Slade and Andrews (2001) have shown in adults 18 years and over that DSM-IV GAD is associated with greater disability than ICD-10 GAD.

The Longitudinal Ageing Study Amsterdam (LASA) used a two-stage design to investigate the consequences of anxiety disorder and anxiety symptoms in people aged 55–85 years (de Beurs et al., 1999). The anxiety disorders studied were panic disorder, GAD, OCD, and phobic disorders. Older people with an anxiety disorder, or with anxiety symptoms, reported worse perceived health, greater loneliness, worse life satisfaction, and greater health services utilization than age-matched controls (de Beurs et al., 1999). In a US study of people aged 60–80 years who were seeking treatment for GAD and a matched control group, Wetherell and colleagues (2004) analysed quality of life using the 36-item Short Form Health Survey (SF-36). In this study, GAD was associated with worse health-related quality of life across almost all SF-36 domains and these associations were present regardless of whether GAD was complicated by comorbid psychiatric disorder. In addition, Porensky and colleagues (2009) demonstrated that older people with DSM-IV GAD have higher disability, worse health-related quality of life, and greater healthcare utilization than matched comparison participants without GAD.

The MentDis_ICF65+ study estimated the 12-month prevalence of anxiety disorders in people aged 65 to 84 years in five European countries and Israel (Canuto et al., 2018). The overall prevalence of any anxiety disorder adjusted for site, gender and age was 17.2% (95% CI: 14.0–20.4). The prevalence of any anxiety disorder was significantly greater in women (23.5%; 95% CI: 20.5–26.6) than in men (9.5%; 95% CI: 8.1–11.0) ($p < 0.001$). There was a significant linear downward trend in prevalence with age ($p < 0.001$). The prevalence of the individual anxiety disorders was as follows: panic disorder 3.8% (95% CI: 2.6–5.0), agoraphobia 4.9% (95% CI: 3.3–6.6), social phobia 1.3% (95% CI: 0.6–2.1), generalized anxiety disorder 3.1% (95% CI: 1.9–4.3), post-traumatic stress disorder 1.4% (95% CI: 0.4–2.4), and obsessive-compulsive disorder 0.8% (95% CI: 0.3–1.4). Of the individual anxiety disorders, agoraphobia and generalized anxiety disorder occurred more commonly in women.

The *incidence* of anxiety disorders in older people has been less well studied. However, using data from Wave 2 of the US National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) based on the Alcohol Use Disorder and Associated Disabilities Interview Schedule-IV (AUDADIS-IV), Chou et al. (2011) estimated the weighted three-year incidence of non-hierarchical DSM-IV anxiety disorders in 8,012 persons aged 60 years and over as follows: GAD 1.63%; specific phobia 1.35%; panic disorder 0.76%; and social phobia 0.58%. Incidence estimates for other anxiety disorders were not reported. Participants

Anxiety disorders in older people

aged 80 years and over were at greater risk of incident panic disorder than participants aged 60–79 years. PTSD at baseline predicted incident GAD, panic disorder, and specific phobia, whereas panic disorder at baseline predicted incident social phobia. In addition, personality disorder at baseline predicted incident GAD, panic disorder, and social phobia, but not specific phobia. Interestingly, after adjustment for other psychiatric disorders and sociodemographic factors, neither adverse life events nor measures of general health were related to incident anxiety disorder in this particular cohort (Chou et al., 2011; Mackenzie et al., 2011). It is not appropriate to compare the incidence rates from NESARC with the prevalence rates from NSMHWB as the age ranges, cohort characteristics, and diagnostic instruments all differed.

A significant minority of older people with an anxiety disorder also meet diagnostic criteria for a comorbid psychiatric disorder. For example, of older people with a DSM-IV 12-month anxiety disorder in the NSMHWB study, 60% met diagnostic criteria for a single anxiety disorder, 14% met criteria for at least one additional anxiety disorder, and 26% met criteria for at least one additional mood or substance use disorder. Similarly, of older people with a DSM-IV 12-month anxiety disorder, 78% had a comorbid physical disorder (Australian Bureau of Statistics, 2007). In contrast, of older NSMHWB participants with a 12-month history of affective disorder, 45.5% also had a 12-month history of anxiety disorder. These observations are important because there is a long-standing myth that pure anxiety disorder is uncommon in older people. Bereavement reactions are also commonly complicated by anxiety disorders, particularly GAD and PTSD (Zisook et al., 1990).

Although the prevalence of anxiety disorders in community-residing older people is lower than in young or middle-aged persons, older people with other health problems have been shown to experience a high prevalence of anxiety disorder. Smalbrugge and colleagues (2005) found that 29.7% of 333 Dutch nursing home residents had anxiety symptoms, 4.2% had subthreshold anxiety disorders, and 5.7% had an anxiety disorder. Residents with stroke or depression were at greater risk of an anxiety disorder. Chemerinski and colleagues (1998) assessed 398 patients with Alzheimer's disease and found that 5% met diagnostic criteria for GAD over the previous four weeks. In the Cache County study, Lyketsos and colleagues (2001) found that anxiety symptoms were present in 10–12% of patients with Alzheimer's disease of varying severities. Anxiety also occurs commonly in the context of mild cognitive impairment (Monastero et al., 2009). Moreover, it seems that individuals with normal cognition, but who are at increased risk of developing the clinical manifestations of Alzheimer's disease in the future, also have increased anxiety. Lavretsky and colleagues (2009) found that anxiety symptoms in middle-aged and older adults without dementia were associated with cerebral amyloid load, as demonstrated by 2-(1-{6-[(2-[fluorine-18]fluoroethyl)(methyl)amino]-2-naphthyl}-ethylidene)malononitrile positron emission tomography (FDDNP-PET) binding.

Anxiety disorders in older people

Burden of disease

The 2010 global burden of disease study aimed to identify all cases of DSM or ICD anxiety disorders worldwide and estimate associated levels of disability (Baxter et al., 2014). Anxiety disorders were ranked sixth in terms of years of life lived with disability (YLDs) in both high-income and low- and middle-income countries. There was marked regional variation in age-standardized disability-adjusted life years (DALYs) associated with anxiety, with the highest DALYs being found in North Africa, the Middle East, North America, Central Europe and Australasia and the lowest DALYs being found in East Asia, Eastern Europe, Sub-Saharan Africa, and Southeast Asia. DALYs associated with anxiety peaked in the 20- to 24-year-old age group and declined steadily with advancing age in both males and females.

In a total population study conducted in Denmark, mortality from natural and unnatural causes was increased in people with an anxiety disorder (Meier et al., 2016). For deaths from natural causes, the mortality rate ratio was 1.39 (95% CI: 1.28–1.51), and for deaths from unnatural causes, the mortality rate ratio was 2.46 (95% CI: 2.20–2.73).

Biological factors

Although the prefrontal cortex is involved in social cognition, it is the more phylogenetically ancient *limbic system* that is most involved in fear and anxiety responses. The limbic system includes the insular cortex, the cingulate gyrus, the hippocampus, and the amygdala. The amygdala is particularly important for the generation of panic (Davis, 1992) and there is evidence that fear responses in the amygdala are ‘hard-wired’ and difficult to extinguish (Sah and Westbrook, 2008). The presence of fear-related circuits involving the amygdala, insula, and anterior cingulate has been demonstrated in humans on neuroimaging studies with both functional magnetic resonance imaging (fMRI) and PET (Sehlmeyer et al., 2009).

The hippocampus modulates the activity of the hypothalamic–pituitary–adrenal axis, dampening down stress responses (Davis, 1992). There is evidence that both hippocampal volume and neurogenesis are implicated in the response to stress. Although more research in humans is needed, individuals with greater hippocampal volume and intact hippocampal neurogenesis appear to have greater resilience (Martin et al., 2009). In research on twins discordant for combat exposure in Vietnam, those with smaller hippocampi were vulnerable to PTSD following combat exposure, whereas twins with normal hippocampi or without combat exposure did not have an elevated rate of PTSD (Gilbertson et al., 2002). Thus, both the biological vulnerability demonstrated by small hippocampi and the environmental stimulus of combat exposure were necessary before PTSD developed.

Anxiety disorders in older people

Studies in monozygotic and dizygotic twins indicate that about 30–40% of the variation in the risk of anxiety disorder is of genetic origin (Norrholm and Ressler, 2009). No genes of large effect have yet been identified (Schumacher et al., 2011), so polygenic influences are likely. There is some evidence that genetic factors might play a greater part in the aetiology of panic disorder than of GAD. Polymorphisms in the promoter region of the 5-HT transporter gene have been linked to risk of anxiety disorder (Xie et al., 2009). Individuals who are homozygous for the s allele of this promoter exhibit greater fMRI responses in the amygdala to fearful stimuli and report higher levels of neuroticism (Davis, 1992). In a study of survivors of the Rwandan genocide, Kolassa and colleagues (2010) found that the risk of PTSD depended upon both the traumatic load and the catechol-o-methyltransferase Val(158)Met polymorphism. Individuals with Val polymorphisms developed PTSD following trauma in a dose-response manner, whereas trauma-exposed individuals homozygous for the Met/Met polymorphism were at high risk of PTSD regardless of the level of their traumatic exposure. A meta-analysis which examined 14 studies with 15,883 subjects confirmed this association (Zhao et al., 2017). This same genetic polymorphism might also predict response to treatment (Lonsdorf et al., 2010), although more work is needed before these findings are translated into clinical practice.

Experiments in laboratory animals demonstrate the importance of the early environment in the development of anxiety. Rats separated from their mothers for several hours a day in the early postnatal period demonstrate increased hormonal reactivity to stress and increased anxiety-related behaviours (Kalinichev et al., 2002). In addition, rats raised by mothers with impaired licking and grooming behaviour are at increased risk of developing anxiety, with cross-fostering experiments indicating that this effect is mainly of environmental origin (Liu et al., 2000). Although it is clear that anxiety symptoms and anxiety disorders are due to a combination of genetic and environmental factors, a question that arises is whether genetic influences are less important in later life. Gillespie and colleagues (2004) found that this was not the case for late-life anxiety and depression, although there were differences between genetic influences in men and women. More specifically, there were additional midlife and late-life genetic influences in women. Thus, it seems that genetic effects are still operating strongly in later life.

Psychological factors

Normal anxiety is conventionally divided into trait anxiety and state anxiety. Both are dimensional rather than categorical constructs. Levels of trait anxiety are relatively stable over the lifespan, indicating the influence of genetic and early environmental influences. In contrast, levels of state anxiety fluctuate over time, reflecting responses to aversive stimuli throughout life. However, state anxiety is also influenced by genetic factors. In the dimensional ‘five-factor’ model of normal personality, high neuroticism is associated with anxiety symptoms and all anxiety disorders. In addition, high conscientiousness is associated with

Anxiety disorders in older people

GAD and OCD, whereas low extraversion is associated with social phobia (Rosellini and Brown, 2011). In older adults, neuroticism and GAD are both moderately heritable (0.47 and 0.27, respectively), and approximately one-third of the genetic influence on GAD is shared with trait neuroticism (Mackintosh et al., 2006). Even in people with Alzheimer's disease, informant-rated premorbid neuroticism has been found to be associated with current anxiety on the Neuropsychiatric Inventory (Archer et al., 2007).

In both laboratory animals and humans, a new fear response develops when a harmless context or cue (conditioned stimulus (CS)) is paired with an aversive event (unconditioned stimulus (US)). Although the fear response to the CS can be extinguished by habituation—repeated exposure to the CS in the absence of the US—it is rapidly reinstated by either simultaneous re-exposure to the CS and US or sequential re-exposure to the US followed shortly by the CS, indicating that learned fear is strongly retained (Sah and Westbrook, 2008). This observation is likely to at least partially explain the chronicity of many anxiety disorders and why the response to short-term treatment is often poorly sustained. Avoidance behaviour leads to a temporary reduction in anxiety, which negatively reinforces (increases) avoidance behaviour. However, avoidance is not a successful long-term strategy as it makes anxiety worse by preventing habituation to the feared stimulus. Avoidance is thus key to maintenance of the fear response, and dealing with avoidance is critical to successful treatment of most anxiety disorders. Exposure and behavioural activation paradigms that reduce avoidance behaviours have been used as the basis for interventions for anxiety disorders (Cherbuin et al., 2008).

Hyperventilation is a common symptom of panic attacks, and for many years it was also considered to be a cause of panic (Griez and Schruers, 1998). However, inhaled carbon dioxide precipitates panic so it appears that it is hypercapnia, not hypocapnia, that leads to panic. This makes physiological sense, and has been referred to as the suffocation false alarm theory (Klein, 1993; Maddock, 2001). The relationships between panic, acid-base metabolism, and hyperventilation are complex and poorly understood, although it has been argued that chronic hyperventilation is a response to metabolic acidosis (Sikter et al., 2007).

There is evidence that anxiety disorders in later life are associated with childhood abuse or neglect. Analysis of data from the US National Comorbidity Study Replication (NCS-R) showed that childhood sexual abuse was associated with social phobia, panic disorder, GAD, and PTSD, whereas childhood physical abuse was associated with specific phobia and PTSD (Cougle et al., 2010). There is evidence also that childhood physical abuse is associated with an earlier age of onset of GAD (Gonçalves and Byrne, 2012a).

Anxiety symptoms

Anxiety disorders in older people

Anxiety symptoms are diverse but are conventionally clustered under the three headings of physical, mental, and emotional. Physical symptoms are multifarious and can be experienced in any bodily system. They include palpitations, dyspnoea, chest tightness, dizziness, sweating, itch, blushing, nausea, teeth grinding, choking, butterflies in the stomach, diarrhoea, frequent urination, fatigue, weakness, muscle tension, tremor, and insomnia. Mental symptoms include worry, rumination, depersonalization, derealization, poor concentration, and memory impairment. Worry can be about many different topics. Emotional symptoms include fear, dread, anger, depression, emotional numbness, irritability, and tearfulness. Fear can be directed towards many objects or situations. Anxiety is also associated with a variety of behaviours, including avoidance of feared objects or situations, and repetitive checking or washing.

Panic

Panic attacks are conventionally defined as rapidly escalating anxiety episodes in which fear and apprehension rise to a crescendo within ten minutes and then subside over several hours. Panic attacks are associated with a wide variety of physical symptoms, including shortness of breath, tachycardia, palpitations, a choking sensation, chest tightness, sweating, tremor, paraesthesiae, nausea, and hot or cold flushes. People experiencing a panic attack commonly catastrophize about their symptoms and fear collapse, stroke, or death. Sometimes they think they will 'go crazy' or embarrass themselves in front of others. People having a panic attack often make frantic attempts to escape from the situation in which the panic attack occurred. They often go on to develop anticipatory anxiety about having further panic attacks.

Worry

Worry is a core manifestation of generalized anxiety and can be conceptualized as an attempt to solve feared events with uncertain outcomes (Borkovec et al., 1983). Overall, older people report fewer worries than young or middle-aged people (Lindesay et al., 2006; Coelho et al., 2010). Worry in later life is often directed towards different content areas than in younger adults. While older people are more likely than younger adults to worry about the health and welfare of loved ones, they are less likely to worry about work, health, and interpersonal relationships (Gonçalves and Byrne, 2013). Thus, there appear to be developmental aspects to worry content. At first glance, it might seem counterintuitive that older people should report fewer worries than younger people, given the common challenges of ageing and likely reduced opportunities for older people to habituate through exposure. The consistently verified reduction in worry frequency with age has been attributed to several complementary factors, including increased emotional regulation, changes in daily demands, the influence of cognitive habituation mechanisms, and cohort effects (Gonçalves and Byrne, 2013). Other factors, including data censoring due to premature

Anxiety disorders in older people

death or institutionalization of worriers, and the use of assessment measures that are inappropriate for older people, might also explain some of the measured differences in worry prevalence (Gonçalves and Byrne, 2013).

Fear of crime among older people, especially older women, is a particular category of worry that is commonly promoted by mass media (Reiner, 2007). In most countries, it is associated with the paradox that older people are the least likely group to be either victims or perpetrators of crime. Of course, older people have lived longer than younger people and have thus had the opportunity to observe both more actual crime and more reports of crime. In a small US study, predictors of fear of crime among older people were found to be female gender, non-Caucasian ethnicity, depressive symptoms, and social isolation (Acierno et al., 2004). Housebound older women might experience greater levels of fear of violence than other groups (Barnett et al., 2007). In a UK study based on the Whitehall II cohort (middle-aged adults), fear of crime was associated with poorer physical and mental health and lower quality of life (Stafford et al., 2007). The specific association of fear of crime with anxiety disorders in later life needs further study.

Avoidance

Avoidance behaviour in older people can take many different forms and clinicians sometimes underestimate its severity and extent. Older people might avoid participating in everyday social activities by referring to commonplace physical complaints. They might give up driving a motor vehicle prematurely or stop doing the shopping. The risk for clinicians is that they might misinterpret this social withdrawal as the inevitable consequence of retirement or ageing, when it actually reflects avoidance behaviour associated with pathological anxiety. Identification of avoidance behaviour is important because avoidance makes anxiety worse, leading to its exacerbation and persistence. The persistence of avoidance behaviour in older people is often supported by well-meaning family members or carers, and sometimes by domiciliary services. Severe avoidance behaviour of the sort seen in agoraphobia almost always means that the patients have one or more supporters who help them maintain their behaviour. Even severe avoidance behaviour can be concealed for many years before coming to clinical attention, often precipitated by a change in care arrangements. Sometimes the term 'dependency' is used to describe the situation in which an older person is overly reliant upon others, although in many instances this should really be reframed as avoidance behaviour related to anxiety disorder.

Somatic symptoms

Older people have many more somatic symptoms than younger people due to the exponential rise in the prevalence of general medical problems with normal ageing. Older people are also thought to be more likely than younger people to minimize psychological symptoms and to convert

Anxiety disorders in older people

psychological distress into physical symptoms, although it is unclear the extent to which this is a cohort effect or a direct effect of psychophysiological changes associated with ageing. It is often difficult for the clinician to disentangle the symptoms of general medical conditions from somatic symptoms of anxiety. Indeed, both types of somatic symptoms are often present simultaneously in the same person.

Obsessions and compulsions

Obsessional ruminations and compulsive rituals are core features of OCD but are also found in other mental disorders, especially major depressive disorder. Obsessional ruminations commonly involve aggressive, sexual, repugnant, immoral, or religious themes, on the one hand; or doubt, contamination, checking, superstition, symmetry, or order, on the other (Garcia-Soriano et al., 2011). They seem to exist on a continuum with intrusive thoughts experienced by individuals without OCD. The level of insight that accompanies obsessional phenomena varies, with some people with OCD believing that their intrusive thoughts will come true. In some cases of severe OCD, obsessional thoughts may be difficult to distinguish from delusions. Compulsive behaviours also appear to exist on a continuum with normal rituals and they can sometimes be difficult to distinguish from one another (Muris et al., 1997). Rituals generally involve similar themes to obsessional ruminations, and often involve washing and checking behaviours. True compulsions are generally more frequent, more intense, and associated with more affect than normal rituals. Starcevic and colleagues (2011) investigated the functions of compulsions in adults with OCD and, not unexpectedly, found that compulsions are usually performed automatically to decrease stress or anxiety.

Flashbacks

During a flashback the older person re-experiences a traumatic event during the waking state, in contrast to dreams or nightmares in which this occurs whilst asleep. Flashbacks are a core component of acute stress disorder and PTSD.

Depersonalization and derealization

In depersonalization, patients feel as though they are watching themselves as if in a dreamlike state. There is a sense of unreality about the self. In contrast, in derealization, patients feel a sense of unreality about the outside world. Depersonalization and derealization are common phenomena in people with anxiety disorders, and are part of the reason that panic attacks can be associated with a sense of impending doom or the thought that one is losing one's mind.

Anxiety disorders

Anxiety disorders in older people

Panic disorder

To meet DSM-5 diagnostic criteria for panic disorder, panic attacks must be accompanied by at least four symptoms from a list, must peak within minutes, and must be unexpected. The practical problems with this definition are that panicky feelings are not always accompanied by the requisite four symptoms, do not always rise to a crescendo within minutes, and are often cued by contextual factors. As a consequence, panicky episodes are more prevalent than narrowly defined panic attacks, and subthreshold panic disorder is more prevalent than panic disorder. So, panic in older people is a larger clinical problem than the epidemiological data would suggest. While panic attacks are the defining feature of panic disorder, they occur in many other mental disorders, including major depressive disorder, GAD, alcohol withdrawal, and delirium. Older people with panic disorder are seen in the emergency department, where panic attacks mimic a variety of medical emergencies, including asthma and acute coronary syndrome. Panic attacks and panic disorder commonly precede the development of agoraphobia.

Agoraphobia

Agoraphobia involves fear and avoidance of situations from which escape might be difficult or in which help might not be available if a panic attack should occur (American Psychiatric Association, 2013). People with agoraphobia often avoid entering supermarkets, restaurants, or crowded shopping malls. They often have less trouble entering feared situations when accompanied by a trusted family member or friend. As time goes by, people with agoraphobia often gradually increase the range of situations they avoid, until they are quite limited in the situations they feel they can enter safely. People with agoraphobia tend to present for clinical care many years after the first onset of their panic attacks or avoidance behaviour. Agoraphobia is often a hidden problem in the sense that both patients and their family supporters tend to conceal it due to embarrassment.

Social anxiety disorder

People with social anxiety disorder (social phobia) experience fear, embarrassment, or humiliation in social situations, and experience anticipatory anxiety about forthcoming events. They avoid situations in which they feel other people may judge them. When avoidance is not feasible, they feel anxious and self-conscious around other people. Social phobia can be restricted to a certain social situation, such as public speaking, or it can be generalized. Social phobia can be precipitated by another psychiatric disorder, such as major depressive disorder or panic disorder. It is also commonly associated with substance use disorders, particularly alcohol abuse and dependence. Although social phobia is not an uncommon diagnosis in epidemiological surveys, older people with this condition rarely present for treatment. This might be because older people are not particularly disabled by social phobia due to reduced

Anxiety disorders in older people

social and occupational demands in later life. There has been some controversy about the nosological status of social phobia, including concerns about medicalization of normal shyness.

Generalized anxiety disorder (GAD)

As conceptualized in DSM-5, the diagnosis of GAD requires the patient to have multiple worries that are experienced as excessive and that have persisted for six months or more. Older people with GAD report similar worry content to older worriers without GAD, but greater worry frequency (Diefenbach et al., 2001). This observation highlights the issue of whether GAD should be conceptualized as a dimensional disorder, rather than a categorical disorder. In comparison with non-pathological worriers, those with GAD differ also in the extent to which they can control their anxiety and in the level of distress associated with their anxiety (Ruscio, 2002). Worry is the predominant symptom in GAD, to the extent that Andrews et al. (2010) have argued that the disorder should be renamed *generalized worry disorder*, *major worry disorder*, or *pathological worry disorder*, in DSM-5. GAD appears to precede Major Depressive Disorder (MDD) more often than MDD precedes GAD. Gonçalves and colleagues (2011) found that GAD in older people was associated with functional limitations, psychiatric comorbidity, and increased medication intake.

Specific phobia

Specific phobia involves avoidance of feared objects (e.g. spiders, moths) or situations (e.g. flying, lifts). Although specific phobia is highly prevalent, it is not often the focus of therapeutic attention in old age psychiatry practice, mainly because it is generally associated with little distress or disability, apart from when the patient is actually confronted by the phobic stimulus. Older people are often able to avoid their phobic stimuli. Some specific phobias resolve without formal treatment, but some cause significant distress and disability.

Fear of falling is a relatively distinct psychosyndrome in later life with features of both specific phobia and agoraphobia (Coelho et al., 2010). It is associated with considerable disability for many older people. At least 30% of persons aged 65 years and over fall each year and one-fifth of these falls require medical attention (Stel et al., 2004). Falls are even more prevalent in older people with dementia (Allan et al., 2009) and in those taking psychotropic medication (Hill and Wee, 2012). Approximately one-quarter of those who fall develop fear of falling (McClure et al., 2005).

Post-traumatic stress disorder

PTSD is reported to develop in about 15–20% of older people exposed to life-threatening trauma but the measured prevalence might increase following removal in DSM-5 of the requirement to experience ‘intense fear, helplessness or horror’ at the time of the traumatic exposure

Anxiety disorders in older people

(Friedman et al., 2011). Classically, PTSD follows combat exposure, armed holdup, rape, and violent assault. It is also seen in emergency workers required to deal with multiple trauma cases, and following disasters. In older people, PTSD has often developed earlier in life during military service, but can also develop *de novo* following adverse life events in later life. Sometimes PTSD does not develop immediately following exposure to the traumatic event, but following an extended delay. Characteristic symptoms of PTSD include intrusive re-experiencing of the traumatic event through flashbacks and nightmares. These intrusive phenomena are usually accompanied by hyperarousal, emotional numbness, and avoidance behaviour. Symptoms of hyperarousal include impaired concentration, lowered startle threshold, hypervigilance, and insomnia. Emotional numbness leads individuals to feel that they can no longer experience emotions normally and that their interpersonal relationships are impaired. Avoidance behaviour commonly involves avoiding the scene of the traumatic exposure or avoiding reminders of the trauma. Many other symptoms occur in PTSD, including dissociation and substance abuse. In older people, PTSD has often been present for many years following combat exposure or wartime rape and other atrocities. Older refugees are particularly at risk of PTSD. Older victims of natural disasters such as floods, fires, and earthquakes are also at risk of PTSD.

Obsessive-compulsive disorder

OCD is characterized by obsessional ruminations and compulsive rituals. Obsessions are thoughts, images, and impulses that lead to psychological distress. Patients experience obsessions as being the product of their own mind and generally have insight into them. Compulsions can be observable behaviours (rituals) or unobservable behaviours (mental compulsions). Compulsions are considered to represent an attempt by the patient to undo obsessional thoughts, prevent harm, or reduce anxiety. Although obsessions and compulsions are the defining characteristics of OCD, they do occur in other mental and neurological disorders.

Of particular relevance to OCD in older people, hoarding is often performed because of a perceived need for collected objects rather than for reasons common to other compulsions. Hoarding behaviours appear to occur commonly in the general population (Timpano et al., 2011) and are linked to compulsive buying behaviours (Mueller et al., 2009). There is also evidence that hoarding is associated with multiple neurological and psychiatric disorders, including depression and anxiety (Mataix-Cols et al., 2011; Reid et al., 2011). Hoarding also overlaps with severe domestic squalor (Snowdon and Halliday, 2011). Moral or religious scrupulosity is often viewed as a symptom of OCD. Although more commonly encountered in older members of the clergy, it can be seen among laity as well.

Anxiety disorders in older people

Mixed anxiety and depression

Some older people experience a mixture of anxiety and depressive, although the prevalence of these mixed states is in dispute. As previously noted, there is some comorbidity between GAD and major depressive disorder. In addition, there is a group of older people who experience symptoms of both anxiety and depression without meeting diagnostic criteria for a mood or anxiety disorder. The diagnostic entity of mixed anxiety and depressive disorder exists in ICD-10 and ICD-11, but not DSM-5. Because of the dimensionality of both anxiety and depressive symptoms, and because mixed subthreshold states appear to be common among older people, this is a useful diagnostic category.

Anxiety and agitation in dementia

One question that arises is can *anxiety* be distinguished from the *agitation* associated with dementia? It is difficult to give a straightforward answer to this question because both anxiety and agitation are words that describe complex arrays of human behaviours. There is clearly some overlap between the constructs (Twelftree and Oazi, 2006), but also many differences between the two. The term agitation is commonly used to describe a broad range of behaviours in people with dementia. Agitation is also used to describe a category of behaviour in people with delirium and a different category of behaviour in people with depression. So, the legitimate question arises if anxiety can reliably be distinguished from agitation? In a large factor analytic study of untreated patients with dementia due to Alzheimer's disease, Spalletta and colleagues (2010) found that anxiety and agitation loaded on separate factors. Anxiety loaded on a factor with depression, whereas agitation loaded on a factor with irritability and aberrant motor behaviour. Although this finding alone is unlikely to settle the matter, it does suggest that these terms should not be conflated.

Anxiety and suicide

There is robust evidence linking suicide attempts with anxiety disorders. Using data from the US NESARC study, Nepon and colleagues (2010) found that among adults reporting a lifetime history of suicide attempts, 70% had an anxiety disorder. In multivariate models, PTSD and panic disorder were independently associated with suicide attempts. Individuals with PTSD or panic disorder who also had a personality disorder had an even greater risk of suicide attempts (Nepon et al., 2010). In a 15-year national clinical survey of suicide in the UK, Voshaar and colleagues (2015) found that of the 4,481 persons aged 60 years and over who died by suicide, 742 (16.6%) had either a primary or a comorbid anxiety disorder.

Assessment

Anxiety disorders in older people

Every psychiatric assessment interview should include screening questions for anxiety symptoms, given the high prevalence of anxiety symptoms and anxiety disorders. At a minimum, worry, panic, obsessions, and compulsions should all be covered. It is important to be aware of limited-symptom panic attacks. These subthreshold panic attacks are characterized by fewer than the four panic symptoms required by DSM-5 definition of a panic attack. The clinician should also make specific inquiry about the nature and extent of avoidance behaviour in older people presenting with anxiety symptoms. Avoidance behaviour can manifest as 'taking to the bed' with non-specific somatic symptoms, or be more subtle or camouflaged in some way, perhaps with the older person declining routine social invitations, only leaving the home in the company of others, not watching the television news, or avoiding talking about or even thinking about certain topics. As anxiety increases the risk of suicide attempts, the clinician should ensure that suicidality is covered during the assessment of older people with anxiety. Anxiety often flares up in response to adversity, so assessment of exposure to adverse life events is essential. A life-history approach is often useful to chart the correspondence between life events and anxiety symptoms. If a behavioural intervention is intended, then a behavioural analysis is a necessary preparatory step.

Informant interviews

Informant interviews are an essential component of the assessment of older people with suspected cognitive impairment or dementia. They are also useful in older people with anxiety disorders. Some older people minimize the extent of their avoidance behaviour or the relationship of this to their anxiety symptoms. An appropriate informant, usually a close family member, can often shed useful light on this avoidance behaviour. An informant can also often provide collateral information about the use of substances, including alcohol and benzodiazepines. In most countries, older people are free to consult as many different doctors as they wish. In so doing, they are at liberty to obtain multiple prescriptions for sedative and hypnotic drugs. When older people with anxiety disorders are seen in specialist settings, they have generally been referred by only one of the doctors with whom the patient has had contact. In such circumstances, an informant can provide an important insight into the drug-seeking or drug-using behaviour of the patient. Of course, consent must be obtained from the patient before consulting an informant.

Rating scales

It is often useful to measure the severity of anxiety during assessment or treatment. Many scales are available to measure anxiety in adults, but very few have been specifically designed for use in older people. Self-report scales for use by older people, particularly the frail older person, require certain modifications. Ideally, such measures should avoid multiple somatic items, reversed items, and complex response scales (Dennis et al., 2007). The Short Anxiety Screening Test (SAST) is a 10-

Anxiety disorders in older people

item self-report measure with a four-item response scale (Sinoff et al., 1999). The SAST was designed specifically for use in older people, although it does contain multiple somatic items. The Geriatric Anxiety Inventory (GAI) is a 20-item self-rating scale designed to assess generalized anxiety in older people (Pachana et al., 2007a). It employs straightforward language and dichotomous (agree/disagree) ratings, and minimizes the use of somatic items. There is also a five-item version for screening (Byrne and Pachana, 2011). The GAI is now available in 20 languages. The Geriatric Anxiety Scale (GAS) is a 30-item self-rating scale with a four-item response scale (Segal et al., 2010). There is also a ten-item version of the GAS. The psychometric properties of the GAI and the GAS were compared in a sample of 110 older people with a mean age of 75 years (Gould et al., 2014). Both the GAI and GAS had good psychometric properties, with the GAI having better discriminant validity.

Substance abuse

Older people with clinically significant anxiety often abuse alcohol or benzodiazepines. They frequently minimize their intake of these substances or minimize the likely link between their intake and their anxiety symptoms. Substance abuse and dependence can be the direct cause of anxiety symptoms or can be the consequence of self-medication of a pre-existing anxiety disorder. In older people with mild cognitive impairment or dementia, particularly those living alone, alcohol abuse can be unsuspected, even by members of their immediate family. In office practice, it helps to have a knowledgeable informant who can provide collateral information about substance use. A domiciliary visit can often help clarify an older person's likely alcohol intake. Clinicians should maintain a high index of suspicion for substance abuse and dependence in older people with anxiety disorders.

Medications associated with anxiety

Many medications used to treat mental disorders and general medical conditions are associated with anxiety symptoms, and sometimes the most effective intervention is the cessation of unnecessary medication. Sympathomimetics, corticosteroids, oestrogen, antihistamines, interferon, TNF-alpha, and thyroid hormones have all been associated with anxiety symptoms. In addition, psychotropic drugs, including anxiolytics, antidepressants, mood stabilizers, and antipsychotics can cause anxiety symptoms.

Physical work-up

Older people who present with anxiety symptoms for the first time in later life should be investigated for underlying general medical problems. Even those older people who have a distant past history of anxiety symptoms but who have been symptom-free for many years should undergo screening tests for potential underlying general medical problems. At a minimum, a systems review should be undertaken and vital signs should be recorded. In first-onset cases of anxiety disorder in later life, more

Anxiety disorders in older people

detailed neurological and cardiovascular examination is prudent. Selected laboratory tests, including full blood examination, serum electrolytes, serum glucose, thyroid stimulating hormone (TSH), and urinalysis should be ordered. If psychotropic medication is to be prescribed, then pre-treatment liver function tests and an electrocardiogram (ECG) should be added to the list. If there is any suggestion of substance abuse then a urine drug screen should be ordered. Electroencephalography (EEG) can help exclude epilepsy and delirium, if these are suspected clinically. Neuroimaging has a low yield in late-life anxiety disorders, but if underlying cerebrovascular disease is suspected then a structural brain scan (MRI or CT) might be warranted to assess the extent of this. Serological tests for syphilis, hepatitis, HIV, and other infections should be reserved for particular cases in which the history suggests greater than normal risk. Older patients with unusual presenting symptoms should undergo more detailed physical investigation.

Management

There is actually quite a lot for the clinician to do when managing anxiety in older people. Paying close attention to some straightforward general principles is likely to greatly assist the patient, so these are described here first. Anxiety of moderate severity or greater is likely to require formal psychological treatment, pharmacological treatment, or both. Several classes of drugs have been used in the treatment of anxiety symptoms and anxiety disorders in older people and several types of behavioural and psychological treatments have been used.

General measures

Substance use

Both excessive consumption of nicotine, caffeine, and alcohol and withdrawal from these substances are commonly associated with anxiety symptoms. People with anxiety disorders also self-medicate with these substances. Some older people require specific advice about minimizing their exposure to these legal substances. Medications used to treat general medical conditions may also be associated with anxiety and insomnia. These include sympathomimetics, corticosteroids, thyroid hormones, antimicrobials, oestrogen, and antihistamines. Diuretics commonly disrupt sleep and are generally best taken earlier in the day. Stimulants including methylphenidate and dexamphetamine are used occasionally to treat adult attention deficit hyperactivity disorder (ADHD) and apathy in older people. These medications are commonly associated with weight loss, insomnia, and anxiety. Some antidepressant medications have stimulant effects in vulnerable older people, and selective serotonin reuptake inhibitors (SSRIs) commonly cause an initial increase in anxiety and insomnia.

Although older people are less likely than young or middle-aged people to use illicit substances, there are cohort effects at work that might lead to

Anxiety disorders in older people

increased rates of substance abuse in older people in the future (Wu and Blazer, 2011). Cannabis, amphetamine, cocaine, and opiates can all cause anxiety symptoms. Thus, a careful review of current substance use, both licit and illicit, is recommended.

General medical conditions

Many general medical conditions are associated with anxiety, either directly or indirectly. Although a direct mechanism has not been fully elucidated, it is likely to involve cytokine production at sites of inflammation. An indirect mechanism involves a psychological reaction to pain, discomfort, and disability, as well as increased dependency upon others and a sense of an altered future, associated with many diseases. Hyperthyroidism, paroxysmal supraventricular tachycardia, atrial fibrillation, asthma, chronic obstructive lung disease, epilepsy, and systemic lupus erythematosus have all been associated with anxiety disorder. Parkinson's disease is associated with a particularly high rate of anxiety disorder (Broen et al., 2016). Thus, optimal management of patients' general medical conditions is an integral component of management of their anxiety disorder.

Physical activity

In older people, physical activity has general benefits for health, particularly in maintaining or improving bone density, muscle strength, and cardiovascular fitness. In addition, physical activities such as walking, cycling, and swimming have anxiolytic effects. Exposure to interoceptive stimuli, such as increased rate and depth of breathing, increased heart rate, and perspiration, acts as a form of non-specific exposure in people with anxiety disorders. This exposure to interoceptive stimuli is associated with reduced anxiety sensitivity (Barbour et al., 2007). If the physical activity is undertaken outdoors, or in a public setting such as a gym, it also acts as exposure to exteroceptive stimuli.

Sleep hygiene

Sleep architecture changes gradually with increasing age and sleep continuity declines in many older people (Harbison, 2002). Some people interpret these normal changes as indicative of a sleep disorder, when they are not. Nevertheless, insomnia does reduce the quality of life of many older people, particularly those who suppress their REM sleep with hypnotic medication, or those who worry excessively about their sleep continuity or duration. Improvements in sleep duration and quality can lead to reduced anxiety. Routine sleep hygiene recommendations include ensuring that the sleeping environment is satisfactory. In practice, this means having a comfortable bed and pillow, maintaining the bedroom at an appropriate temperature, and ensuring the sleeping environment is both quiet and dark. It is also important to reserve the bedroom for sleep and sexual activity, and not remain in bed if unable to sleep. In this way, the bedroom is associated with sleep, rather than wakefulness. It is also

Anxiety disorders in older people

recommended that people with a sleep initiation problem do not undertake vigorous physical exercise in the hours immediately before bedtime, although physical exercise during the day generally assists initiation and maintenance of sleep (Loprinzi and Cardinal, 2011).

Because of their potential to stimulate some people with insomnia, it is recommended that television and other electronic displays should not be watched in the bedroom. From a behavioural perspective, it is useful to have a bedtime routine that conditions one to expect sleep.

Psychological interventions

For pragmatic reasons, psychotropic medications are commonly used as first-line treatments for anxiety disorders in older adults, particularly in primary care settings. However, expert opinion generally advises the use of a psychosocial intervention for anxiety disorders of mild to moderate severity and combination treatment with a psychosocial intervention and a psychotropic medication for more severe anxiety disorders. In old age psychiatry services, most anxiety disorders will be at least moderate in severity and will often occur in comorbid relation to other disorders, including mood disorders, psychotic disorders, and substance use disorders. Thus, combination treatment with a psychosocial and psychopharmacological intervention will generally be indicated in these specialist mental health care settings.

Therapeutic alliance

A supportive relationship with a mental health clinician is likely to be of considerable value to the anxious older person, and time spent developing a durable therapeutic alliance is well worth the investment. Psychological and behavioural interventions that provide older people with an improved set of coping skills are likely to be of enduring benefit to them. Older people with anxiety disorders are often helped by a longer-term relationship with a mental health worker. Patients who are allocated to medical personnel who move rapidly through different treatment teams as part of their training should also be allocated a case manager or staff psychologist who has a continuing appointment. In this way, continuity of care can be provided. An effective therapeutic alliance is likely to be particularly important if the clinician will be recommending to the patient either formal exposure therapy (e.g. systematic desensitization) or a reduction in avoidance behaviour. The perceived counterintuitive nature of these interventions requires patients to trust their clinicians to a greater extent than usual.

Psychoeducation

Many older people with anxiety symptoms and anxiety disorders suspect that they have serious physical problems. As a consequence, psychoeducation is an essential component of any anxiety management plan. In some cases, psychoeducation alone leads to a clinically significant improvement in anxiety symptoms as the older person reframes their problem. In people with cognitive impairment or

Anxiety disorders in older people

intellectual disability it is essential that psychoeducation is provided to their family and carers.

Relaxation training

Relaxation training is an essential component of the treatment of anxiety symptoms and anxiety disorders in older people. Many different types of relaxation training have been described, although three techniques are in common use: progressive muscular relaxation, reciprocal inhibition via visual imagery, and controlled breathing. Progressive muscular relaxation is most suitable for those older people without significant sarcopenia or joint deformity, whereas the other two techniques can be used by most older people without cognitive impairment.

Cognitive behaviour therapy

There is a growing body of evidence in support of the use of cognitive behaviour therapy (CBT) to treat GAD in older people. A meta-analysis of CBT versus control conditions for GAD in older people identified 11 small clinical trials with usable data (Gonçalves and Byrne, 2012b). CBT was superior to control conditions with a pooled odds ratio of 0.33 (95% CI: 0.17–0.66). The superiority of CBT was demonstrated in those studies that used usual care or a waiting list as the comparison condition, but not in those that compared CBT to an active comparator. This observation raises questions about the specificity of CBT and suggests that other interventions could have similar efficacy. Similar findings have been reported from a randomized controlled trial of group CBT targeting tolerance of uncertainty in older people with GAD undertaken in Beijing, PRC (Hui and Zhihui, 2017). Suitable modifications for the use of CBT or its components in older people have been detailed by Laidlaw and colleagues (2003) and by Pachana and colleagues (2007b). These include an increased number of sessions to allow more time for participants to develop an understanding of the therapy and its associated homework tasks, explicit learning aids, and manuals with larger print size. CBT techniques are also used in the management of several other anxiety disorders in older people, although without the same level of empirical evidence. Various modifications to CBT have been elaborated. Roberts and Sedley (2016) detailed the rationale for acceptance and commitment therapy with older people, and Helmes and Ward (2017) demonstrated the efficacy of mindfulness-based cognitive therapy for anxiety symptoms in older nursing home patients.

Behaviour therapy

In some older people with anxiety disorders, it is not practicable to implement the cognitive components of CBT. This can occur when the older person has significant cognitive impairment or intellectual disability. It can also occur when older people do not view their problem in psychological terms and remain impervious to psychoeducation. In such situations it makes sense to apply behavioural interventions alone.

Anxiety disorders in older people

The principles of behavioural activation can be employed (Ekers et al., 2011; Snarski et al., 2011). These emphasize graded activity scheduling and a reduction in avoidance behaviours. In one study involving adults with major depression, behavioural activation outperformed CBT and was comparable to antidepressant medication (Dimidjian et al., 2006). There is preliminary evidence that such an approach might be applicable to older adults with anxiety disorders as well (Pachana et al., 2007b).

Exposure therapy is the treatment of choice for agoraphobia, social phobia, and specific phobia. As flooding is rarely appropriate or practicable, systematic desensitization is the usual exposure method employed. This involves the preparation of a hierarchical list of phobic cues in close consultation with the patient. The phobic cues are listed from least aversive to most aversive. Exposure tasks are then designed to enable the patient to systematically work through the list from least aversive to most aversive. An individualized approach is necessary, as the time needed to master each step will vary from patient to patient. Many patients find themselves unable to engage in exposure therapy without the assistance of a confederate. This should usually be a clinician rather than a family member, as family members often overtly or covertly sabotage exposure activities. However, the ultimate aim of systematic desensitization is for patients to be able to repeatedly expose themselves to the phobic object or situation without the assistance of another person. In OCD, compulsive rituals are generally treated with exposure and response prevention. This is an effective treatment when rigorously applied. Obsessional ruminations can be treated with either antidepressant medication or CBT, or both. Because exposure therapy does lead to a temporary increase in psychological distress, it must be undertaken with the informed consent of the patient. Deception is not part of exposure therapy for anxiety disorders.

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) uses four principal models to engage the patient. These models address i) issues that arise in relation to grief following loss of a loved one, ii) conflict in relationships, iii) adapting to change in life circumstances, and iv) social isolation. It is not difficult to see that generalized anxiety symptoms and phobic avoidance behaviour could easily arise in relation to each of these challenges that occur commonly in later life. Despite this, there are limited data in support of the use of IPT in the management of anxiety disorders in older adults, although it is used for the management of depression in late life (Reynolds et al., 1999).

Problem-solving therapy

A reduced capacity to solve everyday problems has been linked, directly and indirectly, to anxiety. The indirect link is with impaired problem-solving and worry, which in turn lead to anxiety (D’Zurilla and Nezu, 2007, pp. 80-81). The clinical approach to problem-solving therapy

Anxiety disorders in older people

involves iterative cycles of problem definition and formulation, generation of alternative solutions through brainstorming and other techniques, and identification of the most effective solution (D’Zurilla and Nezu, 2007, pp. 95–148). Although much of the research on problem-solving therapy has been conducted in young and middle-aged persons, or in older people with depression rather than anxiety, there has been some recent work in older adults with anxiety. In a pragmatic randomized controlled trial conducted in the Netherlands, six weeks of bibliotherapy involving problem-solving techniques and systematic desensitization was superior to treatment as usual in older primary care patients with an anxiety disorder but no comorbid depression (Seekles et al., 2010). In contrast, a Hong Kong clinical trial that compared brief problem-solving therapy with group viewing of health videos in primary care patients with elevated Hospital Anxiety and Depression Scale scores did not find a significant difference between treatment arms (Lam et al., 2010). There is evidence of the superiority of problem-solving therapy to supportive therapy in older people with depression (Alexopoulos et al., 2011), but further research is needed in older people with anxiety disorders in order to establish the place of PST in late-life anxiety disorders.

Other types of therapy

If anxiety symptoms arise in the context of interpersonal conflict, within a marital relationship or its equivalent, or within a family, then consideration should be given to couples therapy or family therapy. Psychoanalytic psychotherapy has been used historically to treat chronic anxiety symptoms, but not commonly in older people. There is little conventional evidence for this approach in this age group.

Medication

Drug therapy is generally unhelpful in the management of specific phobias, which usually respond to behaviour therapy, particularly exposure-based treatments employing systematic desensitization. Drug therapy does have a role in the management of the other anxiety disorders, particularly in combination with some type of psychotherapeutic intervention. A meta-analysis of clinical trials of psychotropic medication for GAD in older people identified nine brief clinical trials with usable data, including eight trials with a placebo comparator (Gonçalves and Byrne, 2012b). Medication was superior to the control condition with a pooled odds ratio of 0.32 (95% CI: 0.18–0.54). Benzodiazepines, antidepressants, and quetiapine all demonstrated short-term efficacy.

Benzodiazepines

Benzodiazepines operate at the GABA_A receptors of the brain’s main inhibitory neurotransmitter GABA (γ-aminobutyric acid). There is cross-reactivity with alcohol at this receptor complex. Benzodiazepines remain in widespread use in older people with anxiety disorders, although the evidence in support of their use is rather limited. They appear to have

Anxiety disorders in older people

short-term efficacy in the management of panic attacks, generalized anxiety, and insomnia. However, their long-term effectiveness is uncertain and their use is associated with a range of adverse effects in older people, including anterograde amnesia, confusion, and falls. Tolerance develops rapidly and abrupt cessation of benzodiazepines is often associated with withdrawal phenomena. Both patients and clinicians find it difficult to distinguish benzodiazepine withdrawal phenomena from the pre-existing anxiety, thus perpetuating the use of these agents. Benzodiazepines suppress REM sleep (Hemmeter et al., 2000) and rebound effects can be encountered following their withdrawal. Withdrawal phenomena appear most severe following long-term use of high doses of short-acting agents. A small proportion of older people prescribed benzodiazepines develop paradoxical effects such as excitement or agitation. When benzodiazepines are used in the management of anxiety symptoms, including insomnia, they should ideally be used for short periods (two to four weeks) while other treatments are introduced. Drugs such as oxazepam and temazepam, which do not undergo hepatic oxidation, are generally preferred in older people. Because of its slow rate of absorption, oxazepam is useful for the treatment of middle insomnia, whereas temazepam is more useful for initial insomnia. Modern benzodiazepine replacements such as zopiclone, zolpidem, and zaleplon have shorter half-lives than the benzodiazepines and are less likely to be associated with morning sedation. However, they otherwise seem to confer few advantages. Although the benzodiazepines have short-term efficacy in many of the anxiety disorders, they are considered ineffective in OCD and of limited value in PTSD.

Antidepressants

Antidepressants are preferred for the pharmacological treatment of the anxiety disorders, although their use in this context does have some challenges. The SSRI antidepressants are the usual first-line medications in older people with panic, social phobia, GAD, OCD, and PTSD. They appear to be of no value in specific phobia. SSRIs take effect much more slowly than benzodiazepines, with longer-term effects on the sensitivity of auto-receptors leading to increased availability of synaptic 5-HT. The SSRIs are commonly associated with an initial increase in tremor, insomnia, and anxiety, and anxious older patients should be warned about this, lest they become concerned that their underlying disorder is deteriorating. It is sometimes necessary to use a low-dose benzodiazepine for a week or two to get the patient through the initial adverse effects of an SSRI, particularly in somatically focused patients. A greater challenge for prescribers is that patients who have had experience with the rapid onset of action of the benzodiazepines are often dissatisfied with the relatively slow onset of action of antidepressants. There appears to be little to choose between the available SSRI antidepressants in terms of their anxiolytic effects. However, paroxetine has more anticholinergic effects than the other drugs in this class and for this reason is generally less favoured in older people. The long half-life of fluoxetine is associated

Anxiety disorders in older people

with both risks and benefits, but fluoxetine is generally not the first choice in older people. Citalopram and escitalopram are associated with prolongation of the electrocardiographic QTc interval and it has been recommended that they be restricted to 20 mg and 10 mg daily, respectively, in older people (Medicines and Healthcare Products Regulatory Agency, 2011). Fluvoxamine is a sedating SSRI, which is often well tolerated in anxious individuals, although it does have a greater potential for drug–drug interactions than the other drugs in its class due to effects on the hepatic enzyme system.

The SSRIs have significant adverse effects in older people. These include initial worsening of anxiety and insomnia, hyponatraemia, sexual dysfunction, and falls. They are also associated with increased bruising and bleeding in patients on anticoagulants and antiplatelet drugs. Hyponatraemia occurs most commonly in women on thiazide diuretics, and often within six weeks of initiating antidepressant treatment. The symptoms of hyponatraemia can mimic those of worsening anxiety or depression, and can also include fatigue and confusion. The true prevalence of hyponatraemia is unknown but it is a frequent occurrence on inpatient wards. The clinician is advised to check the serum sodium in older patients on antidepressant medication whose clinical condition is deteriorating. All antidepressants can precipitate mania and hypomania in vulnerable individuals, but this is relatively uncommon and is not a reason to avoid these drugs in older people with clinically significant anxiety. The reported increased risk of suicide in patients commenced on SSRI antidepressants does not seem to be relevant to older people, in whom treatment with SSRIs is associated with a reduced suicide risk (Barbui et al., 2009).

Other classes of antidepressants, including the serotonin and noradrenaline receptor inhibitors (e.g. venlafaxine, desvenlafaxine, duloxetine), drugs with mixed receptor activity (e.g. mirtazapine), and the older tricyclic drugs are also used in the pharmacological management of anxiety in older people. Among the tricyclic antidepressants, nortriptyline appears to have the best safety profile in older patients. Historically, clomipramine has had a special place in the treatment of severe OCD, although its adverse effect profile makes it challenging to use in many older people. However, it is not entirely clear whether clomipramine is superior to intensive exposure and response prevention (Foa et al., 2005). The noradrenaline reuptake inhibitor reboxetine and the older, irreversible, monoamine oxidase inhibitor drugs are not usually used in the management of anxiety disorders in older people. The serotonin antagonist and reuptake inhibitor (SARI) trazodone does have anxiolytic effects, but it is not well studied in older people with anxiety disorders.

The 5HT_{1A} receptor partial agonist buspirone has been used in treatment of GAD in older people for many years. It has a slow onset of action and seems to be most useful in benzodiazepine naïve patients. It has a number of drug–drug interactions and should not be used by people who are currently taking or who have recently been taking monoamine

Anxiety disorders in older people

oxidase inhibitors. Agomelatine is an antidepressant with melatonergic (MT₁, MT₂) receptor agonist and 5-HT_{2A} receptor antagonist properties that appears to reduce sleep latency without causing daytime drowsiness. There is some limited evidence for its efficacy in GAD in adults (Stein et al., 2008), but there have been no clinical trials for this indication in older people.

In older people, antidepressants are generally commenced at half the usual starting dose used in younger adults and the dose is titrated upwards more slowly. Sometimes the final antidepressant dose is lower than that used in younger people, although many older people require the same final doses as younger people to achieve efficacy. As a broad generalization, the antidepressant dose required to treat anxiety disorders is often the same or greater than that required to treat depression.

Antipsychotics

Atypical antipsychotic drugs, particularly quetiapine and risperidone, are sometimes used in the management of the symptoms of both GAD and PTSD in adults. However, evidence for the use of antipsychotics for these indications in older adults is meagre (Ahearn et al., 2011; Gonçalves and Byrne, 2012b). Cerebrovascular adverse events (strokes and transient ischaemic attacks) and excess mortality have been described in association with the use of antipsychotic medication in older nursing home residents with dementia complicated by behavioural and psychological symptoms (Sacchetti et al., 2010), although a case-control study conducted in patients with dementia in the primary care setting did not identify similar problems (Laredo et al., 2011). Nevertheless, it would seem prudent to minimize the use of antipsychotic medication in older people with nonpsychotic disorders in the absence of long-term efficacy and safety data.

Anticonvulsants

There is some evidence for the use of anticonvulsants in adults with anxiety disorders, including the use of gabapentin in social phobia, lamotrigine in PTSD, and pregabalin in social phobia and GAD (Mula et al., 2007). However, there is a scarcity of evidence relating specifically to the use of anticonvulsants in older people with anxiety disorders.

Other drugs

Lithium carbonate is rarely used for the treatment of anxiety disorders, apart from when it is used to augment other agents that are being used to treat comorbid disorders. Lithium is not recommended for the treatment of older people with anxiety disorders. Beta-adrenergic blockers, principally propranolol, have been used to reduce performance-related tremor in musicians. Clonidine has been used to assist in the management of preoperative anxiety.

Anxiety disorders in older people

Conclusion

Anxiety disorders occur commonly in older people and are associated with considerable emotional distress and disability. Anxiety disorders in later life tend to be both underdiagnosed and undertreated. Anxiety disorders are often seen in comorbid relation to other mental disorders and to general medical conditions. Effective treatments exist for anxiety disorders, although greater effort is needed to make these treatments routinely accessible to older people, including those with physical frailty or cognitive impairment.

Late-onset schizophrenia

Chapter: Late-onset schizophrenia

Author(s): Ellen E. Lee, Baichun Hou, Ipsit V. Vahia, and Dilip V. Jeste

DOI: 10.1093/med/9780198807292.003.0043

Introduction

The literature on late-onset schizophrenia (LOS) is growing, although slowly. It points to important diagnostic, treatment, and prognostic differences from the more common early-onset schizophrenia (EOS). Yet, there remain some gaps in our understanding (Jeste and Nasrallah, 2003), suggesting a need for further research. As of 2000, it was estimated that only 1% of the literature on schizophrenia focused on the older population, with an even smaller proportion specific to the late-onset subgroup (Cohen et al., 2000). Unsurprisingly, schizophrenia with onset in late life remains a challenge to both clinicians and researchers, despite the one-year prevalence rates of 0.6% and 0.2% among individuals aged 45–64 years and 65 years and over, respectively, and lifetime prevalence of 1% and 0.3% reported by the Epidemiologic Catchment Area (ECA) study (Robins and Regier, 1991) and the rising numbers of older adults.

Late-onset schizophrenia

Research on this topic has been hampered by lack of consensus regarding nomenclature and diagnostic criteria as well as heterogeneity in clinical samples, often resulting in a variety of clinical syndromes included under the same broad diagnostic category (Castle and Morgan, 2008). For example, 'late-life schizophrenia' is an umbrella term that can be applied to two different groups of individuals: those diagnosed with schizophrenia in early adulthood and those who developed the illness in middle or late life (Palmer et al., 1999).

A significant increase in the older population is expected, resulting in a doubling of the number of seniors with severe mental illnesses by 2050 (Cohen et al., 2000). More frequent cases of LOS are to be expected, but it needs to be emphasized that individuals with onset of symptoms prior to age 45 will still account for approximately 85% of patients with schizophrenia encountered in clinical settings (Cohen et al., 2000). In this chapter, we focus primarily on schizophrenia first manifesting in late life, and subsequently on chronic schizophrenia in older people and its distinction from LOS.

Nomenclature

Historical background

While the current terms late-onset schizophrenia (LOS) and very-late-onset schizophrenia-like psychosis (VLOSLP) have gained acceptance in recent years, previous terms such as late paraphrenia and the French term *psychose hallucinatoire chronique* remain in use occasionally in the world literature and are commonly used by clinicians, especially outside the US (Dubertret et al., 2004; Harris and Jeste, 1988; Howard et al., 1994; Riecher-Rössler et al., 2003).

In his use of the term 'dementia praecox', Kraepelin (1899) implies an early onset and rapidly deteriorating course. A decade later, Eugen Bleuler (1950) de-emphasized age of onset as a defining feature. Kraepelin later recognized that sometimes the illness presented later in life and he described cases with onset as late as the seventh decade, although these accounted for only 0.2% of the 1,054 patients he studied.

Manfred Bleuler, Eugen's son, may be considered the first to explicitly introduce in 1943 the concept of LOS. Setting the ground with criteria still applied today, he stated that these cases should begin after age 40, with symptoms not fundamentally different to those seen in schizophrenia with an earlier onset, and that there should be no amnesic syndrome or physical sign that indicated a degenerative brain disease as the most likely aetiology (Bleuler, 1943). Using this definition, he found that 15% of schizophrenic disorders began between 40 and 60 years of age, with only a small number of cases presenting later. Prior to Manfred Bleuler's work, others in Germany had attempted to distinguish cases of later onset, including Gaupp in 1905, followed by Stransky ('dementia tardiva'), Berger ('paranoia chronica'), Kleist ('involutional paranoia'), Albrecht

Late-onset schizophrenia

(‘presenile paraphrenia’), Serko (‘involutional paraphrenia’), and Medow (‘stiffening involutional psychosis’). British psychiatrists employed the term ‘late paraphrenia’ to describe ‘a well-organized system of paranoid delusions with onset after age 45, with or without hallucinations existing in the setting of a well-preserved personality and affective response’ (Roth, 1955). Post (1966) doubted the frequency of schizophrenia with onset in late life and felt that a heterogeneous group of disorders were more likely, hence the expression ‘persistent persecutory states of late-life’.

The *Diagnostic and Statistical Manual (DSM)* has changed its stance on distinguishing late-onset from earlier-onset schizophrenia over the past four editions. Published in 1980, the DSM-III had eliminated the category ‘involutional paranoid states/paraphrenia’ and did not allow for the diagnosis of schizophrenia if symptoms emerged after the age of 45 (American Psychiatric Association, 1980). This criterion was modified in the revised edition with the introduction of the ‘late-onset’ specifier for onset after 44 years old (American Psychiatric Association, 1987). However, the term was eliminated from the DSM-IV (American Psychiatric Association, 1994) and the DSM-5, which notes, ‘Such late-onset cases can still meet the diagnostic criteria for schizophrenia, but it is not yet clear whether this is the same condition as schizophrenia diagnostic prior to mid-life (e.g., prior to age 55 years)’ (American Psychiatric Association, 2013, p. 103). The World Health Organization included no qualifier for late-onset in its *International Classification of Diseases, 8th edition* (ICD-8). In the ICD-9, however, the category of ‘paranoid schizophrenia’ included the subtype of ‘paraphrenic schizophrenia’. In the ICD-10 the entity was included as ‘paraphrenia (late)’ in the delusional disorders group (World Health Organization, 1992).

Current terminology: International consensus

In 2000, the International Late-Onset Schizophrenia Group proposed the terms ‘late-onset schizophrenia (LOS)’ for cases with onset between 40 and 60 years and ‘very-late-onset schizophrenia-like psychosis (VLOSLP)’ for those presenting first after age 60. The panel concluded that evidence supported these age cut-offs and that these diagnoses had face validity (Howard et al., 2000). The distinction of the VLSOLP was supported by strong empirical evidence, with the LOS age criteria of 40 years more arbitrary; however, the experts felt that both had clinical usefulness and were intended to promote research in the field (Howard et al., 2000). Despite initial concerns, subsequent research has not shown a significant likelihood of affective disorders misclassified as LOS or VLOSLP. Moreover, EOS and LOS appear to be very stable diagnoses; they remained unchanged in as many as 93% of cases in a recent follow-up and only rarely were they reclassified as mood disorders (Taylor, 2001; Vahia et al., 2010). Although stronger evidence supports the distinction of VLOSLP as opposed to LOS, few studies have focused on this diagnosis specifically. In this chapter, we use the term LOS to indicate both LOS

Late-onset schizophrenia

and VLOSLP, except where specified. We also omit use of the term 'late paraphrenia', unless specified.

Epidemiology

Poorly defined diagnostic criteria, diverse terminology, and heterogeneity of samples have limited epidemiological data on psychotic symptoms in older people.

The prevalence of paranoid ideation in individuals over age 65 has been reported to be as high as 6%, although symptoms arising in the context of cognitive impairment account for most of these cases. Forsell and Henderson (1998) found an overall prevalence of 12.1% in those with cognitive dysfunction, compared to 2.6% in those without (Christenson and Blazer, 1984). Older individuals also seem to be more susceptible to both visual and auditory hallucinations, although women appear to be the most at risk in later age than men and they experience a later peak prevalence (Tien, 1991). Rates of one-year psychotic symptom prevalence in the oldest old (over 95 years) have been estimated to be as high as 7.4%. The risk of psychosis appears directly proportional to age in the geriatric population. Van Os and colleagues (1995) suggested that incidence rates increase by 11% every 5 years after age 60. From 10 per 100,000 person-years between 60 and 65 years, the incidence rate reached 25 per 100,000 person-years in people 90 years and older. These rates reflect incidence for all nonaffective, nonorganic psychoses, including schizophrenia.

The incidence rates of schizophrenia peak between ages 16 and 25 years and then again in the 46–55 years age group, and there may in fact be a third peak in incidence rates in individuals aged 65 and older (Castle and Murray, 1993). A considerable overlap between late-onset psychosis and schizophrenia exists in epidemiologic studies. In a prospective study assessing new cases of schizophrenia fulfilling DSM-IV criteria, Mats Bogren and colleagues (2010a) found an incidence rate of 8 per 100,000 person-years in the age group of 65 + years (American Psychiatric Association, 1994). Rates of 15.6 and 17 per 100,000 person-years have been suggested for delusional disorder (based on DSM-III-R) and late-paraphrenia (as per Kay and Roth's criteria), respectively (American Psychiatric Association, 1987; Copeland et al., 1998; Holden, 1987; Kay and Roth, 1961). New onset of psychosis in late-adulthood therefore frequently occurs outside the context of schizophrenia or schizoaffective disorder. One-year prevalence rates of LOS in a Dutch catchment area of 25,600 adults aged 60 years and older was 0.14%, compared to EOS (0.35%) and VLOS (0.05%) (Meesters et al., 2012).

There is evidence that incidence rates are higher for women, and women:men ratios vary from 1.7:1 to as high as 45:2 (Bleuler, 1943; Herbert and Jacobson, 1967; Howard et al., 2000; Meesters et al., 2012). Whether gender ratios represent real differences in incidence rates based

Late-onset schizophrenia

on true risk factors or whether they are impacted by research bias or cohort effects remains subject to debate.

In a 1997 study conducted in the UK, African-Caribbean people were underrepresented among very late-onset (first symptoms after 60 years) compared to very early-onset cases that were diagnosed before age 25 years (4% and 40%, respectively), but older adults from this ethnic background had higher incidence rates of broad schizophrenia (diagnosed 30–64 years of age) and VLOSP compared to Caucasians (Bhugra et al., 1997; Castle et al., 1997; Mitter et al., 2004; Mitter et al., 2005; Reeves et al., 2003; Reeves et al., 2001; Reeves et al., 2002).

Risk factors and correlates

As with epidemiology, the literature on LOS is limited by lack of standardization in outcomes criteria, populations, and evaluation tools, as underscored in a systematic review by Brunelle and colleagues (2011). Longitudinal studies assessing predictors of LOS are few and current knowledge relies primarily on cross-sectional data (Köhler et al., 2007).

Genetic risk

A significant family history of psychotic disorders has not been reported with LOS, although this probably reflects a lower familial burden in LOS compared to EOS rather than a complete lack of association. A wide variation can be noted in the reported prevalence rates of schizophrenia in relatives of both EOS and LOS subjects, which can be attributed to the different age cutoffs and/or diagnostic criteria used. To our knowledge, only Köhler et al. (2007) have prospectively studied the risk imparted by a positive family psychiatric history. Neither depressive nor psychotic disorders appeared to increase risk, consistent with cross-sectional evidence. Jeste and colleagues (1995) found no difference in family prevalence of depression in persons with LOS or EOS, or unaffected controls.

More recently, data from linkage-analyses seem to suggest that the age of onset is, at least in part, dependent on genetic predisposition, and that genes also have an effect on the phenotype (Hamshere et al., 2011). This may partly explain differences in clinical presentation of LOS and EOS. Several genetic risk factors have been proposed for LOS. The *DRD2* gene and specifically one of its polymorphisms, *rs2734839*, was strongly associated with older age of onset, although the number of subjects above age 40 was insufficient to draw any firm conclusions (Voisey et al., 2011). A link between the CCR5 32-bp deletion allele and LOS has also been suggested (Rasmussen et al., 2006). Dopa-decarboxylase seems to affect the age at first presentation, with certain genotypes containing the 1-bp deletion potentially increasing the likelihood of LOS in men (Borglum et al., 2001). These findings point toward a genetic susceptibility to psychosis even in late-onset cases, which could be both specific to LOS

Late-onset schizophrenia

and shared with EOS, though the genetic susceptibility seems lower for LOS than for EOS.

Gender

The higher incidence rate of LOS in women does not necessarily imply causality. While it may indicate higher risk, other factors like access to care, proportion of individuals at risk, or even diagnostic bias may underlie this higher rate. It has been hypothesized that differences in life-expectancy between genders could also contribute to the increased incidence found in older women compared to men (Howard et al., 1994). As the gap in longevity between men and women has narrowed between 1970 and the twenty-first century, and might continue to do so over the next decades, it would be interesting to see if this is accompanied by a corresponding trend of the incidence rates for LOS to even out between both genders (Pinkhasov et al., 2010). Surprisingly, no difference in incidence rates of late-onset psychosis was found in a systematic review of longitudinal risk factors, possibly because higher incidence in women does not translate into a higher risk ratio in prospective studies (Brunelle et al., 2011). Huang and Zhang (2009) studied Taiwanese individuals older than age 60 admitted with a diagnosis of schizophrenia and reported that the difference in gender proportions was not significant between the early- and late-onset groups, women representing 44.8% and 34.7% of all cases, respectively.

Interestingly, as the familial burden of schizophrenia increases, the effect of gender on age of onset appears to lessen. Several authors have reported comparable men-to-women ratios in patients with a positive family history, even in late-onset cases (Abel et al., 2010; Leboyer et al., 1992; Rasanen et al., 2000). The observed gender differences in prevalence rates for LOS have led to the so-called oestrogen hypothesis of schizophrenia—the onset of symptoms in older women due to the loss of the previous protection conferred by the oestrogenic influence (Häfner et al., 1998; Seeman and Lang, 1990). Oestrogen modulates several neurotransmitter systems, including the dopaminergic, serotonergic, GABA-ergic, noradrenergic, and cholinergic pathways, all of which have been implicated in psychotic disorders (Behl et al., 1995; Brann et al., 2007; Kölsch and Rao, 2002; Lee and McEwen, 2001). However, attempts to identify specific polymorphisms of the oestrogen receptors responsible for schizophrenia or LOS have been mostly inconclusive, and there are currently no data supporting the hypothesis that a genetic variant would have a specific influence on age of onset other than through the general mechanisms (Ouyang et al., 2001). Using first admissions data for VLOSLP, Reeves and colleagues (2002) found that male patients were significantly more likely to be lost at follow-up, which points to differences in help-seeking behaviours between genders.

In summary, the question of whether female gender is itself a significant risk factor for the development of LOS is not fully understood yet, but women constitute a higher proportion of the clinical population. However,

Late-onset schizophrenia

gender does not seem to exert any direct effect outside its association with age at onset (Häfner, 2003; Häfner et al., 1998; Leboyer et al., 1992).

Sensory loss/medical comorbidity

Sensory loss has been consistently implicated in the development of late-life psychosis since an association with hearing loss was reported for the first time by Kay and Roth (Kay and Roth, 1961; Roth, 1955). Symptoms of paranoia following experimentally induced deafness have been described and the literature suggests that adjustments to hearing aids can lead to the resolution of symptoms (Eastwood et al., 1981; Khan et al., 1988; Zimbardo et al., 1981). Authors have reported that hearing loss in those cases is more often conductive and usually severe, bilateral, and appearing early in life (Cooper, 1976; Cooper and Curry, 1976; Cooper et al., 1974; Prager and Jeste, 1993). The association between schizophrenia and hearing impairment appears stronger for VLOSLP than for LOS, but these associations have not been confirmed in longitudinal studies. Less convincing evidence exists for an association with visual deficits (Howard et al., 2000), though prospective studies have demonstrated that people with visual deficits are at significantly increased risk of psychosis, although it has not been demonstrated specifically for LOS (Blazer et al., 1996; Forsell, 2000; Köhler et al., 2007).

Although the existing evidence suggests a correlation, specific aetiological pathways linking sensory deficit and psychosis have been disputed. Proposed theories include sensory loss, reinforcing premorbid tendencies toward isolation (Corbin and Eastwood, 1986), or that persons with sensory loss would simply be less likely to seek treatment.

Comparing patients with early- vs very-late-onset, Rodriguez-Ferrera and colleagues (2004) obtained a higher than expected prevalence of hearing loss in their very-late-onset group (54%), with only 15% in the younger onset group including cases of EOS and LOS, with a mean age of onset of 36 years (SD = 11.3). Almeida and colleagues (1992) reported very similar rates of 41% and 6.6% for LOS and EOS, respectively. Reported prevalence rates of hearing deficits in the literature in the general older population range between 25% and 80% (Newman and Sandridge, 2004). A recent review suggested that hearing deficits severe enough to impair conversation affect approximately 10% of the general population and as many as 40% of adults over age 65, with 80% of all cases of hearing loss occurring in older people (Huang and Tang, 2010). In light of these numbers, the high frequency of hearing impairments in patients with VLOSLP and to a lesser extent LOS is hardly surprising.

There is very limited literature on medical comorbidity in people with LOS, especially considering the significant burden of medical issues in the older population in general and in the psychiatric population in particular. Indeed, some 'geriatric syndromes' are specific to this group, which is also at higher risk of accumulating concurrent medical illnesses, with resulting adverse effect on functional and cognitive status. At least 20–30% of people over 65 years of age are believed to suffer from chronic

Late-onset schizophrenia

diseases (De Luca d'Alessandro et al., 2011). Moreover, medical issues are often overlooked in this population. Data from a chart review of 79 consecutive geriatric psychiatry hospital admissions (University of California, San Diego, Senior Behavioral Health Unit) indicate that 34% of the patients had unrecognized medical conditions (Woo et al., 2003).

An association between occlusive carotid and vertebral arteries disease and late-onset of psychiatric disorders has been reported and cardiovascular risk factors seem to be increased in subjects with LOS, but also late-onset affective disorders (van der Heijden et al., 2010). Barak and colleagues (2002) indicated that medical comorbidities were frequent in both groups of older people with either VLOSLP or chronic schizophrenia (71.4% vs 57.1%, respectively, although it was not significant), with hypertension being the most frequent medical condition, followed by ischaemic heart disease and diabetes. The rates of medical comorbidities seem to be higher in late-onset delusional disorder than schizophrenia, with also more neurological conditions in the first group (Riecher-Rössler et al., 2003). Evidence for potential medical risk factors from longitudinal studies is limited. Henderson and colleagues (1998) found that current physical symptoms increased the risk of delusions and hallucinations, although causality was not established for past physical illnesses. There is a dearth of data about the topic of a history of obstetric or perinatal complications in LOS patients. To our knowledge, only one longitudinal study has been published discussing the rates of perinatal complications in LOS, retrospectively looking at a small sample of 12 LOS patients and concluding against any predisposing effect (Castle et al., 1997; Reulbach et al., 2007).

Cognitive patterns and psychopathology

Cognitive patterns and psychological mechanisms have been discussed extensively in the general literature on LOS. 'Theory of mind', 'mentalization', and 'social cognition' are related concepts that describe the processes used by human beings to make sense of their environment and interact with others. It has been proposed that decreased social exploration is an expected phenomenon with normal ageing and that its interaction with cognitive impairment could increase the susceptibility to psychotic symptoms in people with otherwise healthy development and mentalization patterns. Similar to what has been reported for EOS patients, those with LOS have been found to make significantly more mentalizing errors on testing than older controls, but they did not demonstrate the impaired performance in probabilistic reasoning and exaggeration in self-attribution bias typical of the early-onset individuals (Moore et al., 2006). The literature on social cognition has been burgeoning over the last years in the field of schizophrenia in general, and the extent of the deficits appears to mirror those in neurocognition; whether this will prove relevant in the LOS population remains to be determined (Hofer et al., 2010). Fromholt and colleagues (1999) described the psychological characteristics of 20 individuals with late paraphrenia and found that the subjects' emotional reactions and coping

Late-onset schizophrenia

mechanisms appeared congruent to their subjective views of the problem. That is, their reactions would have been deemed rational or logical if the patients' perceptions corresponded to the reality. This was replicated in a later study by Quin and colleagues (2009). Fromholt and colleagues (1999) also noted that in all but one patient the delusional ideas were plausible, i.e. they 'did not violate physical laws or include references to any supernatural phenomena'. One study found that EOS patients had significantly lower scores on the Hinting Task, a measure of Theory of Mind abilities, compared to age-comparable LOS patients and controls, after adjusting for educational achievement (Smeets-Janssen et al., 2013). The authors proposed that better Theory of Mind functioning might be protective and delay the age of onset of schizophrenia.

In the historical literature on social tendencies and LOS, there are contradictions. While the late paraphrenia described by Roth has been thought to occur mostly in older women with a lifelong tendency toward solitariness and suspiciousness, Janzarik's 'Kontaktmangelparanoid' was described in women with a previously high level of vitality and poor tolerance to solitude who found themselves newly isolated by factors inherent to the ageing process (Janzarik, 1957, 1973; Kojo, 2010; Roth, 1955). In most cases, a progressive deterioration in social networks often prefigured the onset of psychosis and initiated a process of 'life-review' in which subjects reminisced over hostile relationships with some family members, expressed regrets for past actions, and described well-established patterns of solitary coping styles that could be related to the perception of having always been different or 'outsiders' as described by most patients (Quin et al., 2009). Whether they might be the origin or a consequence of LOS remains unclear. Comparing older people with late-onset of depression or schizophrenia and unaffected age-matched controls, Giblin and colleagues (2004) demonstrated that LOS patients had significantly higher scores in the following domains on the Schema Questionnaire: 'rejection and disconnection', 'impaired autonomy and performance', 'other-directedness', and 'over vigilance and inhibition'. They were also more likely to have a low morale about the ageing process, even compared to those with major depression. However, they had the highest severity of current depressive symptoms, which could have introduced a significant recall bias (Schmidt et al., 1995). Contrary to these findings, there is evidence pointing toward a lack of aetiological association between depressive schemas and LOS. Indeed, McCulloch and colleagues (2006) found that not only was there no indication of depressive cognition or self-conception in individuals with late-onset psychosis, but also there was nothing to suggest changes over time; hence the possible contribution of depression to the onset of symptoms was limited.

Unfortunately, to our knowledge only two groups have assessed this topic longitudinally. Köhler and colleagues (2007) found that lifetime depressive symptoms at baseline were not associated with the onset of psychosis (not restricted to schizophrenia) in individuals over age 50,

despite a significant effect in younger cohorts. Interestingly, although there was a trend toward lower influence with older age of onset, 'neuroticism' retained its significance as a contributive factor in late-onset psychosis. This is congruent with the analysis from Bogren and colleagues (2010b) of premorbid behavioural and personality-related signs and symptoms predictive of psychosis, with only the two clusters 'nervous-tense' and 'abnormal-antisocial' reaching significance for schizophrenia. The description of the latter cluster indicates what would now be more suggestive of cluster A personality disorders.

Abnormal premorbid personality traits have often been implicated. Fuchs (1999b) found high rates of personality pathology in a sample of 38 late paraphrenia patients and indicated that 39% had met the criteria for paranoid or schizoid personality disorders prior to the psychosis, and the frequency of characteristic traits has been reported to be as high as 70% in older literature. Subjects affected by late-onset psychotic disorders have been described by early British authors as 'suspicious', 'quarrelsome', 'hostile', 'sensitive', 'unsociable', 'reticent', 'odd', 'eccentric', 'histrionic', 'pretentious', and exhibiting a long-standing difficulty to establish or maintain intimate relationships (Giblin et al., 2004; Herbert and Jacobson, 1967; Howard et al., 1994; Kay and Roth, 1961; Post, 1966). In LOS specifically, Pearlson and colleagues (1989) noted patterns of having been 'reclusive and introverted', with 'few friends, poor interpersonal relationships and peculiar religious beliefs'. Brodaty and colleagues (1999) described persons with LOS as 'odd and eccentric', 'suspicious and detached' compared to normal controls, and similar to previously described traits in late paraphrenia. Longitudinally, no premorbid condition has been clearly associated with the onset of psychotic symptoms; anxious manifestations may potentially be predisposing and a prior diagnosis of post-traumatic stress disorder had been given to several LOS patients with significant childhood trauma (Reulbach et al., 2007; Sachdev et al., 2000; Tien and Eaton, 1992). Although substance-related disorders are more common in older people with schizophrenia than without, LOS specifically has not been well studied (Jeste et al., 1996; Mulsant et al., 1993). Reviews of the longitudinal studies were inconclusive (Brunelle et al., 2011; Köhler et al., 2007; Tien and Eaton, 1992; Wiles et al., 2006).

Pathophysiologic processes

Sociodemographic factors

Some sociodemographic characteristics of the subjects affected by LOS are likely not predisposing factors and reflect the direct consequences of later age of onset. However, they are important to the understanding of the pathogenesis of schizophrenia in late life, and are mentioned here.

Studies consistently show that subjects with LOS may have similar marriage rates as normal controls (especially for VLOSLP) and are much more likely to be, currently or formerly, married than their earlier-onset

Late-onset schizophrenia

counterparts (Barak et al., 2002; Girard and Simard, 2008; Hassett, 2002). It has also been suggested that they might have higher rates of divorce (or initiating the divorce) and widowhood (Almeida et al., 1992; Rees, 1971; Fuchs, 1999b; Girard and Simard, 2008; Herbert and Jacobson, 1967; Howard et al., 1994; Jeste et al., 1995; Kay and Roth, 1961). One exception emerged from a comparison of EOS and LOS in chronically hospitalized patients in Taiwan, with high rates of marriage in both groups, possibly corresponding to a cultural phenomenon (Huang and Zhang, 2009). Compared to those with early-onset, patients with LOS might have fewer friends and fewer children than normal controls (Barak et al., 2002; Brodaty et al., 1999; Gurian et al., 1992; McCulloch et al., 2006; Rodriguez-Ferrera et al., 2004; Romero-Rubiales et al., 2004; Semple et al., 1997).

While an association with academic achievement remains unclear, better work performance and employment history reflected a much better level of premorbid adjustment for schizophrenia patients diagnosed later in life (Barak et al., 2002; Castle et al., 1997; Fuchs, 1999b; Girard and Simard, 2008; Girard et al., 2011; Jeste et al., 1995; Vahia et al., 2010). These findings, however, have not been replicated in longitudinal studies (Brunelle et al., 2011). Functional limitations have not been studied in relation to schizophrenia and there is inconsistent evidence as to whether they increase the risk of psychosis in older people directly (Blazer et al., 1996; Forsell, 2000). Although there are very limited data on this topic, it is possible that an urban status at birth might predispose to LOS, as has been suggested already for EOS (Marcelis et al., 1998).

Adverse life events

Negative experiences early in life can affect developmental tasks and thereby increase susceptibility to psychosis when they occur early in life, but psychosocial stressors may exert a larger impact on the psychotic episode's development. Both have been described in relation to LOS, although the specificity and wide range of adverse events described in the literature likely impairs generalization. Results from a systematic review of longitudinal studies on LOS indicated that both the number and intensity of negative life events can contribute to the onset of psychotic symptoms later in life, and exposure to the Holocaust has been implicated for schizophrenia specifically (Brunelle et al., 2011; Reulbach et al., 2007). Childhood traumas and experiences perceived as discriminating, humiliating, or threatening have been frequently identified in subjects with LOS (Fuchs, 1994, 1999a,b; Gurian et al., 1992; Rockwell et al., 1994). For those with EOS, early life events have not been associated with the persistence of psychotic symptoms in older age, but the accumulation of stressors throughout the lifetime has been implicated (Cohen et al., 2011). Psychosocial adversity can play a role during adulthood as well, and certain ethnic groups such as African-Americans have been diagnosed more frequently. While diagnostic bias, perceived discrimination, and stress related to the migration have been implicated for these associations, none has emerged as a significant predisposing

Late-onset schizophrenia

factor in longitudinal evidence (Blazer et al., 1996; Brunelle et al., 2011; Forsell, 2000; Forsell and Henderson, 1998; Mitter et al., 2005; Mitter et al., 2004; Reeves et al., 2003; Reeves et al., 2001). In a recent article on LOS from Japan, psychosocial stresses were deemed causally related in 65.8% of the cases, and in 36% of those the subjects reported a sense of loss. Similar associations with acute stresses or losses have been reported in other studies (Rees, 1971; Fromholt et al., 1999; Janzarik, 1973; Kay and Roth, 1961; Yasuda and Kato, 2009). This is compatible with the view of LOS and EOS as unique single disorders, with LOS manifesting later in more resilient individuals (Schmid et al., 2011).

Neuropathology

Neuropathological mechanisms remain central to contemporary conceptualizations of schizophrenia, including: i) dysfunction of the neurotransmitter pathways in the central nervous system, primarily implicating dopamine, glutamate, and serotonin; ii) neurodevelopmental alterations, suggested by regional brain abnormalities on both structural and functional imaging; and iii) modifications at the cellular level, with a postulated reduction in oligodendrocytes and/or aberrant neuronal cytoarchitecture (Pickard, 2011). However, the extent to which these processes contribute specifically to illness manifestation in late life and the role of alternative mechanisms is not well understood.

The first brain imaging study of the late-onset population was published by Haug (1962) involving seven patients with a first episode of 'psychosis' after the age of 45 years. Using the technique of pneumoencephalography, he reported evidence of cerebral atrophy and dilated ventricles. It took almost a twenty-five years for the next study reporting on brain imaging in patients with LOS, when Miller and colleagues (1986) reported computer tomography (CT) results on a small sample of five women with late paraphrenia, and noted that three had cortical or subcortical changes and another showed signs of normal pressure hydrocephalus. Several subsequent studies all determined that ventricle-to-brain ratios (VBRs) were larger in the patients than the normal controls group (Naguib and Levy, 1987; Pearlson and Rabins, 1988; Rabins et al., 1987). More recent investigations have mostly used magnetic resonance imaging (MRI) techniques, in an attempt to assess periventricular and deep white matter changes better. The first two studies (Breitner et al., 1990; Miller et al., 1989) described the MRIs of subjects with a broader diagnosis of 'late-life psychosis' or 'late-onset paranoid illness'. In the first study, 20% of them had evidence of 'silent vascular disease' and tumours were discovered in another 12%. The second group reported vascular lesions in the pons or medulla of seven out of eight subjects, but none in normal controls. Miller and colleagues (1991) later wrote that white matter lesions affected 42% of subjects, presenting with first onset of 'psychosis' after age 45, as opposed to only 8% of the age-matched healthy comparison subjects, predominantly in the

Late-onset schizophrenia

temporal and frontal lobes. However, no definite pattern of white matter lesions has been established.

A literature review published in 2010 suggested that extracranial arterial pathology also contributed to the development of LOS. A significantly higher burden of premorbid cardiovascular risk factors was described in those with late-onset psychiatric disorders, including schizophrenia (van der Heijden et al., 2010). It is possible that this finding reflects a distinction between LOS and VLOSLP.

Volumetric studies have failed to pinpoint any abnormality specific to late-onset patients and findings are mostly concordant to those with EOS. The only notable difference was the larger thalamic volumes found in patients with LOS compared to their early-onset counterparts (Barta et al., 1997; Corey-Bloom et al., 1995; Rabins et al., 2000; Sachdev and Brodaty, 1999b; Sachdev et al., 2000; Sachdev et al., 1999; Sachdev and Brodaty, 1999a; Symonds et al., 1997). One recent study showed larger gray matter volumes in the left precuneus of LOS patients compared to EOS patients and non-psychiatric controls (Egashira et al., 2014). However, there have been no demonstrated alterations in the size of the frontal lobes, hippocampus, parahippocampus, thalamus, or basal ganglia structures in patients with LOS compared to older controls (Howard et al., 1995). Sachdev and colleagues (2000) later confirmed that the hippocampus and amygdala volumes in older people with LOS and EOS were comparable and were not significantly associated with their cognitive performances.

Diffusion tensor imaging (DTI) results have confirmed the integrity of frontal lobes and frontal cortical tracts, which had already been suggested by volumetric studies (Jones et al., 2005). However, studies using single photon emission tomography (SPECT) have suggested that up to 83% of LOS patients suffered from frontal or temporal hypoperfusion. In one study, the regional cerebral blood flow of patients with LOS showed a different pattern of alteration than that of subjects with EOS. Reduced blood flow was observed bilaterally in the postcentral gyrus for LOS patients, while the precentral and inferior frontal gyri were more affected in the EOS group. It was postulated that these changes were more likely attributable to the age of onset rather than the chronological age of the subjects (Wake et al., 2011; Wake et al., 2016). One case study found resolution of differential blood flow in the striatum and thalamus compared to the left frontal and temporal cortex after successful treatment for VLOS with catatonia (Tsujino et al., 2011).

Lohr and colleagues (1997) reported a significant difference in the frequency of minor physical anomalies in those two sets of patients. While the subjects with Alzheimer's dementia did not differ from normal controls, older people with LOS or EOS, as well as those with unipolar depression, all had more anomalies. Pathological examinations have been rarely reported, but the absence of Alzheimer's disease as defined by extensive neurofibrillary tangles seems to be consistent (Bozikas et al.,

2002; Casanova et al., 2002). Although the proportion of tangles was not abnormal, other neuritic changes have been observed. On the basis of their studies, Casanova and colleagues have proposed the concept of a 'restricted limbic tauopathy' that affects LOS and, to some extent, EOS patients (Casanova et al., 2002; Casanova and Lindzen, 2003). In patients with schizophrenia, the familial loading for Alzheimer's, vascular, or Lewy body dementias has not been found to be higher in those with a later compared to an earlier onset of symptoms (Brodaty et al., 1999; Howard et al., 1997). From a systematic review of the longitudinal studies on the risk factors for late-onset psychosis, cognitive impairment not reaching the threshold for dementia emerged as a probable predictor for psychotic symptoms at follow-up, but not for schizophrenia per se (Brunelle et al., 2011; Forsell, 2000; Henderson et al., 1998; Tien and Eaton, 1992). The Wechsler Adult Intelligence Scale-Revised (WAIS-R) similarities subtest and the California Verbal Learning Test (short- and long-delay free recall) may be the two most sensitive neuropsychological measures discriminating between LOS and Alzheimer's disease in patients already diagnosed with LOS or VLOSLP (Girard et al., 2011; Zakzanis et al., 2003). However, neuropsychological testing in individuals without psychosis was not shown to have any predictive value regarding the likelihood of subsequently exhibiting schizophrenia manifestations (Blazer et al., 1996; Henderson et al., 1998).

In summary, LOS does not appear to be related to Alzheimer's disease or other dementia pathology. However, it is still unclear whether a neurodegenerative process is at play in this condition, mainly because of the lack of distinction in the literature between cases of LOS and VLOSLP and the pooling of various psychotic disorders together in studies. Current evidence indicates that VLOSLP might be more associated with a neurodegenerative disease, while LOS is more aetiologically similar to EOS, although this is not completely clear.

Inflammation

A number of studies have reported elevated levels of inflammatory markers and oxidative stress markers in schizophrenia, though few studies have examined inflammatory markers specifically in LOS (Joseph et al., 2015; Lee et al., 2016a,b). In 2014, Wium-Andersen and colleagues (2014) reported that elevated levels of C-reactive protein (CRP), a biomarker of systemic inflammation, were associated with a six- to 11-fold increased risk for LOS and VLOS based on a 20-year longitudinal Danish cohort study of over 78,000 individuals. Mean CRP levels were higher for persons with schizophrenia (EOS and LOS subtypes) compared to those without schizophrenia, even when adjusting for age and gender. This was the first study examining a large cohort for LOS and VLOS in regards to inflammatory markers.

Clinical features

Late-onset schizophrenia

Positive and negative symptoms

The conclusions of the International Consensus on Late-Onset Schizophrenia Group pointed toward greater similarities than differences in the clinical presentation of schizophrenia arising in early and late life, especially regarding the positive symptomatology and between ages 40 and 60 years. However, in clinical samples, cases with very late onset were associated with a low prevalence of formal thought disorder and affective blunting and a higher prevalence of visual hallucinations (Grahame, 1984; Howard et al., 1993; Howard et al., 2000; Jeste et al., 1995; Jeste et al., 1997; Kay and Roth, 1961; Pearlson et al., 1989; Post, 1966).

Whether LOS patients experience more severe positive symptoms overall compared to those with early-onset is not fully clear. Yasuda and Kato (2009) found that the paranoid subtype applied to over one-half of their LOS sample and was significantly higher than in the older group with earlier onset. Mason and colleagues (2013) reported similar findings of increased paranoia in the LOS group, however the differences dissipated when the analysis matched for age (Mason et al., 2013). On the other hand, Vahia and colleagues (2010) suggested similar rates for the early- and late-onset groups, although positive symptoms were less severe overall among those with LOS. The absence of significant difference in positive symptomatology has been replicated in other studies (Hanssen et al., 2015; Huang and Zhang, 2009; Jeste et al., 1995; Pearlson et al., 1989; Rodriguez-Ferrera et al., 2004). Some specific features do appear to be more common in the LOS population, such as persecutory, elaborate, and systematized delusions. Delusions and hallucinations may become more prevalent with older age rather than with older age of onset, but delusions of partition or 'the belief that people, objects or radiation can pass through what would normally constitute a barrier to such passage' are especially frequent in those with LOS and much rarer in older and young EOS patients (Howard, 2006; Howard et al., 1992). Individuals with a later onset are also more susceptible to experience visual, olfactory, or tactile hallucinations and in several sensory modalities simultaneously (Alici-Evcimen et al., 2003; Castle et al., 1997; Girard and Simard, 2008; Howard et al., 1993; Pearlson et al., 1989; Sato et al., 2004; Wynn Owen and Castle, 1999).

It has been increasingly recognized that a later onset might not be as protective as originally assumed, with recent evidence suggesting comparable severities of negative symptoms in EOS and LOS and even in VLOSLP (Girard and Simard, 2008; Jeste et al., 1995; Vahia et al., 2010). Indeed, VLOSLP seems to be characterized by prominent positive symptoms but not less negative symptomatology than LOS, although it is rarely specifically assessed on its own. The level of psychomotor activity appears to distinguish the two conditions, with LOS patients presenting with more apathy and abnormal psychomotor activity (Barak et al., 2002; Girard and Simard, 2008).

Late-onset schizophrenia

Cognition

Cognitive changes are among the cardinal features of schizophrenia, regardless of age of onset, and had been under consideration for inclusion as a distinct dimension in the DSM-5 section on schizophrenia—though ultimately they were not included (Bora et al., 2010; Keefe and Fenton, 2007; Laughren, 2011).

Consistent with the overall literature on schizophrenia, late-onset patients were found to have lower cognitive performance than normal controls. Ting and colleagues (2010) reported that LOS patients were more impaired than age-matched controls on most cognitive tests, with the exception of those for the recall of newly learned verbal information (using the California Verbal Learning Test: Woods et al., 2006). However, those with LOS outperformed patients with Alzheimer's disease on every measure, including retrieval, the only notable exception being a nonsignificant difference in learning new verbal material. These more recent findings are very similar to the first neuropsychological descriptions of LOS patients, attributed to Hopkins and Roth in 1953. Comparing older subjects belonging to several different diagnostic categories, they reported that those with late paraphrenia had a much better performance on all tests than those with dementia. The severity of impairments was similar in late paraphrenia and affective patients, but the two groups showed distinct patterns on neuropsychological assessment (Hopkins and Roth, 1953). One longitudinal study found no difference in risk of developing dementia between patients with LOS and late-life depression (Rabins and Lavrisha, 2003).

Rajji and colleagues (2009) conducted a meta-analysis on cognitive deficits found in subjects with a first-episode in adult life, youth-onset, or LOS. From the nine studies selected, the authors concluded that LOS patients have an overall better cognitive performance than those with youth-onset or first-episode schizophrenia, though the patterns of cognitive deficits differ in each group. The LOS patients had more impairment on measures of attention, fluency, global cognition, IQ, and visuospatial construction than the other two subgroups, while arithmetic, digit symbol coding, and vocabulary were mostly preserved. Similarly, a study of LOS patients, EOS patients matched for duration of illness, and age-matched controls showed that LOS patients had intermediate memory performance—better than the EOS patients but worse than the controls (Brichant-Petitjean et al., 2013). This challenges the assumption of minimal differences in the cognitive functioning of patients with EOS and LOS (Heaton et al., 1994; Jeste et al., 1995; Sachdev et al., 1999). It is possible that this design allowed for the detection of results that did not reach significance in isolated studies because of small sample sizes; but it might also reflect the patient groups in the analysed studies. Unfortunately, in most studies, older adults with LOS are compared to older adults with EOS. It has been suggested that the younger the age of onset, the greater the severity of cognitive and functional impairments; however, while chronicity contributes significantly to the cognition

Late-onset schizophrenia

scores, it has not been shown to alter the effect of age of onset on specific measures. LOS subjects most consistently perform better on measures of abstraction/flexibility, semantic/verbal memory, and learning. These findings have been replicated by other authors, although some also noted lesser impairment in processing speed for the late-onset group (Girard et al., 2011; Jeste et al., 1997; Tuulio-Henriksson et al., 2004; Vahia et al., 2010).

Comparisons of executive functions in LOS and EOS are inconsistent and the current consensus is that impairments are manifest regardless of age of onset (Rajji and Mulsant, 2008). A positive correlation exists between family history of schizophrenia, younger age of onset, and poorer cognitive performance, although familial loading might not have such a significant effect in late-onset cases. How this contributes to the neurocognitive features in LOS has, however, not been well studied (Goldberg et al., 2011; Tuulio-Henriksson et al., 2004). One 2015 study found no significant neuropsychological differences between LOS and VLOSLP, when controlling for age (Hanssen et al., 2015).

Mood

Compared to normal controls, patients with LOS appear to endorse a higher level of depressive symptoms (Jeste et al., 1995; Moore et al., 2006). However, there was no evidence of depression in the LOS group in a study by McCulloch and colleagues (2006) comparing LOS patients to depression patients and healthy controls; both LOS and normal subjects exhibited a better self-esteem than the depressed individuals. When comparing with older EOS patients, Jeste and colleagues (1995) found no significant between-group differences, and a study by Rodriguez-Ferrera and colleagues (2004) showed a trend toward higher depression levels in EOS, though significance was not reported.

Differential diagnoses of psychotic symptoms in older people

Several conditions can present with psychotic symptoms in older patients. A detailed discussion of all possible causes is beyond the scope of this section, but we summarize the major differential diagnoses.

Early-onset schizophrenia

Table 43.1 provides a summary of the differences between EOS and LOS. Recent studies suggest that LOS is likely a distinct subtype of schizophrenia due to psychopathological and mechanistic differences from EOS (Maglione et al., 2014).

Late-onset schizophrenia

Table 43.1 Characteristics of various types of late-life psychosis.

	EOS	LOS	VLOSLP	PoD
Family history of schizophrenia	+	+	-	-
Female preponderance	-	+	++	-
Minor physical anomalies	+	+	-	-
Specific brain abnormalities (MRI)	-	-	+	+/-
Dementia-like cognitive decline	-	-	+	++
Magnitude of cognitive impairment	+	+	++	+++
Paranoid subtype	+	++	+++?	N/A
Visual vs auditory hallucinations	+/-	+	+	++
Complex vs simple delusions	++	+	+	+/-

Late-onset schizophrenia

Thought disorder	+/++	+	-	-
Negative symptoms	++	+	-	-
Required neuroleptic dose	++	+	+	+/-

EOS, early-onset schizophrenia; LOS, late-onset schizophrenia; MRI, magnetic resonance imaging; N/A, not applicable; PoD, psychosis of dementia; VLOSLP, very-late-onset schizophrenia-like psychosis; +, moderately present; ++, strongly present; +++ very strongly present; -, not likely to be present; ?, only partially supported by the literature.

Late-onset schizophrenia

Delusional disorder and other primary psychoses

Significant overlap exists between LOS, delusional disorder (DD), and late paraphrenia, to the extent that authors have challenged the validity of any diagnostic division (Howard et al., 1994; Jørgensen and Munk-Jørgensen, 1985). Riecher-Rössler and colleagues (2003) proposed that 'since clear and aetiologically meaningful differentiation between these diagnostic categories is not possible, they should not be separated by artificial diagnostic criteria for research purposes'. However, other authors have reported some evidence to support the clinical distinction of DD from schizophrenia with onset after age 40 (Evans et al., 1996). A diagnosis of DD is more often seen in older patients and is not an uncommon expression of psychosis in this population. For example, Alici-Evcimen and colleagues (2003) described 27 cases of late-onset psychosis in the 420 inpatients admitted to the sole geriatric psychiatry unit of a Turkish hospital between 1993 and 2002. From those 27 patients, five had EOS. Eight were diagnosed as having LOS, six with VLOS, and eight had DD. In a study of older people with schizophrenia, it was found that 27% of those diagnosed after age 60 met the criteria for DD, as opposed to none in the early-onset group (Rodriguez-Ferrera et al., 2004). In fact, diagnostic classification seems to rely heavily on age. Results from another group suggest that age accounted for 22% of the variation in the two diagnoses of schizophrenia and DD (Riecher-Rössler et al., 2003).

Schizophreniform disorder resembles schizophrenia, but lasts less than six months. Older patients with this disorder often demonstrated good premorbid adaptation, and the sudden onset of florid psychotic symptoms generally leaves them perplexed and confused. The episode might end as abruptly as it had begun, often with a return to the premorbid level of functioning (Jørgensen et al., 1997).

Schizoaffective illness in older patients has not been well described, probably because it is often included with cases of LOS. Among 27 very-late-onset psychosis cases described by Rodriguez-Ferrera and colleagues (2004), two received a diagnosis of schizoaffective disorder. Holden (1987) did describe a schizoaffective subtype of late paraphrenia associated with a high prevalence of auditory hallucinations but almost no visual manifestations. Affected patients had low rates of psychiatric antecedents and sensory deficits and were most likely to be alive at ten years compared to the other subgroups.

Isolated hallucinations can be found in visually impaired individuals (Schadlu et al., 2009). They have been described as a commonly occurring phenomenon in persons who have experienced widowhood, described in approximately 4% of widowers (Rees, 1971; Khouzam et al., 2005).

Delusions of misidentification, e.g. the Capgras syndrome, might occur in people with primary psychotic disorders but should herald the possibility of an underlying organic condition. They are relatively common in

Late-onset schizophrenia

Alzheimer's dementia and other neurological or medical conditions (Khouzam et al., 2005). Paranoid personality can increase the risk of late-life psychosis, but premorbid suspiciousness can also worsen with age (Manford and Andermann, 1998; Paulsen et al., 2000).

Affective disorders

Psychosis is an especially frequent accompanying feature to depressive episodes in later life. Delusions or hallucinations are mood-congruent in the majority of the cases and somatic manifestations are especially common (Jørgensen et al., 1997; Khouzam et al., 2005).

Grandiose delusions commonly appear during manic episodes. Although mania tends to emerge as an early feature in the course of bipolar disorder, it can occur for the first time in late life or can reappear as a consequence of medication changes. Mania in older people should be differentiated from frontotemporal dementia (Almeida et al., 1992; Sajatovic and Chen, 2011).

Delirium and substance-induced psychotic disorders

While substance use disorders are comparatively less common in the older population, they are still observed with some frequency. Also, older adults are at risk for withdrawal due to sudden lack of access because of financial, mobility-related, or medical conditions. Alcohol and benzodiazepines are associated with especially high risk of psychotic phenomena during both intoxication and withdrawal and their use is not uncommon (American Psychiatric Association, 2000; Blazer and Wu, 2011; Khouzam et al., 2005). Delirium from any cause should also be suspected in first onset of psychosis and behavioural disturbances in late life (Reeves and Brister, 2008).

Dementia

Psychotic manifestations, especially visual hallucinations, can present in virtually every type of dementia and occur in up to 50% of patients at some point over the course of the illness. They are a characteristic feature of Lewy body dementia. Certain gene mutations such as progranulin (*PGRN*) and *C9ORF72* have been associated with hallucinations and psychosis in patients with frontotemporal dementia (Le Ber et al., 2008; Snowden et al., 2012). Also, people with dementia are especially vulnerable to anticholinergic side effects of medications and the resulting delirium. Psychosis can be a poor prognostic marker in this population, where antipsychotic treatment is associated with an increased mortality rate (American Psychiatric Association, 2000; Hardy, 2003; Kales et al., 2007; Paulsen et al., 2000).

Management

Late-onset schizophrenia

Clinical evaluation

The evaluation of older people presenting with schizophrenia manifestations requires assessment similar to that for any psychiatric illness in late life. Extra focus should be given to collateral information, owing to the high risk of guardedness and poor insight due to psychosis and cognitive impairment. It is also important to assess the impact of the disease on the social network. Assessment of safety includes ruling out the risk of violence toward others, even though this is reportedly more common in younger rather than older adults (Martínez-Martín et al., 2011).

The pharmacological history should focus on potentially contributing medications, including over-the-counter, herbal remedies, interactions, recent changes, and medication adherence (e.g. anticholinergic medications are often implicated as a cause of psychotic symptoms in older adults). Sexual and substance use histories should be gathered considering the risk of intoxication, withdrawal, neoplastic lesions, and sexually transmitted diseases. A complete review of personal and familial antecedents, both medical and psychiatric, with a specific focus on psychotic and neurodegenerative disorders, is mandated and should include a discussion of the premorbid level of functioning. Information should be obtained on the current pattern of impairment, course of symptoms, and accompanying physical or psychological manifestations. During physical examination, the clinician should look for evidence of neglect, abuse, decreased hygiene, incontinence, or cachexia, as well as for any sign of delirium or any indication of its aetiology. Neurological assessment should rule out increased intracranial pressure, localizing lesions, or neurodegenerative conditions like Huntington's and Parkinson's disease or Lewy body dementia, lesions of the basal ganglia or cerebellum, or seizures. A basic cognitive evaluation is mandated in all patients and should be repeated over time to rule out fluctuations in the context of delirium.

A basic work-up should consist of a complete blood count, blood chemistry profile (glucose, electrolytes with calcium and magnesium, blood urea nitrogen, creatinine, and liver function tests), urinalysis (and urine culture, if indicated), thyroid function studies, toxicology screening, vitamin B₁₂ and folate levels, and serological tests for syphilis. Brain imaging is recommended, especially for cases with acute deterioration, altered consciousness, or abnormalities on neurological examination. Some authors also present evidence for electrocardiography and routine chest radiography (Boyce, 2008; Howard et al., 2000; Reeves and Brister, 2008). It may be useful to obtain a baseline lipid panel, weight, height, and waist circumference before an antipsychotic trial, in order to monitor metabolic side effects.

Ancillary investigations should focus on ruling out other suspected aetiology based on the history and physical examination. The decision to

Late-onset schizophrenia

perform comprehensive neuropsychological evaluation should be guided by clinical judgment, especially in settings with limited resources.

Pharmacology

Antipsychotics

No pharmacologic treatment guidelines for LOS have been established to date, mostly due to the limited evidence in this specific population. The bulk of the literature in this regard pertains to older patients with chronic schizophrenia; moreover, studies on the late-onset population usually failed to distinguish between LOS and VLOSLP. Arunpongpaissal and colleagues (2003) published a Cochrane systematic review on antipsychotic drugs use in older people with LOS, and revised it in 2012. While the 2003 search found no randomized controlled trials meeting their inclusion criteria and upon which to base any guidelines, the 2012 review identified a single randomized controlled trial of risperidone and olanzapine that was of acceptable quality (Essali and Ali, 2012). Due to the paucity of published trials, clinicians must for now use 'clinical judgment and habit to guide prescribing' (Arunpongpaissal et al., 2003; Essali and Ali, 2012). However, a more recently published study by Jin and colleagues (2013), which specifically studied older adults on antipsychotic medications, found that quetiapine may have the highest incidence of adverse events. The study also noted that older adults on antipsychotics had high discontinuation rates, limited improvement in psychotic symptoms and a 36% incidence of metabolic syndrome (Jin et al., 2013).

Atypical antipsychotics are now favoured, mainly because of the propensity of first-generation neuroleptics to induce extrapyramidal symptoms (EPS) and tardive dyskinesia (TD), to which older individuals are more prone. Benefits have been observed in older patients initially treated with risperidone or olanzapine after the switch from a typical antipsychotic (Jeste et al., 1999a,b; Ritchie et al., 2003; Ritchie et al., 2006). In older people, as many as 2–30% of patients per year may develop TD with typical antipsychotics and they are also less likely to experience remission compared to younger individuals. Newer agents have a safer side-effect profile but are not risk-free; TD still emerges in approximately 5% of treated older patients each year, in keeping with the young to old risk ratio of 1:5 observed with first-generation medications (Correll et al., 2004). Older people are also more sensitive to EPS, even with second-generation antipsychotics like risperidone, and this risk may be higher for those with EOS (Jeste et al., 1995; Lemmens et al., 1999). Other related side effects include orthostatic hypotension, cardiac conduction abnormalities, agranulocytosis, and neuroleptic malignant syndrome (NMS). Hyperprolactinaemia from dopamine blockade is associated with osteoporosis, increasing the risk of hip fractures (Boyce, 2008; Reeves and Brister, 2008; Sachdev and Brodaty, 1999a). Both classes of antipsychotics have been implicated in increasing cardiovascular and all-cause mortality (Isaac and Koch, 2010; Kales et al.,

2007; Kelly et al., 2010; Schneider et al., 2005). Age-related changes in liver and kidney function, decreased lean body mass, and polypharmacy may additionally impact the pharmacokinetics and pharmacodynamics of antipsychotics (Sable and Jeste, 2002; Tsuboi et al., 2011).

The International Consensus suggested that one-half to one-quarter the doses of that used in younger patients could be used in LOS patients and as low as one-tenth in VLOSLP. The initiation of therapy should be made at a very low dosage, with cautious increments up to the lowest effective dose (Howard et al., 2000). For example, risperidone should be introduced at 0.25–0.50 mg/day and titrated by no more than 0.50 mg/day to a target range of 1.25–3.50 mg/day. Starting and target dose-ranges of olanzapine should be 1–2.5 mg/day titrated up to 5–15 mg/day. With quetiapine these should be 12.5–25 mg/day titrated to 100–300 mg/day (Alexopoulos et al., 2004; Jeste et al., 1996; Reeves and Brister, 2008). Recent data suggest the efficacy of aripiprazole with doses as high as 15–30 mg/day, but some recommend the more modest target of 10–15 mg/day, introduced at 2 mg/day (Coley et al., 2009; Kohen et al., 2010; Madhusoodanan et al., 2004; Rado and Janicak, 2010). Lower dosing strategies have been suggested for late-life psychosis in the context of delusional disorder or dementia (Tsuboi et al., 2011). Amisulpride has also been demonstrated to be comparable to risperidone in older patients and doses of 200–400 mg/day have been used, introduced at 50 or 100 mg/day (Psarros et al., 2009). More recently, the ATLAS trial (Howard et al., 2018) reported that a daily dose of 100 mg of amisulpride was effective and well tolerated. Depot medications may have a more continuous delivery and are often used in nonadherent patients, minimizing the plasma level fluctuations that can be especially problematic in older people (Lasser et al., 2004). Long-acting risperidone at doses starting at 25 mg every two weeks was shown to be safe in older patients followed for one year. Some patients received and tolerated doses as high as 75 mg every two weeks (Kissling et al., 2007; Lasser et al., 2004; Singh and O'Connor, 2009). As in the younger population, depot formulations have not been found to be more effective than oral antipsychotics if adherence is good (Reeves et al., 2002). Paliperidone extended-release (ER) consists of the active metabolite 9-hydroxyrisperidone in a tablet using patented extended-release technology to provide continual and consistent delivery over 24 hours. It has theoretical advantages in older people, like a once-daily schedule, minimal hepatic metabolism, potentially fewer side effects, and limited plasma fluctuations in cases of missed doses (Turkoz et al., 2011). In a 30-week trial involving patients around age 70 with EOS and LOS, paliperidone ER was found to be safe and well tolerated, with an age-related increase in somnolence and tachycardia. Age of onset did not impact these findings. Paliperidone also seemed to be effective at reducing symptoms, but the study was not powered to assess this outcome. Dose range was 3–12 mg/day and started at 6 mg/day (Tzimos et al., 2008).

Late-onset schizophrenia

According to a survey of expert clinicians in the US, risperidone should be the drug of choice in late-life schizophrenia, and quetiapine, olanzapine, and aripiprazole are good second-line options (Alexopoulos et al., 2004). There is more limited evidence regarding the use of ziprasidone and clozapine and none for LOS specifically. Clozapine especially should be used with caution considering its side-effect profile and important anticholinergic activity, and polypharmacy using more than one antipsychotic should be avoided.

Adjunctive medications

Although younger age is correlated with a more frequent use of adjunctive mood stabilizers for schizophrenia, recent data support their use in older people as well. Adjunct ER valproate (mean dose 587.50 mg/day) was effective and well tolerated in an open-label study on 20 older chronically ill patients, and was associated with symptomatic improvement, better global function, and lower depression scores (Sajatovic et al., 2008; Sim et al., 2011). The resolution of comorbid depressive symptoms with adjunctive phytoestrogens in a woman with LOS was discussed in a case report (Rakesh et al., 2011). Cholinergic neurotransmission has been implicated in psychosis and visual hallucinations, but there is currently no evidence regarding the use of cholinesterase inhibitors for this purpose, although there seem to be a role for them in management of associated cognitive deficits (Patel et al., 2010; Ribeiz et al., 2010). There is also a theoretical rationale for the use of memantine and reports of a positive impact in cases of catatonic schizophrenia (Zdanys and Tampi, 2008). To our knowledge, there are no data supporting the addition of these agents in older adults, particularly those with LOS.

Addition of SSRIs, specifically citalopram, has been shown to be effective in treating subsyndromal depressive symptoms in older persons with schizophrenia. More importantly, such treatment may reduce risk of suicide.

There is supporting evidence regarding electroconvulsive therapy (ECT) and repetitive transcranial magnetic stimulation (rTMS) for refractory symptoms in younger patients with schizophrenia (Matheson et al., 2010). To date, there are no publications reporting LOS treatment with ECT, but rTMS in LOS has been the focus of a case report, describing one individual with auditory hallucinations successfully treated with both acute and maintenance rTMS (Poulet et al., 2008).

A few recent studies have suggested efficacy of oestrogen therapies for schizophrenia, although the overall evidence is weak. Several open label and randomized controlled trials of estradiol derivatives and conjugated oestrogen in premenopausal women have demonstrated improvements in positive symptoms (Akhondzadeh et al., 2003; Ghafari et al., 2013; Kulkarni et al., 1996; Kulkarni et al., 2015; Kulkarni et al., 2001, 2002) and cognition (Ko et al., 2006). However, two studies did not report any

significant symptom improvement with oestrogen treatments—one using a combined estradiol-progestin therapy and the other studying a conjugated oestrogen therapy (Bergemann et al., 2005; Louza et al., 2004). Two studies of raloxifene, a selective oestrogen receptor modulator (SERM), have reported improvements in cognition (Weickert and Weickert, 2017) and brain activation (Ji et al., 2016; Kindler et al., 2015) in premenopausal women. The raloxifene studies in postmenopausal women generally include only EOS patients and have shown some improvements in positive and negative symptoms (Kianimehr et al., 2014; Kulkarni et al., 2010; Usall et al., 2011; Usall et al., 2016). In men, one study showed that two-week estradiol treatment rapidly improved psychopathological symptoms (Kulkarni et al., 2011) and that eight-week raloxifene treatment led to greater improvements in negative symptoms and general psychopathology (Khodaie-Ardakani et al., 2015). One case report described improvement in psychotic symptoms with hormone replacement therapy alone in a perimenopausal woman with LOS (Bergemann et al., 2007). Notably, the largest published study of raloxifene plus antipsychotics versus placebo plus antipsychotics in 200 severely ill decompensated postmenopausal women with schizophrenia or schizoaffective disorder was a 16-week double-blind randomized controlled trial. It reported that individuals in the active treatment arm had *worse* outcome than those in the placebo arm. The authors concluded that their data do not support the use of raloxifene in severely decompensated patients with schizophrenia or schizoaffective disorder.

To date, no published trials have examined the therapeutic use of oestrogens or SERMs in LOS patients of either gender.

A recent open-label trial of yokukansan, an herbal remedy with serotonergic, dopaminergic and glutamatergic actions that has been studied in treatment-resistant schizophrenia and dementia patients with agitation (Matsuda et al., 2013), found significant improvement in psychotic symptoms in patients with VLOSLP compared to placebo (Miyaoka et al., 2013).

Valbenazine, a selective vesicular monoamine transporter 2 (VMAT2) inhibitor was approved by the FDA in April 2017 as the first and only approved treatment for tardive dyskinesia in adults. Unlike tetrabenazine, a VMAT2 inhibitor that is approved for Huntington's chorea, valbenazine is dosed once daily and had few side effects related to monoamine depletion (Huntington Study, 2006). The once-daily dosed medication was shown to significantly improve movement systems as rated by the Abnormal Involuntary Movement Scale and Clinical Global Impression of Change—Tardive Dyskinesia over a six-week trial and was well-tolerated in the participants (Hauser et al., 2017; O'Brien et al., 2015). These trials were conducted in patients aged 18–85 years old, with average age 55 to 57 years. More than half of the participants were diagnosed with schizophrenia or schizoaffective disorder, though a number of participants with mood disorders and gastrointestinal disorders were also included. It is unclear what proportion of these participants had LOS

Late-onset schizophrenia

compared to EOS. Further studies on the effects of this new tardive dyskinesia treatment in LOS are warranted to finetune its use in older persons.

Psychosocial treatments

Most trials of psychosocial interventions for older persons with schizophrenia have targeted patients with EOS. Keeping in mind the significant differences in premorbid psychosocial functioning between those with EOS and those with LOS, there is a need for studies comparing results of psychosocial interventions in early- and late-onset patients. Psychosocial interventions can have significant benefits other than immediate symptomatic relief. For example, a socially stimulating group intervention targeting lonely older individuals with schizophrenia has been associated with better cognitive functioning, improvements in wellbeing, and lower mortality (Pitkala et al., 2011; Routasalo, 2009). This is particularly relevant to the LOS population impacted by high prevalence of social isolation, which has also been found to increase the risk of dementia (Wilson et al., 2007). Three nonpharmacological treatments have been designed specifically for the older population with schizophrenia and they are all group based.

Functional Adaptation Skills Training (FAST) and its modified version for older Latinos—Programa de Entrenamiento de Aptitudes para Latinos (PEDAL)—are manualized therapies implemented in the group format. Both have been found to improve social and everyday functional skills and to decrease the short-term use of emergency medical services (Mausbach et al., 2008; Patterson et al., 2006; Patterson et al., 2003).

Cognitive-behavioural social skills training (CBSST) is another group intervention designed for older people with schizophrenia. It combines two modalities with efficacy in younger patients. CBSST is based on the concept of challenging the common beliefs that interfere with treatment in this population and by providing repetitive practice of behaviours to improve retention and skill development. It has been associated with learning of new coping skills and better social functioning after treatment and also at one-year follow-up. However, gains in cognitive insight following CBSST appear to not be maintained at follow-up. This suggests that improvements in function are not necessarily an outcome of better insight (Granholt et al., 2005; Granholt et al., 2007; McQuaid et al., 2000).

Enhanced skills training (ST) and healthcare management (HM) combine skills training for daily living and medication management plus preventive nursing visits to address medical comorbidities in older adults with severe mental illnesses (SMI). ST + HM has been associated with improved social functioning and independent living skills, whereas functioning remained constant or declined for the HM-only group. The two groups receiving HM demonstrated increased use of preventive health services and identification of previously undetected medical

Late-onset schizophrenia

disorders (Bartels et al., 2004). A derivative, Helping Older People Experience Success (HOPES), is an integrated model of psychosocial rehabilitation and healthcare management and appears helpful in improving community living skills (Pratt et al., 2008).

The potential benefits of employment are numerous and older adults with SMI often manifest a desire to work despite low rates of paid jobs (Auslander and Jeste, 2002; Twamley et al., 2005). Ageing with schizophrenia can be associated with challenges in the workplace (Jeste and Nasrallah, 2003; Kurtz, 2005). However, competitive employment and, specifically, supported employment (SE) has been associated with better outcomes compared to conventional vocational rehabilitation (CVR). The goal of SE is rapid and individualized placement in competitive work with on-site training if required, following the 'place-then-train' philosophy. CVR reflects the 'train-then-place' approach with prevocational training and volunteering and gradual contact with competitive work (Twamley et al., 2005; Twamley et al., 2008).

Treatment adherence and service utilization

No study has assessed treatment adherence in patients with LOS specifically, but both psychosis and ageing have been linked to adherence problems. Partial adherence to treatment is observed in at least 20–50% of patients in the general population, but these rates approach 70–80% in persons with psychotic disorders. In older patients taking antipsychotics and medications for hypertension, diabetes, or hyperlipidaemia, researchers have reported similar adherence for psychiatric and nonpsychiatric medications. These rates ranged from 52–64%. Several factors related to old age may result in poor adherence, including sensory impairments, cognitive deficits, osteoarthritis, restricted mobility, lack of transportation, social isolation, financial insecurity, polypharmacy, and increased sensitivity to side effects. Poor adherence is associated with recurrence of symptoms and readmission, and with significant personal and societal costs (Masand and Gupta, 2003).

Studies have shown that among the population with chronic psychotic disorders, older age is associated with a lower use of all mental health services, with the exception of case management. This is in keeping with the observed decline in mental health expenditures in older people and the fact that the higher costs of case management and inpatient/crisis residential services among older persons are attributed largely to the population with schizophrenia. A significant drop in the use of outpatient services has been noted with age; this might explain the more frequent use of psychiatric emergency response teams and psychiatric emergency unit admissions (Gilmer et al., 2006; Jin et al., 2003).

These findings are consistent with those of McNulty and colleagues (2003) describing the high level of unmet care needs in a community sample of older people with schizophrenia or related disorders in Scotland, 59% of them with onset of symptoms after age 45. Reeves and

Late-onset schizophrenia

colleagues (2002) also observed that only 59% of older people previously diagnosed with VLOSLP were still in contact with psychiatric services after three years. A 2016 UK study reported low antipsychotic treatment rates (48% at three months, 27% at 12 months) in patients with VLOSLP (Sin Fai Lam et al., 2016).

It is also critical to assess capacity for healthcare and financial decisions. There is considerable heterogeneity in the level of decisional capacity among patients with schizophrenia, and age itself has not been found to strongly predict the lack of capacity to consent. Negative and cognitive symptoms have a more significant impact on the decision-making capacity than psychosis per se, and capacity should be assessed when appropriate, by using instruments such as the MacArthur Competence Assessment Tool for Treatment (MacCAT-T) (Grisso et al., 1997). Advanced care directives should be reviewed in any patient, but even more so in older adults, and should minimally include a discussion on living will and proxy decision-making.

Prognosis

Course of symptoms and functioning

Considerable reductions in schizophrenia symptoms have been observed in persons with LOS treated with antipsychotics. Open studies of typical antipsychotics have reported full remission in 48–61% of patients and higher proportions of at least partial response (Howard et al., 2000; Sable and Jeste, 2002). Better results have been noted with second-generation antipsychotics, even in the VLOSLP population, with substantial improvements noted in up to 77% of patients, with a more favourable response in those from outpatient vs inpatient settings. In older people treated with atypical neuroleptics, a more positive outcome could be seen in those with LOS as opposed to EOS (Barak et al., 2002; Scott et al., 2010).

Mazeh and colleagues (2005) followed 21 inpatients fulfilling criteria for schizophrenia with first onset at age 70 or later for a mean duration of 30 months. They compared this group to 21 older inpatients with onset of schizophrenia before age 40. Worsening of symptoms was reported in only one VLOSLP subject. Most had a single episode with full or partial remission, while almost one-half of the EOS patients experienced a relapse. The choice of the control group might have biased the findings, as the literature suggests that ageing is associated with an overall improvement in psychosocial function and psychopathology in older adults with EOS, although most remain impaired (Auslander and Jeste, 2004; Jeste and Nasrallah, 2003; Jeste et al., 2011). The findings in LOS patients are in keeping with results for the VLOSLP population reported by Reeves and colleagues (2002), with 52% having a single admission. Similarly, Brodaty and colleagues (2003) followed individuals with first onset of schizophrenia at 50 years or older, and observed a considerable decrease in symptomatology over time; 68.4% of them fulfilled DSM-IV

Late-onset schizophrenia

criteria one year after the diagnosis, and only 16.7% met criteria at five-year follow-up.

However, the broader literature tends to suggest partial, rather than complete, symptomatic improvement over time in LOS and VLOSLP, which mirrors the literature on late paraphrenia from the 1960s (Kay and Roth, 1961). Jeste and colleagues (1995) reported that most of the LOS patients in their sample had a chronic course with illness duration longer than two years, with an average of 5.7 years $SD \pm 5.5$. Copeland and colleagues (1998) described residual symptoms and no case with complete recovery in subjects who had developed schizophrenia after age 65, although worsening was not seen either. Meesters and colleagues (2011) observed no significant difference in rates of symptomatic remission among those patients with early, late, or very late onset. Literature on psychotic disorders in late life seems to indicate that female gender, good treatment adherence, and schizoaffective illness are predictors of a favourable outcome. Findings are more inconsistent regarding the impact of cognition, sensory deficits, and ethnicity on the course of illness and psychotic symptoms specifically, although cognitive impairment has been associated with worse functional status (Auslander and Jeste, 2004; Granholm et al., 2008; Harvey, 2001; Palmer et al., 2002). People diagnosed with LOS and delusional disorder do not seem to differ in terms of outcomes. A dose-related effect was shown regarding antipsychotic use. Contact with a community psychiatric nurse also appears to lead to a more favourable course in LOS and late paraphrenia (Hassett, 2002; Holden, 1987; Howard and Levy, 1992; Meesters et al., 2011; Reeves et al., 2002; Riecher-Rössler et al., 2003).

Partial improvement in symptomatology can be achieved in most patients, though this does not necessarily translate into functional recovery (Patterson et al., 2003). Brodaty and colleagues (2003) demonstrated that even though the majority of LOS patients did not meet DSM-IV criteria for schizophrenia at follow-up, they were still functionally impaired, with GAF scores still below 50. Nineteen of the 21 patients included in a follow-up study by Mazeh and colleagues (2005) were able to stay at home for 30 months following discharge. Mild difficulties in the activities of daily living (ADLs), still within the normal range, characterized the 13 subjects with LOS described by Laks and colleagues (2006), with no significant deterioration in the functional scores at the one-year reassessment. These results underscore the heterogeneity in clinical and functional outcomes in the LOS and VLOSLP populations.

Course of cognition

Although there is no indication of an increased risk of Alzheimer's disease in patients with LOS, some data support a general neurodegenerative pathophysiology. In follow-up studies on LOS or psychosis, significant cognitive deficits have been described in up to 50% of patients, especially

Late-onset schizophrenia

in very-late-onset cases (Brodaty et al., 2003; Korner et al., 2008; Korner et al., 2009a, 2009b).

Yet, most of the evidence points towards relative stability in the cognitive abilities of patients with LOS. Palmer and colleagues (2003) found no evidence of cognitive decline for schizophrenia patients in both late- and early-onset groups compared to normal controls, while two Alzheimer's disease comparison groups (persons with very mild deficits and persons with psychotic symptoms at baseline) manifested progressive impairments. The absence of significant change in neuropsychological performance over time in individuals with LOS has been replicated. Although people with LOS do not experience a greater worsening of their cognition compared to age-matched controls, they do not show the same level of improvement following intervention (Granholtm et al., 2010). This could have treatment implications, as it suggests a ceiling effect in response to interventions that have a cognitive remediation component.

Quality of life

In older patients with schizophrenia, symptomatic remission has been associated with a higher reported quality of life (QoL), intermediate between that of younger patients and healthy comparison subjects (Auslander and Jeste, 2004; Bankole et al., 2008). A study by Folsom and colleagues (2009) suggested that older age may, in fact, be associated with greater mental health-related QoL in this population. On the other hand, Meesters and colleagues (2011) could not demonstrate any correlation between symptomatic remission and QoL in older people with schizophrenia, although the remission rates in their sample were lower than those reported from convenience samples. This is consistent with studies indicating significantly greater improvement in psychological and health-related QoL in patients treated with olanzapine rather than risperidone (Ritchie et al., 2003; Ritchie et al., 2006). In light of the significant interplay between cognitive status and social situation with regard to overall function and QoL, the failure to include measures of QoL in most outcome studies on LOS or VLOSLP as well as the exclusion of late-onset patients from some papers on QoL area is a drawback (Meesters et al., 2010).

A similar effect to medications has not been as clearly established with psychosocial interventions. No impact on QoL was demonstrated following participation in FAST (Patterson et al., 2006; Patterson et al., 2003). Improvement in QoL resulting from better functioning following CBSST was postulated by the authors, but as QoL was not part of the outcomes measured, this remains hypothetical (Emmerson et al., 2009). We did not find any mention of QoL in relation to ST + HM (Bartels et al., 2004). However, vocational rehabilitation, particularly supported employment, does appear to lead to better QoL (Bartels and Pratt, 2009; Twamley et al., 2005; Twamley et al., 2008). This could indicate that better functioning seems to be associated with greater wellbeing; other avenues also need to be considered. The importance of positive social

support and interactions cannot be minimized, as married middle-aged and older adults with schizophrenia reported better QoL, despite the presence of depressive symptoms in both groups (Nyer et al., 2010).

Mortality

While increased morbidity and mortality rates have been noted in schizophrenia for decades, recent studies have reported a growing mortality gap between individuals with schizophrenia and the general population (Laursen and Nordentoft, 2011; Lee et al., 2017; Saha et al., 2007). Whether late-onset cases herald a specifically higher mortality risk is not clear. Most outcome studies reporting deceased subjects did not include a control group. The onset of psychotic symptoms in late life was associated with double the risk of mortality at follow-up by Henderson and Kay (1997), while Östling and colleagues (2007) found no such association. A 2015 Finnish registry study reported that VLOSLP had higher mortality risk compared to EOS patients, mostly attributable to physical comorbidities and accidents (Talaslahti et al., 2015). Although the risk of suicide might be somewhat lower in older patients with schizophrenia by approximately 5% compared to younger affected individuals, they are still at risk of suicidal behaviours, and age of onset was not found to mitigate this risk one way or another (Barak, 2004).

in my garden,

red rose,

redbreast,

the raw and its roots - the red and the reason¹

It takes me years to find my garden, sixty-eight to be precise, although there are other gardens of one sort or another before this. Sitting here among the leaf-stripped trees with this sense of fullness and completion, of tranquillity and something akin to contentment though neither joy nor absence of pain describe it fully, sitting here, I watch the robin tremble a bare bough and see the strangled rose shed its crimson to the wind.

Personal experience: The red and the reason

Beginnings

I come from a line of women living traumatic lives. My great-grandmother survives emigration from Ireland and the death of a husband who does not. She self-medicates with alcohol and forgets she is a mother. Her two daughters are farmed out to a family where they are exploited as cheap labour and where unspeakable acts take place. Mama guards her sister with fierce love, and nurses a violent hate towards the abusers. My grandmother goes on to birth two children of her own and to build her life around them. And when my mother is deserted by my father, she comes back home to the love of Mama, with me her daughter in her arms. I grow up in this way, fatherless, but with two mothers, inside of a citadel where men are enemies.

I grow up in a maelstrom of love, loss, and pain, snatched up into a fierceness that twists control from my mother, crushing her into submission as daughter within the fortress that Mama rules. But in this stronghold of love, built to protect us from the world and its wounds, the cruellest wars are waged within. Domestic conflicts between mothers and daughters.

Women at war with one another. Women at war and women in peace, flash truces marked each evening with the wine opened and the beer poured and pain laid temporarily aside. There is laughter, warmth, comforting. Mothers sit down, work done, quarrels mended, the Guinness and the Keystone Port drunk in libation to the mantra that 'iron is good for you.' Mama is anaemic from childhood. Migraine crushes my mother. The heart breaks, the body bears the ills, the bottle brings relief ...

I witness the violence of women on women. These raw memories are not softened by time. Hard words and screams pierce the struggle for charge of the child, where home-front shifts to battleground. Household tasks become war crimes, with sweeping brushes hurled, as tempers bristle and rage rends itself into cleaning frenzy, then the silence so taut it threatens to shatter the windows polished to a thin edge.

I smell the wounds of mother love turned against itself. I taste the gall of married love abandoned. I watch despair lashed out with stinging threats and accusations ...

I am a witness to violence and I am subject to it. My mother's sharp words linger longer than the slaps across the face. And now, in later life, I find myself both war correspondent and war casualty, and surely war criminal also.

Yet my heart's wholeness is comfort to me as I age. It reminds me that, regardless of pain, I am as a child most deeply loved, through many sacrifices and deprivations, on the part of two women to protect me. And I feel such a tenderness for our broken lives, where we try our best and

Personal experience: The red and the reason

do not succeed. I carry the love, the loss, and the longing and I hold no regret. For these are the memories that please and sadden together.

I savour rain steeped in the damp wool of my mother's coat from her long walk to night class, before she sits through the night to sew me a dress. I inhale bleach from Mama's apron as I watch her work while I play and then I feel the grasp of her hand walking me to swim after school and the same chlorine smell from the baths when she towels away at my shivering, before we wait the trolleybus home in the dark night. I sniff the scent of cakes from the oven that could hardly wait to cool before we tear into them and I feel all the love of their baking.

I can never, never as a child remember feeling hungry without the prospect of food to take that hunger away. I can never recall the humiliation of torn clothes as my mother parades me, her velvet princess, around the marketplace, without a penny in her pocket.

Within reminiscences such as these lies the comfort of childhood, but also the remorse that comes with insight; of a generosity taken for granted, of privilege earned through the going without of others, and those many opportunities outside the limits of our family income that come to me not by chance but through maternal determination and belief in a better future.

The good memories far outweigh harder ones in their lasting impact on my survival and spiritual growth. I am able to look on my life as anchored by strong maternal love that, in turn, has enabled a core of resilience, of eventual self-belief, and some sort of wholeness. And I carry a depth of love in return for both of these mothers who have nurtured me.

It is impossible however to negate the traumatic effects of early experiences and the wounds that left untreated have cankered into my body, mind, and soul. In recalling pain as a witness, the actions of the women who love me most must be called to account.

Yet as I flay back time to lay bare the past, I suffer the guilt of family love betrayed. For many years, I choose not to make the inner journey. It feels treacherous to unpick sacrifice and it is only now, in my sixties, that I feel the need to know myself better and understand where my life has led me and why. So let me say, that 'war-crimes' have been absolved long, long ago. What needs to be let go of, forgiven, and forgotten, the pain pushed down and plunged into the recesses of my past. It is only now that I come to confront the red and the reason.

In resurfacing, it is the trauma of generations that tells itself, hurt passed down from mother to daughter, suffering and surviving, familiar in shape and shadow, inevitable in its outcomes.

I trace scars and feel a sadness seeping out from the warp and weft of my mother's coat. Pain worn in silence, its weight stumbling and suffocating, eyes shut against tears spilling. Sssshhh! Sssshhh!

Personal experience: The red and the reason

Sorrow in her voice as she begs the man in the bare room to give her, please, a cup of tea.

How I do recall this visit to my father, where I am still a babe in arms? my mother wonders, when we share the story as adults! Yet I hear the pain of hope lost as if it were yesterday. The shards of broken wedding vows and grief unassuaged in its strongbox imprint upon me the need to lock up my emotions. Strong women have no need for tears. Suffer on in silence. I am denied permission to cry from an early age. Fear however needs no one's permission.

Fear sucked in from the breast and trembling in every fibre of flesh, thought, and feeling.

Fear for the absent father and a carving knife in Mama's hands ever waiting him at the door. Fear of the kindergarten scorn towards a girl without her daddy. Fear when the pretty poppy crumples in my five-year old hand and I dare not own to breaking it. Fear of folk on our street who must never be spoken with because Mama says they are not like us. Fear so crippling I become paralysed at the very thought of other people and I build an inner world as refuge.

Aged nine then, blood on my mother's undergarments and I fear for months till I learn she is not dying. Till I come to discover the meaning of womanhood. Terrified, when my own time arrives, I bury its evidence in the garden. In a house of secrets, I do not allow myself to bleed.

I do not allow myself to bleed unless I control it. I dig down deep to bury the disgrace and I smell the dank earth on my soul. The garden is my hiding place. I guard it anxiously.

In the house of secrets, there are no maps for the body changing from child to woman. Mothers do not share with the daughter-child-woman, the legacies of desire and adult love. Only allowed to know that men are dangerous, unwelcome. Women guard their daughters and deny them knowledge of the flesh.

And at the age of eleven I begin to cut chunks out of my own skin in a rage at my body.

the garden of guilt,
red handed criminal,
red faced disgrace,
the raw and its roots - the red and the reason

And rage suppressed reveals itself in splashes of red.

Red roses on the wallpaper in the room I share with my mother. She is a beauty in her white tight shift with the red roses that she wears, to pierce hearts of the men she traps in triumph. Males keep out! scream the roses

Personal experience: The red and the reason

on the walls. You can look but do not touch, snigger the roses on the dress. Come close and we will draw the blood from your eyes.

Night study brings advancement for my mother. Always a worker, breadwinner by necessity, now an achiever, she flies high from typist to teacher, from teacher to author to expert; ruler in her own domain. She is a queen. Men kneel before her knowledge and they are enslaved. She captures them with her beauty. The queen of roses collects hearts to lock away in her strongbox. She is loved but loves not. Blood for blood, to appease the broken bride.

Violence breeds violence. It leads me to seek out the red in my adult life. The crimson that blossoms early is slashing out the path I will follow. Its seeds planted within the small child.

I ripen to a teenager in the face of the mother queen. Her secret lusts and longings stare her straight back in the eye and mock her. My awakening is a gauntlet thrown to challenge what she most denies. The queen lashes out in a raw red rage and I harvest the yield of her envy.

I feel the fire of the red on my face. I smother the urge to strike back. I rip up photographs, scoring out their smiles. But the images I destroy are never my mother. I tear only at myself.

I feel the power of anger, am paralyzed when there is no place to put it, Rage turns inwards.

The knowledge that I hurt myself more deeply than others can, is exhilarating and addictive.

My mother runs to London. She is called to high places. I am left with Mama and I run wild.

I hurt myself to hurt the mother who cares for her career and who runs away from my pain.

I cry unheard for help, I ask for answers from women who shut their ears to the questions.

So I am drawn to the power of men, one after the other they pursue me, and I hate them all.

The grandmother spoils the pretty grandchild, more kind than she was to her own daughter.

I fritter away new freedoms, find bad company day and night, lose all sense of direction.

I become a precarious woman amongst precarious women in the house of sorrows unshed.

Weekends bring us together. At my most provocative, I flaunt insolent flesh out of spite.

Personal experience: The red and the reason

The queen screams at bared breasts, rails at white thighs, hates the hippy hair in armpits.

The slapping continues until I am twenty and I hit back. My mother never strikes me again.

I meet my man at twenty-one. I move to live with him and the family cease speaking to me. In hospital, I recall the mothers sitting tight lipped and wordless until I am out of danger and they can leave.

I marry my husband within the first year. After one wedded week he punches me in the face. He takes me into the garden and pushes me towards the canal. This is where wives end up. I do not run home to the mothers. Shame bolts me to the marriage bed where I must learn that his violence is all my fault. I've made my bed and I must lie in it, since I chose to leave the mother house; the house that denies all men.

It takes me four years to shake off the shackles of blame and leave him. It takes forty years before I can write about it. It takes forever to become free ...

I survive alone. I am proud of this. I make it through homelessness in the seventies, before the birth of the refuge and the safety of Women's Aid,

And my bed must be any bed. Bed is a child's bunk in a friend's home, bed is the temporary sofa where my presence does not push the unquestioning kindness of work-mates, bed after nights of painting red, is any crash-down with anyone at all. I take any bed because I do not have a bed of my own.

I am proud that I do not splinter. Strong women bear their burdens. I learned the lessons at my mother's knee. And so I push down the pain until my physical body screams in protest. At the age of twenty-six I am asthmatic, arthritic, with a heartbeat that flutters and threatens.

It will take a decade before I break into pieces, ten years until I make the link between the ills of body, mind, and soul. I will dig the roots of distress to shake loose the red and the reason, before I become whole again.

Breaking down and building up

in the garden of pleasure
is the red dress to dance in
Is red wine in the morning
the raw and its roots -
the red and the reason

My late twenties and thirties are a whirl of new experiences and it comes my time to fly high. I land back each Friday to the mothers where I am now on safer ground, where theirs is a house of food and wine and the cosy chatter of women pecking on the scraps of the week. My mother is my role model. Women are achievers. Strong women can do it for

Personal experience: The red and the reason

themselves. I pick up an education. I pick up a career. I pick up a house. I throw off a violent marriage. I am working in a university. I have lodgers to feed the mortgage and I feed them each night. My own home becomes my castle. I fill it with the folk who know how to enjoy.

And I too become a queen. I am the queen of parties and good times. We dance in the garden and we dance down the street. My house is full of the good timers from dusk till dawn and I go from empty to empty with a hunger that I cannot name and do not even taste.

I do not know I am starving. I do not want to think about the deeper hunger, so I do not think. There is always the next thrill to push the pain down, another love to consume the craving.

I am thirty-six when I start to cry and I cry for most of my lifetime in the space of a weekend. The time and the place are irrelevant. It is only important that the tears begin and that once they are pouring down my face, there is no way to quench them.

I sit among my people and I have never felt so lonely. Nothing matters any more but the tears and the clarity that they bring. I cry until the emptiness inside me is flushed out and hung up to dry. I look on with peeled eyes and I weep in despair at what I see ...

I have never felt so lonely and yet I know that I have been this lonely for the whole of my life.

I must howl to the moon. I must dance close up with pain. I must lie in the empty bed, abandoning the lover who gives me his back. I must not be afraid—and if I am afraid I must understand and I must forgive myself.

It is the breaking down that saves me. In the hard months ahead I find the roots of fear and loss and rage. I learn to be alone and to be at peace with myself, to hold the broken bits and not be ashamed. I learn that fear of fear is maybe the greatest fear of all. I trace my body's ills to their spiritual sources and begin to integrate my body mind and soul. I will, I can, heal.

And I build up a better self. I find reason and love, in work, in life, in a reaching out to others. My links to the mothers are stable and calm but I share not my breaking. From this pain will I guard them and I will spare them. I will carry my own broken back as they have taught me well to do. For in their love, they do the best they can, the mothers in their sorrows.

my mother's garden
red shawl on an empty seat
red eyes weeping
the raw and its roots -
the red and the reason

Personal experience: The red and the reason

In my grandmother's ageing, my mother finds a new power. The homestead is hers to rule and her caring becomes the silken ties that hold down Mama within the citadel of kindness. Trapped in blindness as great-grandmother before her, an agile angry mind in a dark prison the final years bring comfort to my grandmother at the price of her independence. Mother is now the giver of food and the maker of rules, coaxing the broth before the brandy, bleaching the unsightly hairs from Mama's chin and scolding the soiling of the bed.

Mama dies at home in the care of daughters. She asks me and I tell her that she is dying. She is so peaceful to know that life will close, for ageing has neither been welcome nor kind. I carry my Mama on my back to the bathroom. We laugh at life with all of its indignities. Her pain is brief and in the final hours, she sees faces that we cannot see. She sees forms that she knows and she speaks with them.

I am happy when spirits visit and lift the veils from her eyes. I feel the freedom of her passing and my tears at her end are tears of joy. My mother feels nothing but loss, inconsolable loss and the gaping hole left after the years of caring. When after weeks, she can weep no more, her skin weeps for her and she succumbs to wretched afflictions of skin and the soul.

Rage not laid to rest, festers raw under the surface, trapped in the grief that won't let go.

My mother ages quickly. She feels emptiness that is not relieved in the company of others. She wants the closeness in the house of mothers where she now lives alone. She is angry when I bring her disappointment for I will not be governed by what has gone before, by rage disguised as duty and in petty little paybacks wrapped up and hidden within the kindness of unstinting daughter love.

We travel on together, my mother and I, sometimes at peace, sometimes at war, meeting by arrangement, always at mercy to the angry flare-ups that set us alight against one another. She longs to nurture and feed. She tears at food with her fingers to put on my plate. She waits by the phone. She plans in smallest detail her life around mine. She will help my work. She will find us evenings of music and theatre. Mother and daughter enjoying themselves.

'She should have died hereafter'—my asthma smothers Macbeth and shakes his soliloquy. I struggle against the silent audience for I must leave my seat, my mother stumbling, clinging on. I gasp and my mother weeps. My mother prays and I gasp. I gasp at her to leave me be. Bereft of breath, I am without care and without kindness. I cannot and I will not hold her pain.

A lifetime of breath suppressed, in the minutes before I can express and I say her concern is concern for herself—she does not see how she makes me worse—that I cannot find air while she panics—that I cannot save her

Personal experience: The red and the reason

and myself at the same time—I fight her for the space to breathe. She says in fury that I push at her when she tries to help. She is angry at being rejected in a time when I need her least.

It is weeks before we forgive one another.

Age will mellow; me in my fifties she in her seventies, we will dig out time for the unspoken.

My mother asks why I am distant and never the dutiful daughter as she herself has been.

'... because you were never there for me ...'

I answer from some untapped pain-source within. I feel in its intensity the stab of unbearable abandonment of the child whose mother puts a career first.

Releasing her own pain, my mother replies:

'... I had to run away because Mama wanted you all for herself ...

... I could never be the mother I always wanted to be ...

... I had to run away to find myself and make a different life for us all ...'

agony in the garden
red alert
red pain at work
the raw and its roots
the red and the reason

I spend more time with her as she ages. We slip into an understanding and an acceptance of one another that honours what has gone before and gives to the moment what is needed.

My mother's death is not easy. Illness comes and kills quickly and without any warning. Her pain grows until she can bear it no longer and an ambulance is sent for. Doctors find the spiteful cancer hiding itself out of sight deep within her. Hours from death, and I would change places to spare her these hours. In a pen packed with older people, she is examined by a doctor, who ignores her cries and forces a feeding tube inside her. The terrified animal in her eyes leaps trembling into my heart and remains there to this very day.

My mother, wheeled unconscious to ICU, where they tell me it is just a matter of time.

I sit at her side and I talk, I talk and I sing. I do not leave her alone in the darkness without the sound of my voice for one moment. Our lovely Father Sean is there, too. In a brief silence as I gather my feelings, my

Personal experience: The red and the reason

mother's eyelids strain to open and she searches for my voice. I tell her that I love her and that I have always loved her and that she is the most beautiful person in the whole world and all of this I say from a true heart. I sit holding her hand for seven hours, though the nurses try and fail to move me.

The nurse tells me that my mother's breath has stopped. The nurse wraps her arms around and hugs me. I have no tears and no pain, nothing but exhaustion.

I must find my mother her prettiest dress, I will drape her coffin all over with sweet red roses. Two hundred red roses say goodnight and god bless to the mother sleeping in the church.

I am the daughter bereaved, not of one mother, but of two. I am the end of history. This tale of mothers and daughters will end with me. No daughters to follow my wake. I travel alone, stripped of status, bereft of their company, the mothers who leave me behind.

the garden smoulders
red flames in the night sky
red flag, mind missing
the raw and its roots -
the red and the reason

My own beloved home is burgled and razed to the ground. Coupled with my mother's death. The mind breaks and I am made mad. Spiritually gutted, burned to ashes; nothing, nothing. I am a refugee from myself. I am refugee and I am orphan. Besieged with fears and regrets, pursued by guilt, all meaning is lost.

I am a wanderer. I am without possessions. All that matters reduced to rubble. A lifetime's work and writings gone up in smoke, beloved books burned to ashes, pictures of mothers consumed by the flames, love charred at the edges within smouldering memories.

But madness is not unkind. I find solace within the visions that hold me. Red tempers reason and I rise from its flames durable, resilient renewed with a core of steel. All that is unwanted is seared away. I have been broken and I have fused myself together.

This is not easy. I am still at mercy to ghosts. But I am learning to live with fear and face it, and to answer the spectres of the past as truthfully as I can. I am integrated into something whole that I can call my ... self.

I am strong woman and I am naked woman, terrified and courageous, fractured and whole. And I am the legacy of my two mothers before me and of all of the women that they become. There are many women that live inside me and I honour them all.

Personal experience: The red and the reason

Ten years on into my sixties and I choose solitude as a partner. My life path is mapped from childhood.

Although alone, I am never lonely. The truth that I love and am loved springs from the heart of a family that tries its best, stumbles often, crawls along on its belly but stays true to love. I recall the mother of my mother, a tiny body filled with such fierce love, a longing to protect, the hunger to possess. I remember my mother and the bleeding heart she wears for a man who goes away. I see a worn wedding band that jumps from her finger at the instant of his death. I never find nor want such attachment. I have chosen for the most part to live alone.

I sit in my garden
red rose red breast
the raw and its roots -
the red and the reason

I permit myself now to live in the house of the mothers and I call it mine. I think increasingly about all of our lives, about their deaths, about time passing and my own death ahead of me. There comes a sweet memory of a dear face, bathed in pure light as the priest blesses her and my mother answers to him calmly that she is ready.

When, I wonder, will I be prepared?

I reflect on my own death. I have no daughter to watch the mother, so I will surely die alone. But I do not fear death. It is legacy from my mothers, that death in itself brings only release. It is living that hurts. Yet it is the losing of life unlived, that seems to me to be so unbearable. Those chances missed, things unsaid or unfinished, the lives we could or should have lived. I feel all of the living left inside of me and I fight against the loss of it. I rail against my frailty; there is much left to do and I am not ready to let go.

I delight in this garden, it is space for peace and purpose, a growing place, healing and alive. I spend hours sitting in silence, feel the wind shake through leafless branches, hear the bird calls on the air. I am no hearty gardener but I sift soil through my fingers and loosen flowers from the weeds that bind and choke,

I have chanced upon this rose, a single rose, red as blood, holding brave against the tangled green of a creeper that threatens to bury it. Will I prise the bloom free to breathe in the light of a winter morning and allow a gust of November wind to flutter its petals?

In my mind's fancy, this proud red rose is the soul of my mother, happy to see me at peace in her garden, dancing gaily with her pretty petals, so windswept and free.

Personal experience: The red and the reason

The robin visits each day and stays for as long as I need it. Within its song each dawn is the gentle reminder of rebirth, renewal and hope. Wise words say that if a redbreast visits often it is a loved one from Heaven reaching out; 'I'm with you, I am watching you and I will always love you.' The tiny robin that does not let me go is surely Mama, guarding me in her garden, ever ready to protect.

In order to tell my story as an older woman, the story of mothers and daughters, I have needed to hold all of our imperfections and not feel treachery where I have decided to tell to myself and to others a tale that is less than kind, in parts, although more loving than words can describe in others. Some details that I have uncovered for myself will stay untold. They need never be shared on this page or any place else. But the story, told or untold, is a heart story, a healing of the heart. And I owe it to us all.

Notes:

1 'the red and the reason' ... a phrase from *Rooms of Consequence* by survivor poet Louise Hunt (unpublished, 2017).

I acknowledge the importance of Louise Hunt's survivor poetry; it is from her that I lifted the phrase 'the red and the reason' and through her that I grew the courage to talk about myself tenderly and without shame.

And I celebrate the pioneering activities of two lived experience organizations, Making Waves UK and Nottingham MAD Network, where I continue to survive and thrive through their wisdom, support, and inspiration.

Oxford Textbook of Old Age Psychiatry (3 edn)

Severe and enduring mental illness

Chapter: Severe and enduring mental illness

Author(s): Catherine Hatfield and Tom Denning

DOI: 10.1093/med/9780198807292.003.0045

Introduction

This chapter addresses the needs of people growing old with long-term, severe mental illness. This group comprises mainly people with schizophrenia and other psychotic mental illness, but also a smaller number with bipolar affective disorder and other diagnoses, including major depression, obsessive compulsive disorder, personality disorders, and substance misuse. Much of the clinical research, and therefore most of this chapter, concerns people living with schizophrenia or psychosis, but the service considerations also apply to those with these other diagnoses.

Moving from institutional to community care

In the nineteenth and for much of the twentieth century, people with long-term functional mental illness in the UK were cared for in large county asylums. Many other countries had similar arrangements. At the peak, in

Severe and enduring mental illness

1955, there were 152,000 inpatient psychiatric beds in the UK. From the 1960s onwards, this model of care was questioned, as the disadvantages of long-term institutionalization became clear, so bed numbers were gradually reduced, with a shift of focus to care in the community. The old asylums have now been closed down.

Older people with chronic psychosis (sometimes referred to as 'graduates', since they graduated from one part of the hospital to another (Jolley et al., 2004) were among the last to benefit from this new approach. In 1975, just over half of the 41,864 people resident in mental hospitals in England for more than five years were aged 65 and over (Department of Health and Social Security, 1978). In addition to the impairments associated with their illness, they were further handicapped by their long hospital stay, which had left them with no independent living skills. Clifford and colleagues (1991), surveying the population of five hospitals destined for closure, found that of those with functional diagnoses hospitalized for over a year, the mean duration of admission was 24.5 years and their mean age was 64.5. Where hospitals were closed, the outcomes for discharged patients were reasonably positive, with more social contacts and higher levels of life satisfaction than people who had remained or been readmitted to hospital (Leff and Treiman, 2000).

The 1990 NHS and Community Care Act made local authorities responsible for providing appropriate community mental health services. This formalized the shift in attitudes over the preceding three decades. It was envisaged that people with chronic mental illness would live independently with support from community mental health teams and social care services and access mainstream education, leisure, and employment facilities. Unfortunately, not all of the expected benefits of community care have been realized. The promise of integration into the community was often not fulfilled and many former patients were merely 'transinstitutionalized' rather than deinstitutionalized, as they moved into nursing homes that differed very little from the wards from which they had come. Services were criticized for being fragmented and failing to meet need (Killaspy, 2006).

Numbers of mental health beds fell by 72.1% from 1987 to 2017. This compares to a 32% reduction in general and acute physical care beds (Gilburt et al., 2014). Lengths of hospital stay reduced but conversely readmission rates increased leading to the advent of the 'revolving door patient' (Jeppesen et al., 2016).

Some people with enduring mental illness have undoubtedly been diverted to the prison or homeless populations (Priebe et al., 2005). Crane and colleagues (2005) found that two-thirds of a sample of 219 homeless people aged over 55 from four UK cities had a mental illness and that, for at least 18% of them, it was a factor in their becoming homeless.

Severe and enduring mental illness

Since the demise of the large institutions it has become more difficult to identify people with enduring mental illness, as they are scattered between different living situations and cared for by different services (if indeed they are receiving any service at all). This has led to them being almost invisible in terms of research and policy. For example, the NICE guidance on interventions and management of psychosis and schizophrenia (National Collaborating Centre for Mental Health, 2014) makes no specific mention of the distinct needs of older people.

Epidemiology

The adult psychiatric morbidity surveys in England found one-year prevalence rates for probable non-organic psychosis in those aged 65–74 of 0.2% using pooled data from the 2007 and 2014 surveys (this compares to 0.5% for those aged 16–74) (McManus et al., 2016). Similarly, in the US, the National Comorbidity Survey Replication also reported a lifetime prevalence rate of 0.3%, which fell to 0.1% among people over the age of 60 (Kessler et al., 2005). These figures are likely to represent an underestimate of the prevalence of older people with psychotic mental illness, both because of the exclusion of those living in institutional care and because even those living at home are unlikely to respond to surveys.

Smaller community surveys have given prevalence rates of 0.1–0.5%, including in Liverpool (Copeland et al., 1998), Camberwell, London (Castle and Murray, 1993), and Lanarkshire, Scotland (McNulty et al., 2003). Regional prevalence figures will be affected by the historical structure of services, in particular the presence of large asylums in some areas. Rodriguez-Ferrera and colleagues (2004) found approximately half the number of cases in rural Suffolk as McNulty and colleagues in Lanarkshire, and that a much higher proportion of subjects in their sample lived independently. They thought this was probably due to some patients having been placed in the county asylum and not returning to their original area.

Reported prevalence rates in older people are thus lower than the 1% lifetime prevalence usually quoted for schizophrenia overall. Some of the difference might be accounted for by incomplete ascertainment, but excess mortality due to suicide and physical ill health earlier in life are also major determinants.

Course and outcome of schizophrenia

The outcome of schizophrenia in older age is a contentious issue. Of necessity, the long-term studies needed to address this question encompass eras with differing diagnostic definitions, treatment options, and social contexts, and this makes their findings difficult to interpret. In addition, patients included in long-term observational studies have tended to be those institutionalized patients with a poorer prognosis.

Severe and enduring mental illness

Despite these limitations, long-term outcome studies of patients in the US and Europe followed up over 22–37 years have consistently shown that approximately half to two-thirds of patients achieve significant improvement or recovery in the long term (Bleuler, 1972; Huber et al., 1975; Tsuang et al., 1979; Ciompi, 1980; Harding et al., 1987; Marneros et al., 1992). The WHO International Study of Schizophrenia (ISS) provides particularly powerful evidence as it included 1,633 patients from 18 centres around the world followed up over 15–25 years. Overall, 50% had a good outcome, increasing to 60% in some centres in low- and middle-income countries (Harrison et al., 2001).

Observed rates of recovery are dependent to a very large degree on the criteria used, specifically whether these are entirely symptom based or incorporate aspects of social functioning. The relationship of symptoms to function is not simple, as patients may develop coping mechanisms that allow improved functioning despite ongoing psychotic symptoms. There is good evidence to indicate that cognitive impairment is a better predictor of adaptive function than psychotic symptoms (Green, 1996; Velligan et al., 1997).

Andreasen and colleagues (2005) proposed consensus criteria for defining remission as the absence or low intensity of eight core positive and negative symptoms sustained for a period of at least six months. They distinguished this from recovery, which they conceptualized as a broader concept encompassing cognitive, functional, and social criteria. Recent studies employing these remission criteria in older patients have shown approximately 50% remission rates in two outpatient populations in the US (Bankole et al., 2008; Leung et al., 2008) but only 29.4% in a catchment area sample in the Netherlands containing both community-dwelling and institutionalized subjects (Meesters et al., 2011).

Cohen and Iqbal (2014) followed up 100 older people with schizophrenia from their New York cohort for an average of 4.5 years and found that 35% never attained remission and a quarter of patients relapsed during the follow-up period. However, a further quarter of patients remained in remission throughout the follow-up period and 16% of patients attained remission during that time.

A different approach to outcome is to ask people with schizophrenia about their subjective quality of life (QoL). Although there is no universally accepted definition of QoL, the WHO defines it as ‘an individual’s perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations and standards’ (Saxena and Orley, 1997). Health-related quality of life (HR-QoL) refers to the impact of a disease on a person’s wellbeing. Studies have found that older people with schizophrenia have lower HR-QoL than community controls (Patterson et al., 1996a; Cohen et al., 2003). Depressive symptoms and cognitive impairment have consistently been shown to predict lower QoL (Cohen et al., 2003; Mittal et al., 2006; Meesters et al 2013). However, recent studies have

Severe and enduring mental illness

suggested that mental health-related QoL actually improves with ageing despite reduced physical HR-QoL (Reine et al., 2005; Folsom et al., 2009). In a qualitative study, participants described reduced impact of symptoms and better self-management strategies with ageing (Shepherd et al., 2012).

Overall, it appears that while complete and sustained symptomatic remission is uncommon, this does not preclude a positive functional outcome (Cohen et al., 2008; Jeste et al., 2011). There may be even greater cause for optimism in the future as the cohort of people now entering later life with schizophrenia did not have the benefit of early recognition and effective treatment of their illness and were faced with even greater stigma and social exclusion than exists today. With reduced duration of untreated psychosis (Perkins et al., 2005) and avoidance of secondary disability, outcomes may improve still further for today's cohorts.

Cognitive impairment

Cognitive impairment has long been recognized as a major component of the clinical syndrome of schizophrenia. Although the impairments are global, semantic memory and executive functioning are the most prominently impaired cognitive domains (Heinrichs and Zakzanis, 1998).

Cognitive deficits are often present at first episode and indeed even predate the onset of illness (Jones et al., 1994), but whether these deficits remain static throughout life or continue to deteriorate over time remains controversial (Rund, 1998; Irani et al., 2011; Radhakrishnan et al., 2012). Cross-sectional studies of mostly younger community-dwelling patients with schizophrenia showed no deterioration in performance over time scales of up to ten years (Heaton et al., 1994; Eyler Zorilla et al., 2000), although they were significantly impaired compared to normal subjects. In contrast, studies of older institutionalized patients have shown deterioration over periods of less than three years (Harvey et al., 1999; Friedman et al., 2001). Studies of long-term institutionalized patients may be confounded by the effects of institutionalization itself, use of long-term psychotropic medication, and selection for those with a poorer prognosis.

Structural brain imaging studies consistently show a reduction in gray matter volume at first episode and ongoing gray matter volume loss over time, most marked in the frontal and temporal lobes (Vita et al., 2012). Meta-analysis of cross-sectional imaging studies across the lifespan suggests that the loss of grey matter plateaus in middle age but that white matter deterioration becomes apparent after age 35 and that this is accelerated in comparison to control subjects (Cropley et al 2017). Thus, there may be two distinct pathological processes that explain the early static cognitive deficits and the later cognitive decline observed in clinical studies.

Severe and enduring mental illness

Pharmacological strategies to ameliorate cognitive dysfunction have not been successful to date. Antipsychotic medication has only a modest effect on cognitive impairment (Keefe et al., 2007), and apparent benefits are likely to be due to improvement in psychosis, rather than in cognition per se. Indeed, antipsychotic drugs often have sedative effects that would tend to impair rather than improve cognition. Furthermore, despite some early promise in open-label trials, cholinesterase inhibitors have not been shown to be effective in randomized placebo-controlled trials (Akhondzadeh et al., 2008; Lindenmayer and Khan, 2011).

Psychological and behavioural treatments, in particular cognitive remediation therapy, have demonstrated greater efficacy in clinical trials than drug treatments although the benefits remain modest (Wykes and Spaulding, 2011) and unfortunately, efficacy in older patients with longer duration of illness is reduced compared to early stage participants (Golas et al., 2015; Corbera et al., 2017).

Patients with schizophrenia have a two-fold increased risk of a diagnosis of dementia compared to the general population (Ribe et al., 2015). However, the underlying cause of dementia remains unclear. Older people with functional mental illness are no more likely to have the specific neuropathological brain abnormalities associated with Alzheimer's disease (AD) than the general population (Baldessarini et al., 1997; Arnold et al., 1998; Arnold, 2001) and even subjects with marked cognitive impairment do not show neuropathological abnormalities sufficient for a diagnosis of AD (Rapp et al., 2010). Similarly, cortical beta-amyloid levels are lower in schizophrenia than in AD, and do not correlate with cognitive impairment in patients with schizophrenia (Chung et al 2016). Nonetheless, given the high prevalence of AD, the two conditions can co-occur and it can be difficult to distinguish the cognitive impairments associated with schizophrenia from a new onset of dementia. Short-term memory loss, word-finding difficulties, and disorientation are more associated with AD, whereas frontal executive deficits are more associated with schizophrenia. The time-course of cognitive decline, along with evidence of decline in functioning, is also helpful in making the distinction.

Mental capacity

Lack of insight is very common in schizophrenia and can lead to difficult decisions about whether a patient has capacity to refuse care or treatment, and whether or when to intervene in a person's best interests. In England and Wales, the Mental Capacity Act 2005 provides a clear framework for making decisions. However, in the case of older people with functional mental illness, the decision often hinges on the complex issue of a person's ability to weigh evidence and make a decision rather than on simpler issues of understanding or retention of information. Impaired decision-making capacity is not by any means a universal finding. In one study, 69–89% of subjects with psychotic mental illness were able to score in the same range as control or medically ill subjects

Severe and enduring mental illness

on a test of decisional capacity (Candilis et al., 2008). Cognitive impairment is the best predictor of impaired capacity, and understanding can be improved by repeating or simplifying the information presented (Moser et al., 2006; Palmer and Jeste, 2006), but these improvements tend not to be sustained in the long term (Wang et al., 2016).

Depression in schizophrenia

Approximately 60% of people with schizophrenia experience an episode of major depression during the course of their illness and around a quarter of them experience depression following an acute schizophrenic episode (Martin et al., 1985). Depression is associated with poorer outcomes, including poorer response to drug treatments, longer duration of inpatient care, chronic course, and increased rates of relapse and suicide (Cohen et al., 1996; Siris, 2000; Jin et al., 2001).

Two relevant studies (Diwan et al. 2007; Meesters et al., 2014) found significantly elevated rates of depression (32% and 47.5%, respectively) in community-dwelling older patients with schizophrenia compared to age matched controls (11% and 12.1%, respectively). In both cohorts, depression was significantly associated with physical illness and lack of confiding relationships.

Depression may be confused with the negative symptoms of schizophrenia but can be distinguished by the presence of low mood, early morning waking, and loss of appetite (Felmet et al., 2011). Although evidence is scant, there is reason to believe that treatment is likely to be successful. For example, a double-blind randomized controlled trial (RCT) of citalopram in 198 patients with schizophrenia and subsyndromal depression aged 40–75 demonstrated improvements in mood, social functioning, and QoL (Zisook et al. 2009; Kasckow et al., 2010).

Physical health

People with schizophrenia have a two- to threefold increased mortality rate compared to the general population (Laursen et al., 2012; Talaslahti et al., 2016) and on average their life expectancy is reduced by around 20 years (Laursen et al., 2014). Some of this excess mortality is due to suicide, but there is an increased risk of death from natural causes, including cardiovascular and respiratory disease, infections, and type 2 diabetes (Jeste et al., 1996; Brown et al., 2000). This is likely to be multifactorial and related to lifestyle factors, side effects of medication, and reduced access to healthcare (Laursen et al., 2012).

Patients with schizophrenia are more likely than the general population to have lifestyle risk factors for cardiovascular disease. They are more likely to smoke, less likely to exercise, and more likely to have high-fat, low-fibre diets, even when the study population is controlled for socioeconomic status (Brown et al., 1999; McCreddie et al., 2003; Osborn et al., 2008).

Severe and enduring mental illness

Side effects of antipsychotic medication may also contribute to increased morbidity and mortality. The cardiovascular side effects of antipsychotic medication include lengthening of the QT interval, which may contribute to arrhythmia and sudden cardiac death (Glassman and Bigger, 2001). Significant weight gain, dyslipidaemia, and new onset of type 2 diabetes are particularly associated with newer atypical antipsychotic medications. Conventional antipsychotic medications may significantly elevate prolactin levels, which interferes with sexual functioning and reduces bone density, increasing the risk of osteoporosis.

Patients with schizophrenia are less likely to receive treatment for physical health problems (Kilbourne et al., 2008; Vahia et al., 2008). Data from the Patient Outcomes Research Team (PORT) study in the US (Dixon et al., 2000) showed that 30% of patients reporting a physical health condition were not receiving treatment. Mitchell and Lord (2010) showed that following a myocardial infarction, patients with schizophrenia were less likely to be offered revascularization procedures and less likely to receive optimum medication regimes. Similarly, Bergamo and colleagues (2014) showed that, despite presenting with earlier stage lung cancer than control subjects, patients with a diagnosis of schizophrenia were less likely to undergo appropriate evaluation or to receive stage-appropriate treatment. Their survival was decreased by on average four months but this difference disappeared when adequacy of treatment was controlled for.

People living with schizophrenia may lack the motivation to attend appointments, or cognitive deficits or delusional ideas may make it hard for them to comply with treatment plans, but it is also likely that negative attitudes of care providers towards those with chronic mental illness play a role. Studies have shown that GPs were less likely to offer screening for cardiovascular risk factors to people with schizophrenia than to those with asthma or another diagnosis (Roberts et al., 2007).

Medication

There is a very limited evidence base to guide antipsychotic treatment in older people as they are frequently excluded from large-scale RCTs. A 2006 Cochrane systematic review (Marriott et al., 2006) found only three RCTs conducted specifically in older patients with a total of 252 patients. One trial, comparing olanzapine with haloperidol in 117 patients aged over 60, found that olanzapine was both more efficacious and better tolerated than haloperidol (Kennedy et al., 2003). A further RCT comparing olanzapine and risperidone in 175 older patients with schizophrenia found no significant differences between the two treatments (Jeste et al., 2003). Older patients have been included in other trials, but the number of older subjects is either not specified or too small for meaningful subgroup comparisons.

Severe and enduring mental illness

In very late-onset schizophrenia, the ATLAS trial (Howard et al., 2018) demonstrated a clear treatment benefit of low dose (100mg daily) amisulpride over placebo but the relevance of these results to patients whose onset of psychosis was earlier in life is unclear. However, Pridan and colleagues (2014) conducted a retrospective survey of 30 elderly patients with early onset schizophrenia treated with amisulpride monotherapy and found that it was well tolerated, the mortality rate was significantly lower than that of other first- and second-generation antipsychotics (10% vs 19%), $P < 0.02$) and rehospitalization rates with amisulpride were also significantly lower than those with other second-generation antipsychotics ($P < 0.001$).

Clozapine is the only antipsychotic medication shown to have greater efficacy in treatment-resistant schizophrenia (Kane et al., 1988) and has negligible risks of tardive dyskinesia (TD), but its use is tightly controlled due to rare but serious adverse effects including agranulocytosis, cardiomyopathy, and seizures. More common adverse effects include sedation and postural hypotension. There is very little evidence to guide its use in older patients and this is likely to become an increasingly important issue, as patients who were prescribed clozapine for treatment-resistant schizophrenia as young adults age.

One RCT comparing clozapine with chlorpromazine in patients over 55 found no differences between the two drugs (Howanitz et al., 1999). Barak and colleagues (1999) reviewed the literature and identified 139 reports of patients aged over 65 treated with clozapine for a psychiatric indication. The mean dose used was 135 mg. Clozapine was discontinued in 25% due to side effects, noncompliance, or inefficacy and the rate of leukopenia was 5%. Pridan and colleagues (2015) identified 43 elderly patients (mean age 69.4 ± 8.7 years) with treatment-resistant schizophrenia prescribed clozapine in a retrospective chart review. Clozapine was very well tolerated and the mortality rate was not significantly different from that of patients prescribed other first- and second-generation antipsychotics (18.6% vs 18%); however, rehospitalization rates with clozapine were significantly lower than rates for the five-year period prior to exposure to clozapine (0.41 vs 3.8; $p < 0.001$).

However, in actual practice, rates of stopping clozapine among older patients with schizophrenia seem quite high, mainly due to side effects (Snowdon and Halliday, 2011). Overall, the evidence suggests that clozapine is effective and reasonably safe in older people if it is used and monitored carefully (Bishara and Taylor, 2014).

Older patients usually require lower doses of medication due to physiological changes associated with ageing (see Chapter 13). For example, there is an increase in the proportion of body fat with ageing, which increases the volume of distribution of lipid-soluble drugs and prolongs their action; glomerular filtration rate decreases, reducing clearance of renally excreted drugs such as lithium; and liver metabolism

Severe and enduring mental illness

may also be reduced, leading to increased plasma concentration of drugs such as benzodiazepines.

In clinical practice, one is often faced with the dilemma of weighing up whether to reduce antipsychotic doses as patients become older and frailer versus the risk of relapse of psychotic symptoms in someone who may have been stable for many years. There is little research evidence to guide decision-making, but Harris and colleagues (1997) found that it was possible to reduce antipsychotic medication doses by about 40% in a sample of patients aged over 45 without an increase in symptoms.

A different approach to evaluating dose reduction has come from PET imaging studies (Graff-Guerrero, et al., 2015). In an open label trial, 35 older schizophrenic patients on a stable treatment dose of olanzapine or risperidone underwent PET scanning to determine striatal dopamine D2/3 receptor occupancy before and after a gradual dose reduction of up to 40% from their baseline antipsychotic dose. The lowest D2/3 receptor occupancy level associated with clinical stability was 50%.

Extrapyramidal symptoms (EPS) were more likely to occur with D2/3R occupancies higher than 60%. This suggests that the therapeutic window of striatal dopamine D2/3 receptor occupancy in older patients with schizophrenia is lower than the 65%–80% typically reported in younger patients.

These studies support a strategy of gradual dose reduction over time. How rapidly this is done depends on various factors, such as the potential severity of relapses, and also on the wishes of the patient, as some people will be more cautious about going on to a lower dose than will others. It is also often possible to replace depot injections with oral medication, especially if the person with schizophrenia is starting to receive personal care. This obviously makes it easier to assess the effects of altered dosages.

Older people are more susceptible to side effects from medication. Tardive dyskinesia (TD) is a particular problem with typical antipsychotic medications such as haloperidol and the risk is five to six times higher in older patients (Jeste, 2004). Studies of older hospitalized patients have shown very high rates of TD of 60–90% (Quinn et al., 2001). TD is often irreversible even after stopping medication, and although patients are usually not aware of the movements, they are obvious to others and can be stigmatizing. In severe cases, TD can cause difficulties with eating and swallowing.

Other common side effects are those related to anticholinergic actions, such as cognitive impairment (Tsoutsoulas et al., 2017), constipation, and urinary retention. All of these can be more severe in older people due to the interaction with physiological ageing and the concomitant use of other medication with anti-cholinergic properties. For example, prostatic hypertrophy in older men puts them at higher risk of urinary retention. In some cases, different side effects combine to increase the risk of an

Severe and enduring mental illness

adverse outcome, e.g. antipsychotic medications cause both orthostatic hypotension, which can lead to falls, and reduced bone density, which increases the risk of fracture. Older people are also likely to be taking multiple physical health medications and this increases the potential for drug interactions.

Nonpharmacological treatments

There is now considerable evidence of benefit from cognitive behavioural therapy (CBT) in younger patients with schizophrenia (Tai and Turkington, 2009). CBT is recommended by NICE (National Collaborating Centre for Mental Health, 2014) for improving persistent psychotic symptoms and increasing insight and treatment adherence and it can be delivered in one-to-one sessions with a psychologist or in a group. Other psychological therapies, such as social skills training and cognitive remediation, have also been shown to be valuable in younger adults. Skills training is usually undertaken in a group and may include learning about verbal and nonverbal communication and rules of social interaction using role play and exercises.

The effectiveness of combined interventions including elements of these therapies has also been evaluated. Patterson and colleagues (2006b) developed functional adaptive skills training (FAST) and evaluated it in an RCT in 240 patients aged over 40. They showed significant improvements in social skills and activities of daily living and reduced use of emergency services in the intervention group. Granholm and colleagues (2005, 2007) also used a group cognitive behavioural and social skills training intervention (CBSST) in 76 older outpatients with schizophrenia or schizoaffective disorder, and showed significant improvements in social function and insight that were sustained over a year despite no improvement in symptoms.

In summary, the evidence suggests that older people are able to benefit from psychological therapies, but sadly, in clinical practice these interventions are not yet widely available to older people.

Social functioning

People with schizophrenia are less likely to marry and have children than the general population. About two-fifths never marry and a further quarter are divorced. Two-fifths do not have children (Cohen and Talavera, 2000). They are also less likely to have been in employment and their lives may be disrupted by substantial periods of hospitalization. All of these factors lead to them having substantially reduced social networks. Of those contacts that they do have, most are based on provision of sustenance or support (59% vs 15% for age-matched peers) and few are intimate, confiding relationships (44% vs 67%) (Cohen et al., 1996).

Severe and enduring mental illness

On measures of social skills, they are significantly impaired in accepting and initiating contact with others, group participation, and making friendships (Bartels, 1997b). Social withdrawal may be a mechanism to cope with distressing psychotic symptoms, such as persecutory delusional beliefs or thought interference, or may result from reduced capacity to enjoy friendships due to negative symptoms.

Despite these deficits, older people with enduring mental illness do identify social needs as important. Auslander and Jeste (2002) examined the self-reported needs of a sample of 72 people (41–80 years). Around half of them lived independently and the remainder (47%) lived in an assisted care facility. The study excluded people with dementia or with a comorbid alcohol or substance abuse problem. The main priorities they identified were around social relationships (developing and sustaining friendships), managing their illness, and improvements in mood, physical health, and memory.

Accommodation

With the decline of long-stay wards and psychiatric hospitals, other types of provision have arisen to fill the void. Hostels and care homes run by private sector and voluntary organizations vary from those with 24-hour staffing by qualified staff to those with daytime cover only from a smaller number of staff without specialist qualifications. Group homes are unstaffed facilities where small groups of residents with chronic mental illness live together supported by visits from staff (Macpherson et al., 2004). A more recent model of care is where each individual has his or her own flat or bedsit but within a unit where there is a staff member present and often some communal facilities. There is evidence that this form of support is preferred by patients (Tanzman, 1993).

Many people with enduring mental illness live with their families. Tsai and colleagues (2011), examining data from the large Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study of outpatients aged 18–65 with schizophrenia in the US, found 46% living with family members (vs 18% living independently, 17% in an institution, and 14% with no stable housing). There are no corresponding national data for older people. These percentages are likely to vary depending on cultural expectations and on provision of alternative resources.

Homelessness is also a significant issue for people with enduring mental illness. Around half of the homeless population is aged 50 plus (Lee et al., 2016) and rates of physical and mental illness are high. It is also important that providing a home for someone is more simply having a roof: elements that create a sense of 'home' are also needed (Ogden, 2014).

As people with enduring mental illness become older, physical disabilities or loss of support networks may mean that their needs can no longer be met in their previous setting. Andrews and colleagues (2009) studied

Severe and enduring mental illness

admissions to nursing homes over a ten-year period in New Hampshire in the US. They found a much younger age of entry to a nursing home among those with a diagnosis of schizophrenia (65 vs 80 for those with no mental illness). The rates of admission started to diverge significantly between the ages of 40 and 65 where nursing home admission risk was 3.9 times greater than for peers with no mental illness. The reasons for this are not known, but one could speculate that loss or burnout of the primary carer may have contributed. Bartels and colleagues (1997a) found that cognition, functioning, and behaviour were important predictors of nursing home as opposed to community residence, with cognitive impairment especially important as it was also a predictor of a person's level of functioning. Auslander and colleagues (2001) also found that, among older patients with schizophrenia (age range 40–97), residence in assisted living facilities was associated with never having been married, the presence of cognitive impairment, and poorer quality of wellbeing.

Because their numbers are relatively small, those with functional illness are often placed in settings designed mainly for people with severe dementia that may be inadequate to meet their needs. Opportunities for social interaction and participation in particular are likely to be severely limited and freedoms curtailed. These problems might be overcome by better staff education and individual care planning and risk assessment.

Psychiatric services

There has been much debate about who should provide mental health services to older people with functional mental illness. Patients may continue to be provided for by general adult or rehabilitation services indefinitely or they may automatically 'graduate' to the older people's service on attaining the age of 65. People growing older with functional mental illnesses may perceive a great injustice in being discharged from services they have previously been able to access due to an arbitrary age cut-off of 65 years. Older people's mental health services are often more poorly resourced than rehabilitation services for younger adults and focused around dementia, rather than functional illness. Access to services such as crisis resolution and home treatment teams for acute relapses or assertive outreach teams may be restricted to working age adults. On the other hand, older people's services may be better placed to meet the needs of those with physical frailty or cognitive impairment, whatever their age.

As discussed in Chapter 20, there has been a threat to merge old age psychiatry services into generic 'age inclusive' services. This has led to the development of criteria for old age psychiatry services that are based more on clinical need than on chronological age (RCPsych, 2015; Royal Australian and New Zealand College of Psychiatrists, 2015; see Box 20.3 in Chapter 20). People with enduring mental illness therefore should remain within general adult services, unless i) they have been stable for some time and not in contact with specialist services, or ii) they have

Severe and enduring mental illness

physical health problems that make old age services more appropriate, or
iii) they develop dementia.

Abdul-Hamid and colleagues (2015) conducted a survey of the needs of 74 elderly patients with functional psychiatric disorders in one urban area. Although total needs were not significantly different between those managed by old age and general adult services (8.0 vs 6.5 respectively) the participants in contact with old age psychiatry had significantly fewer unmet needs compared with those in contact with general adult psychiatry (2.8 vs 5.6, $P < 0.03$). Current UK mental health policy (NHS England, 2016) recognizes the evidence for specialist old age psychiatry services and states that 'bespoke older adult services should be the preferred model until general adult mental health services can be shown to provide age appropriate care'.

People with an enduring mental illness have often had many difficult experiences, and this may include their previous contacts with mental health services. Over the years, they may have experienced deprivations of liberty, invasive treatments, traumatic experiences, a lack of autonomy, and discriminatory attitudes. A personal history of this kind can increase their mistrust of healthcare professionals, and make them unwilling to seek help or remain in contact.

Future challenges

As the population ages, the numbers of people surviving into old age with enduring mental illness will increase (Cohen et al., 2015). However, the numbers will always be relatively small in comparison to those with dementia, who form the majority of patients of old age psychiatry services.

There are specific areas of expertise in working with older patients with long-term functional mental illnesses, e.g. around prescribing, medical support, housing and accommodation, and productive activities. Staff working within older people's mental health services need to have access to appropriate training and resources to develop and maintain their expertise. This needs to be recognized in planning and providing services, with suitable arrangements for staff support and supervision.

The lack of research in this age group means that there is a dearth of good quality evidence to guide practice. More research in particular into medication, psychological therapies, and services is urgently needed.

Conclusion

Older people with enduring functional mental illness represent a vulnerable, marginalized group in society. In addition, many have no family members or friends to act as advocates or supporters. They may be the victims of a double discrimination on the grounds of age and mental illness and are likely to receive poor quality care despite having high

Severe and enduring mental illness

needs. It is important that current emphasis on other disorders, especially dementia, does not cause this group to be neglected.

Older people with enduring mental illness need access to good physical and mental healthcare, including screening and health promotion, given their high risk of physical ill health, psychiatric comorbidity, and drug side effects. Despite these challenges, positive outcomes are possible and older people should not be excluded from provision of innovative service models and psychosocial interventions.

Alcohol and substance misuse

Chapter: Alcohol and substance misuse

Author(s): Tony Rao and Katy A. Jones

DOI: 10.1093/med/9780198807292.003.0046

Introduction

The misuse of alcohol and other substances has increased noticeably in older people over the past decade, influenced by the cohort of 'baby boomers' born between 1946 and 1964 (Rao et al., 2015); with the oldest within this cohort crossing the age of 65 in 2011. In Europe and the UK, the number of people over 65 with a substance use problem, or needing treatment for substance misuse is expected to more than double between 2001 and 2020 (European Monitoring Centre for Drugs and Drug Addiction, 2008). In the United States, the number is expected to treble over the same time frame (Colliver et al., 2006). In Europe, the proportion of the population aged 65 or above is projected to rise to 25% by 2050 (European Monitoring Centre for Drugs and Drug Addiction, 2008), so the inevitable rise in older people with alcohol and substance misuse has implications for both the public mental health of older people and for old age psychiatry. The traditional definition of older people has been those aged 65 and over in the UK, but there may be grounds for including those

Alcohol and substance misuse

people over the age of 40 who have misused illicit drugs as they may show evidence of accelerated biological ageing affecting the brain and adverse psychosocial factors (Beynon, 2009). This is mainly because the length of time misusing opioids is often longer than the time spent misusing alcohol in this population and these drugs can exacerbate cardiovascular risk and accelerate premature ageing in other body systems (Beynon, 2009). Adverse psychosocial factors only add to this risk (Bachi et al 2017).

Alcohol and substance misuse in older people present many challenges and degrees of complexity that compound existing difficulties in the assessment, treatment and recovery of older people.

These include co-existing mental disorders (dual diagnosis), physical health problems and psychosocial factors such as retirement, bereavement and social isolation (Rao and Crome, 2016). Ageing also brings with it an increased likelihood of polypharmacy. Drugs available on prescription may be taken for non-medical reasons and those commonly misused include opioid-containing pain-relieving drugs, as well as sedative, hypnotic, and anxiolytic drugs.

This chapter discusses the following areas of alcohol and substance misuse in older people:

- Epidemiology and demography of substance misuse in older people
- Terminology of substance misuse in older people
- Public health and policy
- Examining evidence for benefits of substance use in later life
- Risk factors for substance misuse in later life
- Detecting substance misuse
- Taking a substance misuse history in an older person
- Clinical diagnosis and problems with using current systems
- Assessment of comorbidity
- Drug interactions with substances
- Treatment of substance misuse in older people
- Specific treatment approaches
- Driving and substance misuse
- Developments in policy and practice
- Conclusions and future directions

Epidemiology and demography of substance misuse in older people

The past decade has seen a sharp escalation in morbidity and mortality from alcohol misuse in older people in developed countries. In the UK over the past ten years, there has been a 22% reduction in the proportion of people aged 16–24 who drank any alcohol over the previous week,

Alcohol and substance misuse

compared with a 3% increase for older people (Office of National Statistics, 2017). Over the same time frame, there was a 27% increase in the proportion of younger people who were teetotal, compared with an 18% decrease for older people.

Older people in the UK also showed an increase in exceeding recommended drinking limits on any one day over the previous week, with a 20% increase for older people (from 29% to 35%) compared with a 19% decrease from 72% to 59% for people aged 16–24 (Office of National Statistics, 2017). Between 2015 and 2016, older people formed 20% of hospital admissions related primarily to alcohol (Public Health England, 2017). This has increased by over 40% from 14% between 2010 and 2011. Although the age group at highest risk of alcohol-related deaths in men and women is people aged between 55 and 64 (Office of National Statistics, 2017), this group represents a cohort of ‘baby boomers’ who will soon start to move into the care of old age psychiatry services (Rao et al., 2015).

For older people in acute hospital settings, alcohol misuse is present in 40% of referrals to old age liaison psychiatry services (Rao, 2013).

In the United States (US), the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) found that between 2001–2 and 2012–13, people aged 65 and over showed the largest rises in the prevalence of 12-month alcohol use, 12-month high risk drinking and 12-month alcohol use disorder (Grant et al., 2017). Similar findings arose from the Australian National Drug Strategy Household Survey (NDSHS), with people aged 50 and over showing the highest rises in the prevalence of exceeding daily recommended guidelines, high risk and very high risk drinking (Australian Institute of Health and Welfare, 2017).

In the UK, 11% of men and 10% of women aged 60 and over smoke tobacco (NHS Digital, 2017). Over the past ten years, the prevalence of smoking in men over 60 has not changed, but it has decreased by 23% in women in this age range. Age is shown to be no barrier to stopping smoking: people aged 60 and over have the same quit rate of 28% as those aged 18–34 (NHS Digital, 2017).

Lifetime use of illicit drugs in older people has shown a sharp increase over the past 15 years. The Adult Psychiatric Morbidity Study (NHS Digital, 2016) showed the lifetime rate of cannabis misuse rising from 0.9% in 2000 to 6.8% in 2014. For amphetamines and cocaine, this has risen from 0.1% to 0.6%. In the United States, self-reported cannabis misuse in older people over the previous 12 months rose from 0.15% in 2003 to 2.04% in 2014 (Salas-Wright et al., 2017); in Australia, it rose from 1.5% in 2004 to 3.6% in 2013 (Kostadinov and Roche, 2017).

With increasing longevity, there is an increasing risk of prescription medication misuse in older people. This refers to inappropriate dose prescribing in dose, duration, or clinical indication. Such inappropriate

Alcohol and substance misuse

prescribing occurs in up to 20% of older people, with opioids and benzodiazepines being the most common drugs implicated, both of which have the potential for misuse (Gottlieb, 2004; De Wilde et al., 2007).

Given the rise in the use and alcohol and other substance misuse in older people, the impact on public health and clinical services will need to be met by the provision of integrated care. Such service provision remains sparsely distributed (Rao and Shanks, 2011).

Terminology of substance misuse in older people

In this chapter, the term 'substance' refers to any psychoactive drug that acts on the brain to alter mood, thought processes, or behaviour. The term refers to licit drugs such as tobacco and alcohol, as well as illicit drugs such as opioids, cannabinoids, stimulants, lysergic acid diethylamide (LSD), khat, magic mushrooms, and novel psychoactive drugs. The term is also used to describe 'street' use, use of prescription drugs (e.g. benzodiazepines and opioids) in a manner not indicated or intended by a medical practitioner, and similar use of over-the-counter preparations, such as codeine-based products or drugs bought over the Internet (Royal College of Psychiatrists, 2011).

The chapter covers the most common drugs of misuse, which are alcohol, tobacco, opioids, benzodiazepines, and 'Z drugs' (the hypnotics zaleplon, zolpidem, and zopiclone), although the rising use of cannabis and gabapentinoids mean that these substances are also covered briefly. The term 'polysubstance misuse' is more commonly applied to the misuse of multiple illicit substances with or without coexisting alcohol and tobacco misuse; mostly by younger people who continue this misuse into later life.

The term 'polypharmacy' refers to prescribed drugs with the potential for interaction with each other and commonly refers to the misuse of drugs for pain (opioids); benzodiazepines and Z drugs for insomnia; as well as gabapentinoids for neuropathic pain and anxiety. All these drugs may also interact with alcohol and other illicit substances. The further potential to interact with other prescribed medication and with comorbid mental and physical disorders presents challenges to the overall management of substance misuse in older people (Rao and Crome, 2016).

Occasionally this chapter references early onset (EO) or late onset (LO) substance misuse. The concept of EO and LO problems was introduced by Atkinson and colleagues (1985) to distinguish between two different types of people with alcoholism (now known as Alcohol Use Disorders, AUDs) aged over 60 in a veteran alcoholism outpatient treatment programme (Atkinson, 1990). According to their criteria, EO refers to a drinking problem that occurred before the age of 40, while LO refers to problems that emerged after the age of 40 or 50.

This distinction is relevant because different risk factors are relevant for patients with EO or LO, and people with LO AUDs have a different prognosis to those with EO (Royal College of Psychiatrists, 2011). There

Alcohol and substance misuse

is no formal dichotomy or research for other forms of substance use, such as cannabis or prescription medication.

People with EO are similar to younger people who misuse substances. Factors associated with EO include: on-going or persistent use of alcohol throughout adult life, family history of alcoholism (genetic link) and current psychological instability, particularly major affective disorders (e.g. major depression or bipolar disorder).

People with LO problems make up approximately a third of people with alcohol problems in later life (Mellor et al., 1996). People with LO present differently with no family history and greater current psychological stability. Onset of problems can usually be linked to a specific life event such as recent bereavement, retirement, or decline in physical health (Hurt et al., 1988).

Public health and substance misuse in older people

The earliest public health interventions for substance misuse were based around reducing harm from tobacco smoking, with approaches such as restricting advertising, raising tobacco taxes, banning smoking in public places, health warnings, and plain packaging for cigarettes, and the alternative use of electronic cigarettes to deliver only nicotine. Many of these interventions have already been implemented (Givel, 2015), but improving smoking-related health outcomes has been more effective in higher- and middle-income countries (Chow et al., 2017).

However, addressing alcohol-related harm in older people has been relatively more problematic (Royal College of Psychiatrists, 2011). Older people often reduce or stop their drinking if their health declines. People with poor physical health (a group sometimes referred to as ‘sick quitters’) may bias studies that look at the health outcomes of teetotallers or very light drinkers. Under-reporting in heavy drinkers may also distort the figures. The overall impact may be a false positive finding of ‘protection’ against poor health status in older people drinking within low-risk limits (Stockwell et al., 2016; Naimi et al., 2017). With attrition of younger heavy drinkers through alcohol-related mortality, older drinkers may also represent a group that is healthier than the overall older drinking population, who may be less susceptible to the adverse effects of alcohol. This has led to the observation that regular alcohol consumption in later life is an indicator, rather than a cause, of good health (Holdsworth et al., 2016).

This finding is compounded by variable definitions of what constitutes a ‘drink’, with the UK being the only country that refers to ‘units’ (1 UK unit equals 8 g of pure alcohol). However, there has been a recent revision as to what constitutes ‘low-risk’ drinking, with the UK now defining this as being no more than 14 units of alcohol per week for both men and women of all ages (Department of Health, 2016). This might not apply to older people, where the physical effects of alcohol are more

Alcohol and substance misuse

likely to be affected by an increased fat-to-water ratio, interaction with prescription medication, and comorbid mental and physical disorders such as dementia, higher vascular risk, and reduced metabolism of alcohol and other substances. For this reason, it has been suggested that the UK adopt US guidelines of no more than 7 US drinks (12 UK units) per week for older people (Royal College of Psychiatrists, 2015).

In the UK, public health functions and those functions previously held by the National Treatment Agency were formally transferred in 2013 to Local Authority Health and Wellbeing Boards. This has now brought the responsibility for commissioning substance misuse and health promotion services under Directors of Public Health, rather than addiction services.

Examining evidence for benefits of substance use in later life

Despite government guidelines for low-risk drinking and greater knowledge about the risks of drinking, alcohol is pervasive in UK society and people receive mixed messages about the benefits and risks of alcohol use. Older people who have been drinking for longer are likely to hold certain opinions or attitudes about alcohol. They may also selectively draw on any positive messages about putative benefits of alcohol.

To support people to make sensible cost-benefit judgments about the risks of alcohol (and other substances) compared to the perceived benefits, it is important for practitioners and the public to be informed about the latest evidence.

Overall health: The 'U' or 'J' shaped curve

As described previously, a common message both in the research literature is that 'teetotallers' (e.g. those who abstain from drinking completely) have higher morbidity and mortality than those who drink moderately. This is usually described as a 'U' or 'J' shaped curve. There is now an argument that regular drinking in later life is an indicator of good health, rather than the other way around.

Using data from the English Longitudinal Study of Ageing (ELSA), Holdsworth et al (2016) found that older people with poor or fair self-rated health at the start of the study drank less frequently compared to those with good health. They concluded that messages should be revised about the benefits of moderate drinking in later life. The limitations of these interpretations have been mentioned previously.

Cardiovascular health

The cliché 'red wine is good for your heart' is sometimes quoted by people as a reason for continued consumption. This idea often features in media coverage about the issue (Szmitko and Verma, 2005). The origin of this message was the findings of the Copenhagen City Heart Study (a large longitudinal study observing 13,285 men and women for 12 years). Drinking red wine benefited cardiovascular health compared to drinking

Alcohol and substance misuse

beer and spirits, with wine-drinkers having half the risk of dying from coronary heart disease (CHD) or stroke compared to those who never drank wine (Truelsen et al., 1998). It was speculated that antioxidants and flavonoids in red wine protect against CHD and some cancers (Hertog et al., 1993).

If a patient says they drink red wine for health reasons, it should be communicated that the evidence is not strong enough to encourage patients to *take up* red wine as a strategy to reduce the risk of heart problems (Szmitko and Verma, 2005). A discussion with this patient could include helping them understand the evidence, particularly that other factors related to wine consumption are likely to play an important role in heart health (such as diet, exercise, or socioeconomic status).

Cognitive function

A concern when using substances in later life is whether sustained use has an impact on cognitive functioning, and what level of consumption may be harmful. This can be particularly concerning to older people given the coverage about dementia. There is some evidence to suggest alcohol can benefit cognitive function. For example, Reas and Laughlin (2016) found that compared to not drinking, or drinking less frequently, moderate regular alcohol intake (in this case meaning 3–4 drinks per day, a ‘drink’ classed as a 12-ounce glass of beer, a 5-ounce glass of wine, or 1.25 ounces of spirits) in people aged 51–99 was associated with better cognition (including executive function and visual memory) than lifetime abstainers or former drinkers.

However, despite some evidence showing protective effects, the impact of excessive drinking across the lifespan on cognitive function in later life is unknown. Damage to the brain as a result of heavy alcohol consumption may appear in a ‘dose-dependent fashion, leading to raised triglycerides, hypertension and other factors, which could contribute to adverse cerebrovascular changes’ (Gupta and Warner, 2008).

Most studies that do find positive benefits of moderate intake of alcohol in an older age group do not suggest people should be encouraged to take up drinking to improve their health. Advice to older people about how much alcohol may be ‘safe’ or ‘beneficial’ for them will depend on diagnoses of other problems (see Alcohol-related brain damage section for more information).

Risk factors for substance misuse in later life

Certain individual and sociocultural risk factors may influence substance misuse in an older age group. Psychosocial factors include: retirement, financial situation, peer influence, marital status, and level of social support. Individual factors include gender and coping strategies. These factors may influence assessment, treatment planning, and effectiveness of treatment.

Alcohol and substance misuse

Psychosocial factors

Retirement is a transition that typically occurs later in life. It can be a risk factor for substance misuse due to: more free time, more financial resources, boredom, loss of identity, lack of structure, and frustration with expectations versus the reality of retirement (Kuerbis and Sacco, 2012; Bamberger, 2014). Wang (2007) found that retirement transitions can be particularly difficult for those in poor health, as they do not get to enjoy meaningful activities with their new free time. Bamberger (2014) suggested it is the nature of the retirement period (e.g. deferring retirement or being forced to take early retirement) or a lengthy or stressful transition period that can increase risk of alcohol problems.

A person's financial situation can influence alcohol or substance consumption through availability and access. People receiving a generous pension may have accumulated savings or acquired financial assets over time, and may be able to afford to consume alcohol or other substances more frequently. Availability or access to alcohol in particular may be less of an issue in later life than in younger years as a person may have alcohol in their home, and family members may buy alcohol for them.

Older people have more access to prescription medication, either their own or acquired from their partner or friends.

Peer influence or 'peer pressure' is still perceived as a risk factor for substance misuse in certain groups in later life. Sacco and colleagues (2015) found alcohol use was influenced by both peer consumption and availability in a retirement community, with heavy drinkers having a different social network than those who abstained. When taking a social history, the continuing influence of others and opportunity to consume should be considered. The exploration of normative drinking patterns in current peer group is useful. Identifying specific 'at risk' times such as extended holidays or social events can also be important for treatment planning or brief advice.

Marital status affects intake of alcohol or other substances. People most at risk of alcohol misuse are those who live alone, are widowed, separated, or never married (Holley-Moore and Beach, 2016). Recent bereavement, particularly loss of a spouse, can be a trigger for new alcohol or substance problems, or contribute to relapse. Perreira and Sloan (2001) found that widowhood increased alcohol consumption.

Older men appear to be at particular risk of depression, substance misuse, and suicide after bereavement (Brennan and Moos, 1996). A person's marital biography will interact with their substance use history and should be explored in assessment.

There is evidence for gender differences, for example, recent divorce increases men's, but reduces women's, alcohol use. There is evidence

Alcohol and substance misuse

that re-marriage reduces alcohol consumption in men (Reczek et al., 2016).

Social isolation (defined as having minimal contact with others) and loneliness (defined as a gulf between level of desired and actual contact with others) has an impact on the physical and mental health of older people (Ong et al., 2016), and loneliness crosses over with risk factors for substance misuse.

Older people who say they are lonely are more likely to be female, divorced or widowed, have worsening physical health, and have little contact with friends or family (Pinquart and Sorensen, 2003). Social isolation and loneliness increase the risk of harm from substance use as older people are already more likely to drink alone, and to drink at home, than a younger group, which may mean fewer people looking out for the person or monitoring their consumption (Sacco et al., 2015).

Loss of spouse may also mean less responsibility, and less pressure to cut back. Older people living alone and drinking at home have an increased risk of falls. When discussing loneliness on assessment, an exploration of the breadth and quality of the person's current social network should be elicited. Family involvement in treatment can be important for recovery.

Individual factors

Gender

Older men are more likely to have substance problems (Atkinson, 1990), with 10% of men reporting heavy drinking at some point during their lives (Center for Substance Abuse Treatment, 1998). However, Epstein and colleagues (2007, p. 31) noted, 'the number and impact of female problem drinkers is expected to increase over the next 20 years', and we do not have the treatment services or assessment tools to be prepared for this. Between 1994 and 2012, the proportion of people aged 65–74 in the UK drinking above recommended daily limits increased from 5.3% to 14%, and from 6% to 14.8% in those aged 75 years or more, with increases greatest among women (Knott et al., 2015, p. 2).

An area of consideration when assessing an older female patient may be role changes, particularly loss of parental role or widowhood. Women may be at greater risk as they are more likely than men to outlive their spouses, and life transition changes increase the risk of LO alcoholism for women. Women have a higher risk of abuse of over-the-counter or prescription medications than men, and older women are more likely to be prescribed benzodiazepines (Blow and Barry 2012; Blow, 1998).

Coping with emotional problems

Emotional problems and depression can trigger and/or worsen problems with substance misuse in older people. Older people may be more vulnerable to experiencing emotional adjustment difficulties due to

Alcohol and substance misuse

factors we have already explored (e.g. adjustment to physical changes or mobility, bereavement, and retirement). People who said they are not coping with the stresses in their life were five times as likely to be higher risk drinkers as people who say they coped well (Holley-Moore and Beach, 2016). In the same survey, high-risk drinkers were more likely to say they drank when feeling down or depressed, with only 1% of low-risk drinkers giving this reason. People who felt they had accomplished less than they would have liked to, or felt downhearted or depressed, were nearly four times more likely to be a high-risk drinker. Older people are at risk of using alcohol and other substances as self-medication.

Detecting substance misuse

Identifying substance misuse problems may be complicated by various barriers, which include individual, social and professional factors. Cognitive problems and the symptoms of other medical conditions may make it harder to detect possible substance misuse. Older people may be reluctant to discuss or disclose issues due to embarrassment or shame.

Societal barriers to screening include: ageism, attitudes and assumptions of society (e.g. that older people don't drink or take drugs), lack of appropriate research, and an emphasis on young people's substance use. Professional barriers include individual practitioner factors such as discomfort with raising the topic and failure to recognize symptoms, and organizational factors include a lack of guidance and support around this topic. This lack includes clinical guidelines, diagnostic criteria, suitable detection tools for older adults, and training opportunities.

It should be noted that people with LO problems may be quite difficult to identify. These patients tend to present 'well', and issues about substance use up until now may have been hidden. They may not have discussed drinking or drugs with anyone before (Center for Substance Abuse Treatment, 1998), so they may be embarrassed or inclined to deny any issues. For these people, questions about onset of the problem (including assessment of a recent bereavement or other significant life event), and family history will be important when considering reasons why the person is misusing alcohol or other substances. This information will also be helpful when making treatment recommendations.

To improve detection, and to provide some structure for assessment, there several tools available to assist the assessment of substance use disorders in an older age group (focusing on AUDs).

Table 46.1 provides a comprehensive review of the available alcohol assessment tools, outlining the advantages and disadvantages of each. Tools may be used alone or in combination to complement one another. They may also be selected depending on the context of the assessment, or how long you have with the patient.

Alcohol and substance misuse

Table 46.1 Assessment tools available for detecting alcohol use disorders in older adults.

Clinical assessment using alcohol history		
Main Features	Advantages	Disadvantages
Ask patient if they have consumed alcohol within past three months. If yes, take a full alcohol history A cut-off of 14 units for older men and women showed a sensitivity of 0.92 and specificity of 0.98 for identifying problem drinking and consumption of alcohol on three or more days per week was also associated with high risk of adverse consequences (Mears and Spice, 1993)	Easy to do as part of clinical assessment May be more sensitive than some of the available screening methods, e.g. CAGE and laboratory testing (Mangion et al., 1992)	Not structured and relies on skill of clinician
Screening Questions		
Main Features	Advantages	Disadvantages
'On any single occasion during the past three months, have you had more than five drinks containing alcohol?' (Taj et al., 1998) Two single-item screeners (Dawson et al., 2010): Past year frequency of drinking 5+/4+ drinks on one occasion and maximum drinks	Useful starting point if risk of harm at lower levels of alcohol consumption is considered Accurately identifies patients at risk or who meet accepted criteria for alcohol abuse or dependence Simple to administer and quick to do Preferred by primary care	These studies did not specifically look at an older population and are therefore not validated in this population Low values of maximum quantity that maximized sensitivity and specificity among individuals aged 65 and older support a lower risk drinking threshold for individuals in this age group (Dawson et al., 2010)

Alcohol and substance misuse

consumed on any day Two Screening Questions (Cyr and Wartman, 1988): 'Have you ever had a drinking problem?' and 'When was your last drink?'	physicians due to ease of use	
Laboratory tests		
Main Features	Advantages	Disadvantages
Blood testing e.g. Mean Cell Volume (MCV), gamma-glutamyltransferase levels (Gamma GT) and aspartate aminotransferase (AST)	May show damage relating to alcohol use in older adults at lower levels of consumption therefore being a more sensitive test in the older adults (Caputo et al., 2012) Objective measurement Useful as corroborative evidence as high sensitivity but low specificity (Mears and Spice, 1993)	Di Bari et al. (2002) found CAGE and MCV/Gamma GT to be positive in only a minority of at-risk drinkers. There was a very low concordance of both tests being positive. Participants over 75 years drank less but had similar prevalence of CAGE and MCV/Gamma GT positive. Invasive test, but only minimally Low sensitivity and specificity (Mangion et al., 1992)
CAGE Questionnaire		
Main Features	Advantages	Disadvantages
<u>C</u> utting down, <u>A</u> nnoyance by criticism, <u>G</u> uilty feelings and	Widely used (Culbertson, 2006). Easy to remember and administer and easy to score	Not developed specifically for older adults Focuses on dependence and not harmful use

Alcohol and substance misuse

Eye openers (Ewing, 1984) Positive result is indicated by two positive responses. Developed for use in primary care setting.	A score of 1 or more had sensitivity of 86% and specificity of 78% for detecting alcohol issues in medical outpatients >60 years (Buchsbaum et al., 1992) In older adults aged 70–75 a cut-off score of 2 or more was associated with sensitivity of 29% and specificity of 37%, this improves to sensitivity of 70% and specificity of 92% with cut-off score of 1 or more (Rozzini and Trabucchi, 1993) CAGE is valuable for screening for dependence in the older adults using cut-off of 1 or more (Berks and McCormick, 2008) May have a better role as corroborative evidence alongside other methods as high sensitivity but low specificity (Mears and Spice, 1993) A study comparing CAGE with MAST showed both to have low sensitivities in older adults at conventional cut-off points but CAGE was more effective overall (Jones et al., 1993)	Looks at lifetime use and not current habits so if used should be combined with assessment of current consumption Low sensitivity (Mangion et al., 1992) Identified fewer than half of the heavy drinkers in a group of over 60-year olds, using cut-off of 1 may increase sensitivity. (Adams et al., 1996) Only a small number of at-risk drinkers aged over 65 scored 1 or more on CAGE. (Di Bari et al., 2002) Less than half of those screening positive on either the SMAST-G or the CAGE screened positive on both measures suggesting they may be capturing different aspects of alcohol misuse. Using a combination of tools may be beneficial. (Moore et al., 2002b) May be of useful limitedness as older adults may not be aware current level of intake is hazardous or harmful and as such may never have felt guilty or tried to cut down (Culbertson, 2006)

Alcohol Use Disorders Identification Test (AUDIT)		
Main Features	Advantages	Disadvantages

Alcohol and substance misuse

Not evaluated for use in older adults however has been cross culturally developed by World Health Organization in the 1980s (Saunders et al., 1993) Administered as interview or completed by the patient It contains ten questions, the first three of which cover alcohol consumption (amount and frequency) Responses are scored from 0 to 4 giving a maximum possible score of 40. 8 used as cut-off score.	Its strength lies in its ability to identify those who have problems with alcohol but may not yet be dependent (Berks and McCormick, 2008) Takes only a few minutes to complete Provides information on current quantity and frequency of drinking (Culberson, 2006) In over 65s, cut-off score of 8 or more had sensitivity of 0.48, this improved to >0.85 with cut-off of 5 or more (Aalto et al., 2011) Cut-off of 8 had sensitivity of 0.7 and specificity of 0.95 in >65s (Gomez et al., 2006) A study in older male Koreans found AUDIT had greater diagnostic power than SMAST-G and CAGE (Ryou et al., 2012) Anaesthetists identified 7% of alcohol use disorders using clinical assessments versus 18% for	Not developed specifically for older adults and has performed poorly in older adults in some studies and the lack of yes/no answers may complicate scoring (Culberson, 2006) In older male hospital patients, a cut-off of 8 or more had sensitivity of 33% and specificity of 91%. Cut-off of 4 or more improved sensitivity only to 59% and specificity decreased to 41%. The AUDIT was outperformed by MAST-G and CAGE (Morton et al., 1996) Asking about meeting responsibilities may not be useful in an older population and items concerning the amount of alcohol consumed again may not be appropriate in older adults due to harm at lower levels of consumption.

Alcohol and substance misuse

	AUDIT (Spies et al., 2008)	
AUDIT-C		
Main Features	Advantages	Disadvantages
The AUDIT - C (consumption) is a shortened version of the AUDIT, using the first three questions only, i.e. how often the person drinks, how many drinks on a typical day, and how often the person drinks six or more drinks on one occasion	AUDIT-C was shown to have nearly identical sensitivity as the full audit in the general primary care population (Bradley et al., 2007) Shorter and quicker to administer. Optimal cut-off of AUDIT-C score was 4 in those over 65 years of age (Aalto et al., 2011)	Not developed specifically for the older population.
Michigan Alcoholism Screening Test - Geriatric Version (MAST-G) and shortened version (SMAST-G)		
Main Features	Advantages	Disadvantages
MAST-G contains 24 yes/no questions and SMAST-G ten yes/no questions. Items on the test cover the physical signs of excessive drinking, the connection between drinking and emotional states, problems controlling level of consumption, and the reactions of others to the person's drinking. It can be self-administered or completed by the	The original MAST-G instrument from which the SMAST-G was derived has a sensitivity of 93.9%, specificity of 78.1% when measured against DSM-III-R criteria (Blow et al., 1992). SMAST-G may be useful due to its brief nature.	Takes 10 minutes to administer, which might limit its usefulness in clinical practice and does not differentiate current from past drinking or change in consumption over time and does not include any quantity-frequency questions. Professionals may be unaware of its existence (Naegle, 2008).

Alcohol and substance misuse

physician. It focuses more on harmful drinking than alcohol dependence. It may be more sensitive to picking up problems in older adults as it puts less reliance on the effects of alcohol misuse on routine and commitments and more emphasis on the effects of alcohol misuse on family relationships, the involvement of losses and bereavement in the development of alcohol use disorders, the physical effects of drinking, and the interplay between psychological difficulties and development of AUDs (Naegle, 2008).	Scoring is simple (Naegle, 2008). Blow et al. (1998) found SMAST-G to have sensitivity of 85% and specificity of 97% compared with DSM-III-R diagnosis of alcohol abuse or dependence. In male veterans aged 65 or over scores of 5 or more were associated with 70% sensitivity and 81% specificity using DSM-III-R as gold standard. (Morton et al., 1996). A study investigating the effectiveness of MAST-G, SMAST-G and two-item mini MAST-G in identifying hazardous drinking among older adults with CVA, aged over 50 years found all the measures to be useful with comparable sensitivity. (Johnson-Greene et al., 2009). The SMAST-G correctly identified 52% to 85% of older adults with alcohol problems	Moore et al. (2002b) found that less than half of those screening positive on either the SMAST-G or the CAGE screened positive on both measures suggesting these screening tools may be capturing different aspects of alcohol misuse. Those screening positive on SMAST-G drank less than those positive on the CAGE and SMAST-G may be better at identifying those drinkers. They recommend using a combination of screening measures to identify higher numbers of older persons with AUDs. A study comparing CAGE with MAST (Jones et al., 1993) showed both to have low sensitivities in older adults at conventional cut-off points but they report the CAGE was significantly more effective than the MAST in discriminating between older medical outpatients with and without alcohol abuse or dependence. They did not include the geriatric version of MAST.

Alcohol and substance misuse

	and 93% to 97% of older adults who do not have alcohol problems (Moore, 2001, Blow et al., 1998). Hirata et al. (2001) investigated use of MAST (non-geriatric version) in geriatric outpatients in Brazil compared with DSM-III criteria and found sensitivity of 91% and specificity 84%.	
Alcohol-Related Problems Survey (ARPS) and Short ARPS (sARPS) and Computerized-ARPS (cARPS)		
Main Features	Advantages	Disadvantages
Developed by Fink et al., 2002a in primary care clinics to specifically screen older adults over 65. Self-administered questionnaire of 60 items. Includes items on presence of medical and psychiatric conditions, symptoms of disease, smoking behaviour, medication use, physical function and health status, quantity and frequency of alcohol use, episodic heavy drinking, symptoms of alcohol abuse and dependence, driving after drinking, and gender. It moves away from focus on dependence and abuse to identify a much larger	Found to be more sensitive than the AUDIT and the SMAST-G at identifying those at risk. (Moore et al., 2002a) Validated against CAGE, SMAST, and AUDIT and correctly identified those who screen positively on these tests 91%, 75%, and 100% of the time respectively. Majority of ARPS identified hazardous or harmful drinkers did not screen positive on CAGE, SMAST, or AUDIT.	Sixty items to complete and uses scoring rules system, which may limit its usefulness in busy clinical settings. (Culbertson, 2006). Takes 16 minutes on average to complete.

Alcohol and substance misuse

population who are at risk due to comorbidities, medication use, and functional status. Also identifies dependent drinking.	These drinkers had medical conditions or used medications that placed them at risk none of which was addressed by the other three screens (Fink et al., 2002b)	
ASSIST (Alcohol, Smoking and Substance Involvement Screening Test)		
Main Features	Advantages	Disadvantages
Developed by World Health Organization. Aims to screen for problematic or risky substance use. Eight questions covering tobacco, alcohol, cannabis, cocaine, amphetamines type stimulants, inhalants, sedatives, hallucinogens, opiates, and other drugs. (Khan et al., 2012)	Khan et al. (2012) demonstrated significant correlations with other measures of alcohol use disorders using ASSIST in French geriatric outpatients (over 65 years). Screens for a wide range of substance use disorders and detects substance use, abuse, and dependence. User friendly and quick to administer.	Covers other substances in addition to alcohol and so may be less acceptable to an older population.

Reproduced with permission from Taylor, C., et al. Detecting alcohol problems in older adults: can we do better? *International Psychogeriatrics*, 26(11): 1755–1766. Copyright © 2014, International Psychogeriatric Association. DOI: <https://doi.org/10.1017/S1041610214001641>.

For example, if time is limited, the AUDIT-C may be used to collect brief, reliable information about quantity and frequency of alcohol use (it can also be used to calculate risk thresholds), while the SMAST-G (tailored for older people) can collect brief information about harms the patient may

Alcohol and substance misuse

be experiencing as a result of alcohol use, such as falls, interactions with medication, and memory problems like forgetting.

Taking a substance misuse history in an older person

The approach to assessment is key to obtaining a comprehensive overview of substance use and misuse, with a view to formulating a risk assessment and management plan (Rao et al., 2015).

General principles

Adopting a non-judgmental and non-ageist approach is essential, as is maintaining respect for dignity and autonomy. An interpreter may be required if English is not the patient's first language. The pacing of the interview needs to take into consideration factors such as seating comfort, sensory impairment, clouding of consciousness, level of comprehension, cognitive impairment, and privacy. Underreporting of substance use may occur because of denial, stigma, lack of awareness, or memory impairment.

Additional information from other sources can include relatives, friends, and informal carers. Other information may also come from GP consultations, hospital discharge summaries, home carer reports, day centre reports, reports from housing officers/wardens of supported housing, criminal justice agencies, and results from previous investigations (including cognitive testing and neuroimaging).

The assessment will lead to a formulation and management plan that takes into account possible medical comorbidity, functional abilities, the influence of loss events on mood state, cognitive state (including the influence of substances and physical disorders), and availability of social support. Table 46.2 outlines a systematic approach to assessment of possible substance misuse problems.

Table 46.2 Systematic approach to assessment.

Area of Questioning	Questions to Ask
Substance use (cover alcohol and each substance individually)	• Age of initiation: first tried each substance • Age of onset of weekend use; weekly use; daily use • Pattern of use during each day, i.e. quantity/weight, frequency • (If alcohol) Drink type. If drinking at home: glass size, typical 'pour'. • Route of use and access to substances • Evidence of physical dependence

Alcohol and substance misuse

	• Current use over previous day/week • Number of days of abstinence (reasons for this) • Periods of abstinence and triggers to relapse • Episodes of intoxication, withdrawal or overdose
Treatment episodes for substance misuse	• Dates and length of contact with service • Outcome of intervention
Family history	Alcohol and substance misuse in parents, siblings, grandparents, other relatives, spouse/partner, children
Family psychiatric history	Cover suicide, self-harm, depression, anxiety, psychotic illness, alcohol-related brain damage/dementia
Personal history	• Educational attainment • Psychosexual history, including nature and quality of relationships (e.g. domestic abuse, carer alcohol/substance misuse) • Occupational history
Social history	• Current living arrangements and living conditions • Formal and informal carers and carer burden • Marital biography • Social network • Activities of daily living/self-neglect • Housing • Driving • Finances/benefits/debt • Any safeguarding matters • A typical day

Alcohol and substance misuse

Lifestyle issues	• General physical state • Sleep • Diet • Oral health
Medical history	• Ongoing medical disorders • Mobility, hearing and eyesight • Medication (prescribed and over the counter) • Hepatic, cardiovascular, respiratory, gastro-intestinal, neurological complications. • Blood borne viruses (hepatitis B, C and HIV) • Falls, pain, constipation, sensory impairment • Admission to hospital, dates, problems, treatment, length of admission and outcome • GP contact and health checks
Psychiatric history	• Current mental health problems or disorders • Treatment by GP with psychoactive drugs • Contact with secondary care psychiatric services • Any mental health act assessments
Forensic history	• Cautions, charges, convictions • Types of offences (e.g. acquisitive, offences against the person) • Imprisonment at any time • Ongoing contact with forensic services

Alcohol and substance misuse

Social background/ Personality	• Ethnicity and cultural background • Religious and spiritual beliefs • Coping styles/resilience
Biological and psychological measures	• Biochemistry: alcohol levels, drug screens, liver function tests • Haematology • Virology • Brain MRI • Liver ultrasound • Endoscopy • Cognitive assessment
Further information	• Carers, family, friends • Other service providers
Perspective of patient	• Awareness of problems • Motivation for change - strengths, barriers, support

Multiple assessments are often required to build up a clinical picture, including the need for vigilance around safeguarding. Alcohol misuse may coexist with elder abuse. Alcohol abuse may be present in both the abuser and the victim of the abuse (Choi and Mayer, 2000). Elder abuse can present itself in ways that can be mistaken for alcohol problems; for example, bruising, withdrawal, depression, and malnourishment (Wadd and Galvani, 2014).

Clinical diagnosis and problems with using current systems

ICD-10 (World Health Organization, 1992) divides substance misuse into harmful use and dependence. Harmful use is defined as a pattern of psychoactive substance use that causes damage to either physical or mental health. Older people may still have dependence, but ICD-10 criteria may not be a suitable diagnostic tool for use in this age group. Some limitations of the ICD-10 criteria are detailed in Table 46.3.

Table 46.3 Limitations of ICD-10 diagnostic criteria for substance dependence syndrome in older people.

Alcohol and substance misuse

Three or More of the Following have been Present Over Previous 12 months	Limitations in application of criteria to older people
A strong desire or sense of compulsion to take the substance	Older people may attribute desire to longstanding habit as opposed to compulsion
Difficulties in controlling substance-taking behaviour in terms of its onset, termination, or levels of use	Cognitive impairment may affect self-monitoring Fewer social and family pressures to change substance misuse behaviour
Evidence of withdrawal state through either • Physiological substance specific withdrawal syndrome on reduction or stoppage. when substance use has ceased or been reduced • Use of the same (or closely related) substance with the intention of relieving or avoiding withdrawal symptoms	Older people may not develop physiological dependence Withdrawal symptoms may be atypical
Evidence of tolerance, such that increased doses of the psychoactive substance are required to achieve effects originally produced by lower doses	Older people may not develop physiological dependence Tolerance may occur at lower doses than younger people
Progressive neglect of alternative pleasures or interests because of psychoactive substance use	Coexisting physical and mental disorders may have already led to neglect of other interests
Increased amount of time necessary to obtain or take the substance or to recover from its effects	Pre-existing reduced functional ability and social isolation may make comparison problematic
Persisting with substance use despite clear evidence of overly harmful consequences (physical or mental)	Mental capacity may affect awareness of harm

Alcohol and substance misuse

	Denial or misattribution of harm to physical problems

Source data from International statistical classification of diseases and related health problems, 10th Revision, 2010, World Health Organization.

Older people may already have experienced changes to their independence such that the salience of substance misuse may not be immediately apparent. Cognitive impairment may affect the reliability of self-monitoring. Older people may not experience physiological dependence. They may also attribute a desire for substance use as longstanding behaviour that has been part of a daily routine. Lastly, impairment of mental capacity may render an older person unable to weigh up the risk of harm associated with substance misuse. If these limitations are taken into consideration, it may be necessary to explore changes in drinking behaviour on the basis of collateral information from other sources.

Assessment of comorbidity

Psychiatric disorders

The term comorbidity (or 'dual diagnosis') is used to describe the co-occurrence of one or more mental disorders in the presence of substance misuse. Social problems may also be part of the picture: older people with substance misuse are often very vulnerable, with histories of deprivation, poor educational attainment, and trauma experiences that may even involve violence.

The prevalence of comorbid psychiatric disorders ranges from 21% to 66%, with higher rates seen across in-patient settings for those with more severe mental health problems (Bartels et al., 2006). Older adults with depression are three to four times more likely to have alcohol-related problems than those without (Devanand, 2002), with higher risk of suicide and social/functional impairment (Davis et al., 2008). Those people with dual diagnosis have higher risk of relapse in their mental disorder and hospitalization than those with mental disorder alone (NICE, 2011c).

The inter-relationship between comorbidity and substance use can be complex. Substance use (even one dose) may produce or exacerbate psychiatric or physical symptoms or disorders, and vice versa.

Harmful use may produce psychological and physical symptoms or syndromes. Dependence, intoxication, and withdrawal may all produce psychological and physical symptoms or mental disorders. Comorbid psychiatric disorders are detailed in Table 46.4.

Table 46.4 Comorbid psychiatric disorders accompanying substance misuse

Alcohol and substance misuse

Psychiatric disorder	Clinical considerations
Depression	• Masked by physical presentations, intoxication, different expression of low mood • Alcohol as a mood depressant • Depression as trigger for alcohol misuse • Accompanying anxiety with 'self-medicating' using alcohol • Increased risk of suicide with alcohol misuse
Psychosis	Acute episode or as part of withdrawal states
Alcohol withdrawal	• Early symptoms • Delirium tremens • Pharmacological treatment • Clinical environment
Alcohol-related brain damage	• Direct and indirect mechanisms • Wernicke's encephalopathy • Korsakoff's syndrome • Alcohol-related dementia

Depression

In older people, low mood may be downplayed, misattributed to cognitive impairment by clinicians (so called 'pseudodementia'), and masked by either physical illness or alcohol intoxication. Rather, they present with feeling 'down in the dumps', 'fed up', or 'lonely'. Older people are more likely to 'somatize' their depression through complaints such as worsening pain or abdominal discomfort. Older people also do not commonly present with the classic depressive symptoms seen in their younger counterparts, such as feeling low and being tearful.

Alcohol itself is also directly associated with depression, which is perpetuated when used to alleviate anxiety or low mood as self-medication. Antidepressant treatment should be used with caution because of potential drug interactions and potentially limited efficacy when someone continues to drink. Stopping drinking may uncover low

Alcohol and substance misuse

mood and patients should be advised of this and antidepressant treatment may be required.

Similarly, given the restricted lifestyle of some older people, it is difficult to gauge the extent of any loss of interests. Other symptoms such as loss of appetite and sleep disturbance may be shared with both physical health problems and with alcohol misuse, as may loss of energy. However, the diagnosis is made clearer by the presence of pessimism, hopelessness, thoughts of life not being worth living, and suicidal ideation.

The assessment of alcohol misuse is particularly important in older people who are at the highest risk of completed suicide, where alcohol misuse often accompanies the worsening of depressive symptoms and lowers impulse control.

If the person expresses feelings of hopelessness, it is essential to explore suicidal ideation, particularly the severity and frequency of suicidal thoughts, as well as factors driving this ideation and those holding back the person from attempting suicide. This is particularly important when assessing older people who have presented with an act of self-harm. In such cases, the presence of depression with or without alcohol misuse may (under certain circumstances) require the use of legal detention (e.g. the Mental Health Act in England).

Risk factors for suicide cluster together in risk profiles and include male gender, family history of psychiatric disorder, previous attempted suicide, more severe depression, and hopelessness, as well as comorbid anxiety and alcohol misuse (Hawton et al., 2013).

Psychosis

Approximately 40% of people with psychosis develop substance misuse at some point in their lifetime (NICE, 2011b). Substances such as cannabinoids, stimulants, and hallucinogens can induce an acute psychosis while the withdrawal states accompanying alcohol and/or sedatives/hypnotics are also commonly associated with transient psychotic symptoms. Other substances such as nicotine, opioids, stimulants, and cannabis also have distinct withdrawal symptoms presenting with psychotic symptoms (Crome et al., 2015).

Alcohol withdrawal

The possibility of alcohol misuse and the potential for clinical presentations of alcohol withdrawal should be considered in all acutely unwell hospital patients and for those in the community with an established diagnosis of alcohol dependence syndrome.

An alcohol withdrawal syndrome may mask the development of the potentially life-threatening Wernicke's encephalopathy (see Alcohol-related brain damage). Delirium tremens is a severe form of alcohol

Alcohol and substance misuse

withdrawal that can manifest as a severe mental or nervous system disorder. It is a medical emergency characterized by hallucinations, disorientation, tachycardia, hypertension, fever, agitation, convulsions, and profound sweating and typically sets in following acute reduction or cessation of alcohol. It typically begins 48–96 hours after the last drink and in the absence of complications can last for up to seven days (Mayo-Smith et al., 2004).

Pharmacological treatment is necessary for safe withdrawal from alcohol in patients who are physically dependent. In younger patients, 20mg of chlordiazepoxide four times a day, reduced over seven days, supplemented by additional treatment for symptom suppression, is the usual treatment regimen. For uncomplicated withdrawal in an older patient without significant comorbidity such as liver disease, up to half this dose is indicated, with the dose reduced over ten to 14 days, as withdrawal in older patients may be more severe and prolonged. Other methods of administering benzodiazepines are by ‘front-loading’ (i.e. until light sedation is achieved, at which point no further medication is given) or when ‘symptom-triggered’ (as opposed to a fixed regime). Both these regimens should only be used by suitable trained staff.

Best practice guidance for the use of benzodiazepines in older patients with comorbid physical problems indicates that shorter-acting preparations are preferable (NICE, 2011a). In younger adults, a slow tapering dose of lorazepam starting at 2 mg four times a day is used. Again, up to half this dose is indicated in older patients. Chlormethiazole is not recommended for older patients because of its effect on respiration, cardiovascular complications and the unpredictability of the serum levels achieved (Broadhurst et al., 2003). Carbamazepine has not been evaluated in older populations and is therefore not recommended for the treatment of alcohol withdrawal syndrome.

Pharmacological management needs to be supplemented by regular monitoring of vital signs, adequate hydration, a well-lit environment, and treatment with parenteral thiamine.

Alcohol-related brain damage

There have been major advances in the understanding of the relationship between alcohol consumption and cognitive impairment over the past five years. However, as explored in previous sections of this chapter, research has been hampered by the public focus on the purported health ‘benefits’ from moderate drinking.

Several mechanisms can contribute to the pathogenesis of alcohol-related brain damage (Kim et al., 2012). These include:

- Direct toxicity—frontal and hippocampal damage
- Malnutrition—Wernicke’s encephalopathy/Korsakoff’s syndrome
- Traumatic head injury

Alcohol and substance misuse

- Cerebrovascular damage (stroke from alcohol related hypertension, traumatic intracerebral haemorrhage, subdural haematoma)
- Metabolite toxicity
- Electrolyte imbalance
- Hepatic encephalopathy/infection
- Inflammatory (e.g. TNF- α)
- Modifying factors (e.g. Apo e allele/elevated homocysteine)

These factors listed may also interact with each other to produce complex clinical presentations. AUDs may also complicate primary dementias, increasing adverse effects and cognitive decline (Withall et al., 2014).

Amnestic syndrome

Amnestic syndromes comprise Wernicke's encephalopathy (WE) and Korsakoff's syndrome (KS). WE is associated with haemorrhage into the thalamus and mammillary bodies. The aetiology of this damage is deficiency of vitamin B₁ (thiamine). WE consists of the combination of ophthalmoplegia, cerebellar dysfunction, and altered mental state, but in practice only 20% of patients present with this full triad. A more common presentation is with apathy, disorientation, and poor attention.

Repeated episodes of WE not treated with parenteral thiamine progress to KS, which is characterized by severe anterograde amnesia and retrograde amnesia extending several years before brain damage. Confabulation occurs as events are invented to fill in absent memories (Kopelman et al., 2009, Thomson et al., 2012). There is preserved short-term memory, as the neuroanatomical impairment results in faulty encoding of information from short-term to long-term memory. Amnestic syndromes are confined to memory and are not classified as dementia.

Alcohol-related dementia

Alcohol-related dementia (ARD) encompasses cognitive impairment that extends beyond memory impairment. Clinical criteria have been developed to improve the diagnosis of probable ARD (Oslin and Cary, 1998). The essential diagnostic features of ARD are evidence of cognitive impairment; significant alcohol use-defined by minimum average of 35 standard drinks (>60 UK units) per week for men and 28 (>48 UK units) for women, for a period of greater than five years; with the period of significant alcohol consumption occurring within three years of clinical onset of cognitive impairment.

A probable diagnosis of ARD is supported by presence of alcohol-related end organ damage; ataxia or peripheral polyneuropathy (not attributable to other non-alcohol-related causes); and neuroimaging evidence of cerebellar atrophy.

Alcohol and substance misuse

ARD also differs from degenerative dementias in that cognitive damage and ventricular or sulcal dilatation are likely to show partial improvement within the first 60 days of abstinence, particularly in white frontal white matter integrity (Gazdzinski et al., 2010). The presence of marked language impairment (e.g. nominal dysphasia), focal neurological signs or symptoms (except ataxia or peripheral sensory polyneuropathy), or neuroimaging evidence of cortical or subcortical infarction, subdural haematoma, or other focal brain pathology may cast doubt on alcohol having a direct association with the dementia. Although it is equally difficult to gauge with certainty that alcohol has not been contributory if there is a history of heavy consumption.

ARD shows better performance on semantic and verbal memory but poorer performance on visuospatial tasks and frontal tasks compared with Alzheimer's disease (Rao, 2016; Ridley et al., 2013; Zahr et al., 2011). Alcohol-related cerebellar damage may also disrupt frontal processes such as executive function and poor response inhibition (Pitel et al., 2015).

Traditional screening tools for cognitive function (e.g. the Mini Mental State Examination) do not include tests of frontal lobe function, so if a more comprehensive assessment of cognitive function is required, more detailed instruments such as the Addenbrooke's Cognitive Examination (Mioshi et al., 2006) can be used.

There remains scope for further exploration of the association between alcohol misuse and dementia, and there are many unanswered questions including the rate of progression and possible reversibility; the relative roles of thiamine deficiency compared with more direct effects of alcohol toxicity; the interplay with other pathology and traumatic brain injury; and the role of drug treatment in improving cognitive impairment and behavioural problems.

Physical disorders

Systemic effects of substances include gastrointestinal disease (e.g. damage to the liver and pancreas from alcohol misuse); respiratory disorders (e.g. chronic obstructive pulmonary disease (COPD) and lung cancer from tobacco smoke or cannabis and chronic nasal inflammation from crack cocaine); low blood sugar (from misuse of cocaine and alcohol); cardiac disease from alcohol and cocaine misuse, haemorrhagic stroke from alcohol, cannabis, cocaine, amphetamines, phencyclidine (PCP) and lysergic acid diethylamide (LSD); as well as complications from intravenous drug use.

Acute hazards from intravenous injections include damage to veins, infection, and overdose, with such damage representing the most common harm from misuse of cocaine. Bacterial endocarditis and Hepatitis C can also arise because of injecting drugs.

Alcohol and substance misuse

Physiological changes associated with age, sensory deficits, postural imbalance, chronic health problems, substance misuse, and environmental hazards have all been identified as risk factors for falls. Loss of balance, coordination, judgment, risk taking, autonomic neuropathy, peripheral neuropathy, cardiac disease, osteoporosis, and myopathy may all act synergistically to make a fall more likely. There is an increased prevalence of falls among elderly individuals with substance misuse and therefore the possibility of substance misuse should always be considered in the differential diagnosis of falls. Weight loss and poor self-care may also be manifestations of alcohol misuse. Areas of physical examination to be covered in older people with substance misuse are detailed in Table 46.5.

Table 46.5 Physical examination in substance misuse.	
Area of physical examination	Clinical considerations
Oral	Gum disease and dental caries from poor nutrition secondary to substance misuse
Skin and nails	• Injury • Skin breakdown from pressure areas • Damage from incontinence • Vasculitis, purpura, scleroderma, and Raynaud's syndrome from cocaine misuse • Tar staining of skin from tobacco • Palmar erythema, spider naevi, psoriasis, skin carcinoma, and porphyria cutanea tarda from alcohol misuse • Nail fold infarcts, splinter haemorrhages, Osler's nodes in the pulps of the digits, Janeway lesions (tender nodules in the palms or soles) from intravenous drug misuse
Abdomen	• Hepatomegaly with macronodular surface from alcohol misuse • Caput medusae and ascites from portal hypertension secondary to alcohol misuse
Cardiovascular	• Hypertension from alcohol misuse, smoking, and stimulants

Alcohol and substance misuse

	• Heart failure with ischaemic heart disease from smoking or stimulants • Ischaemic heart disease, vascular disease, heart failure, and stroke • Cardiomegaly from alcohol misuse • Valvular disease, thrombophlebitis, deep vein thrombosis, and subacute bacterial endocarditis from intravenous drug misuse
Respiratory	• COPD from tobacco and cannabis misuse • 'Crack lung' from cocaine misuse • Lung cancer from tobacco smoking
Neurological	Cerebellar syndrome and peripheral neuropathy seen from alcohol dependence

Drug interactions with and between substances

Alcohol, nicotine, opioids, benzodiazepines, and the Z drugs form the majority of substances taken by older people. However, there is now increasing use of pregabalin in the treatment of anxiety. Although there may be the potential for misuse, this is commonly at higher doses and with people who have a history of substance misuse (Schifano et al., 2011). Its potential for misuse in the treatment of older people with anxiety remains to be seen.

Alcohol, nicotine, opioids, benzodiazepines, and Z drugs can interact pharmacodynamically by augmenting adverse side-effects at a receptor level and/or by interaction at the stage of drug absorption, distribution, metabolism, or excretion through pharmacokinetic mechanisms. This latter interaction results in changes to the levels of the substance or other drugs in the body through increased or decreased drug metabolism. At high levels, alcohol, benzodiazepines, and opioid all have a sedative action. If taken in combination, there is an increased risk of falls and respiratory depression.

Alcohol

Alcohol has the potential for several adverse interactions with both prescription and non-prescription drugs. Women are at higher risk of drug interactions with alcohol than men (Baxter and Preston, 2010). Women tend to have a higher fat-to-water ratio and therefore a higher blood alcohol concentration than men for a given amount of alcohol consumed. Food and milk decrease the rate of alcohol absorption.

Alcohol and substance misuse

Polypharmacy is also common in older people, with 40% taking five or more prescription drugs (Wilson et al., 2007).

The most common drugs implicated are benzodiazepines and amitriptyline (Gallagher and O'Mahony, 2008), which potentiate the sedative effect and increase the risks of falls. There is also a potential interaction between opioid-containing drugs (morphine and codeine) and alcohol. Alcohol is also associated with rapid release of morphine from extended-release preparations. Important interactions between alcohol and other drugs are detailed in Table 46.6.

Table 46.6 Drug interactions with alcohol.		
Drug	Interaction	Outcome
Over-the-counter drugs	Topical Pharmacokinetic	Aspirin ↑ risk of bleeding into the gut Heavy drinking ↑ risk of liver damage from paracetamol
Some antibiotics	Pharmacokinetic (Disulfiram like reaction)	Flushing, headache, palpitations, vomiting.
Nicotine patches	Pharmacodynamic	Tachycardia
Psychotropic drugs (antidepressants, antipsychotics, anxiolytics)	Pharmacodynamic	↑ drowsiness
Opioid analgesics	Pharmacodynamic	↑ risk of falls/ respiratory depression
Sedating antihistamines	Pharmacodynamic	↑ risk of drowsiness
Anti-hypertensive drugs	Pharmacodynamic	↑ risk of low blood pressure/falls
Warfarin	Pharmacokinetic	Acute alcohol intake: ↑ levels Chronic alcohol intake: ↓ levels

Alcohol and substance misuse

Anti-emetics	Pharmacokinetic	Metoclopramide ↑ Alcohol levels
Anti-epilepsy drugs and mood stabilizers	Pharmacokinetic	Carbamazepine levels ↓ by heavy drinking; Blood alcohol levels ↑ by meprobamate

Opioids

The two terms, opiates and opioids, have been used interchangeably, but it is now more common to refer to both as opioids. Drug interactions with opioids are shown in Table 46.7. Morphine, naloxone, and naltrexone are relatively less affected by pharmacokinetic interactions with other drugs.

Table 46.7 Drug interactions with opioids.

Drug/food	Interaction	Outcome
Ciprofloxacin Clarithromycin Erythromycin Itraconazole Ketoconazole Ritonavir Diltiazem Grapefruit juice Nefazodone	Pharmacokinetic	↑ effect of buprenorphine, methadone, and loperamide
Carbamazepine Phenytoin Phenobarbitone Rifampicin St John's wort	Pharmacokinetic	↓ effect of buprenorphine, methadone, and loperamide
Fluoxetine Paroxetine Metoclopramide Quinidine	Pharmacokinetic	↑ effect of oxycodone, codeine, dihydrocodeine, and tramadol
Amiodarone Propranolol Ciprofloxacin Rifampicin Duloxetine Fluvoxamine	Pharmacokinetic	↑ effect of pentazocine

Alcohol and substance misuse

Olanzapine Clozapine Caffeine		

Nicotine

On its own, nicotine alone has few interactions with other drugs. Its metabolism is inhibited by ketoconazole, isoniazid, and grape juice, thereby increasing blood levels. Phenobarbitone and rifampicin are associated with enzyme induction and reduced blood levels. The most common exposure to nicotine is through tobacco smoke, which contains polycyclic aromatic hydrocarbons that affect the same enzyme pathway affected by pentazocine metabolism. Carbamazepine levels are decreased by chronic smoking.

Drugs for anxiety and insomnia

Benzodiazepines, buspirone, zopiclone, and the benzodiazepine antagonist flumazenil are metabolized by the same pathway as buprenorphine, methadone and loperamide and are therefore induced and inhibited by the same drugs as these opioids.

Treatment of substance misuse in older people

There are surprisingly few in-depth reviews of treatment options and their effectiveness for older people. This section reviews areas of consideration for treatment for older people. It should be noted that most treatment studies focus on reduction of alcohol and prescription medication, and less is known about treatment for abuse of other substances in this group.

Establishing the patient's goal

From the beginning, there needs to be a sense of what the patient expects or wants to achieve during treatment. Complete abstinence is one approach. However, some patients may still want to continue use but at a lower level. For some people 'controlled drinking' or reduced use of other substances may be a preferred alternative to abstinence. However, it should be considered whether even this 'controlled' level is low enough to be safe for the patient.

Barriers to entering or re-entering treatment

Some of the barriers to detecting substance misuse are discussed earlier in this chapter. Similar individual, societal, and professional barriers also influence entering or re-entering treatment for substance misuse. Some patients, particularly if LO, may be entering treatment for the first time, while others may have been through one or many treatments in the past. Kuerbis and Sacco (2013) describe three inter-related barriers to treatment entry for older patients: the societal myth that older people do not abuse substances; the belief that people who have experienced

Alcohol and substance misuse

problems with substances earlier on in their life cannot get better; and that entering pre-existing treatment groups with younger adults can be daunting due to stigma or shame.

A careful exploration of concerns at this stage may prevent the likelihood of drop out or disengagement in treatment in the future. If the person has been abstinent for a number of years but has now relapsed, this can be disheartening and may contribute to depression or hopelessness about treatment success. Reasons for drop out or disengagement in the past should be collected, as these factors are likely to influence engagement with subsequent treatment.

To motivate the patient, communicate that there is good evidence to show that appropriate treatment can be particularly effective for their age group. As stated by the Royal College of Psychiatrists (2011, p. 8): 'older people can and do benefit from treatment, and in some cases have better benefits than younger people'. Satre and colleagues (2004) found that 20% of older people with alcohol dependence who went through treatment remained abstinent after four years. They also found that women were more likely to remain abstinent compared to men. Thus, it should be reiterated, older people with alcohol and substance use disorders can and do recover and experience an improved quality of life, providing the treatment they receive is tailored to their needs (Han et al., 2009).

Factors influencing effectiveness of treatment

Kuerbis and Sacco (2013) reviewed the factors that influenced the effectiveness of treatment in older people. It should be noted most studies in their review were from the US, and many were with veterans, but nonetheless, the findings are relevant to planning substance misuse treatment for an older person.

- Older people who have sought treatment do better than those who have not (e.g. those who have screened positively for high-risk substance use, and received brief advice about drinking from a doctor)
- Outcomes of treatment are mixed for those who receive brief advice alone.
- The more the person has been exposed to, or attended, treatment, the better the success rate.
- Patients with LO may have a higher motivation for treatment while those with EO are more likely to drop out of treatment (Schonfeld and Dupree, 1991).
- If a person engages with a full course of treatment, outcomes are positive.
- Age-specific treatments are more effective for an older group (this could be due to lower drop-out rate). Examples of age-specific adjustments that can be made include: location of treatment programme (accessibility), materials used (to account for physical or

Alcohol and substance misuse

cognitive functioning problems), slower pace of treatment, and group treatment with others of a similar age (due to stigma).

- Providing education, harm reduction, or brief information about risks of heavy drinking using brief intervention have more benefits than not providing it at all.

The Royal College of Psychiatrists (2015) highlight other factors influencing the effectiveness of treatment in this group. These include:

- Taking into account the complex needs of the patient, such as loneliness or physical disability, increases treatment effectiveness.
- Engaging other services, such as health and welfare agencies, helps provide the patient with additional support to promote recovery.
- Providing an older person with practical advice as well as specific treatment. For example, helping an older person to fill their time after reducing or stopping substance use reduces relapse.
- Engaging and supporting other important people in the older person's life can be helpful, e.g. carers.

Specific treatment approaches

Cognitive behavioural therapy (CBT)

CBT may be a particularly appropriate strategy if the person is using substances to cope with specific thoughts, emotions or physical states. The focus of CBT in this case may be on identifying high-risk situations, working on coping strategies and problem-solving skills, and identifying emotions and stressors as triggers to substance use. CBT can be just as effective for older adults as for younger people (for example, Dupree et al., 1984), though there is a surprising lack of recent research in this area.

Although CBT is an appropriate strategy to improve an older person's ability to cope with stressful life events, consideration should be given to how it is delivered. For example, CBT relies on the use of self-help materials such as workbooks to complete at home, thus treatment materials may need to be adapted for use with older people. For CBT to be effective, the person needs to have insight into their thoughts, emotions, and behaviours. Such an approach may not be suitable for those with cognitive impairment. Finally, the optimal intensity of CBT for best outcomes is unknown, and it is often combined with other approaches, such as motivational interviewing (MI). An example of a successful treatment package will be reviewed later in this section.

Alcohol and substance misuse

Motivational interviewing (MI) or motivational enhancement therapy (MET)

Motivational interviewing is described as ‘a skilful clinical style for eliciting from patients their own motivation for making changes in the interest of their health’ (Rollnick et al., 2008, p.24).

The success of MI can be attributed to the therapist’s ability to develop rapport with the patient by expressing empathy, exploring resistance to change, reflecting back to the patient a discrepancy between current behaviour and future goals, and developing a person’s sense of control and confidence. All of these goals can be therapeutic for an older group. The rebuilding of sense of control or self-efficacy can help with comorbid symptoms such as feelings of low self-esteem and worthlessness, and the development of a relationship with the practitioner can help with loneliness or social isolation. A non-judgmental approach may reduce feelings of shame.

There is evidence that MI can change health behaviour in older adults, though no best practice review exists. As with CBT, MI is often delivered as part of a treatment package so it is difficult to isolate the mechanism for change.

As with other interventions, for MI to be effective with this age group it needs to be delivered at a slower pace, to use repetition to aid memory, and to be flexible enough to adapt to the needs of the individual e.g. those with cognitive impairment (Serdarevic and Lemke, 2013).

Treatments involving the family

Support from family members, or specific family therapy approaches may help an older person to strengthen their social network. Substance misuse can cause relationship problems with spouse and other family members. The person who abuses substances may find themselves increasingly isolated from their family members. Such isolation can worsen problems. On assessment, it is important to consider whether the patient would like family members to be involved in their treatment. Groups such as Al-Anon can be helpful for those who are directly affected by the person’s substance misuse (for example, a person’s spouse, child, or carer).

Alcoholics Anonymous (AA), Narcotics Anonymous (NA), or other twelve-step facilitation (TSF) approaches

Alcoholics Anonymous (AA) or Narcotics Anonymous (NA), based on the twelve-step approach, are popular peer support groups for reduction of alcohol or substance use. There is no specific evidence for AA for an older group; however, Moos and colleagues (2010) integrated AA into a treatment package with other approaches and found that only AA reduced high-risk alcohol consumption and problems at follow-up. AA may however be less effective in complex cases with medical comorbidity or

Alcohol and substance misuse

involving polysubstance (e.g. alcohol and prescription medication) use (Donovan et al., 2013).

Furthermore, the twelve-step approach is based on the conception of substance dependence as a spiritual and medical disease (Nowinski, 1992). Such an approach can be very helpful for some, but may not be suitable for people who do not accept this philosophy. We have already seen that mixed age groups are less favourable for older people, and accessibility or the pace of the group can be a barrier to treatment or a catalyst for drop out. However, AA or NA groups can help people strengthen positive peer networks, and provide mutual support. Group treatments increase social contact, and can be particularly beneficial for those who live alone.

Other approaches

Those with LO who have a clear trigger to substance misuse may particularly benefit from compatible treatment approaches such as bereavement counselling. For those who are lonely or socially isolated, evidence shows that interventions addressing social cognitions are effective. For example, discussion groups to talk about loneliness and develop relationship skills were particularly effective for women (Masi et al., 2011).

Examples of successful treatment programmes in different settings

Treatment effectiveness appears to be influenced by the setting where the treatment takes place as well as by the motivation of the participants. Here we list published examples of effective treatment packages offered in three different settings.

Brief intervention

In the Florida BRITE Project (USA) (Schonfeld et al., 2010) brief intervention was provided after community screening using the SMAST-G (to measure alcohol problems). Abuse of prescription medication was also explored in this study (pain medication, anxiolytics, sleeping medication, and 'medication for loneliness or sadness'). Symptoms of depression and suicide risk was measured by the Short Geriatric Depression Scale (SGDS, Sheikh and Yesavage, 1986). Age-related adjustments were made for the individual in this intervention, for example, home visits if the person had poor mobility. MI was used to increase motivation for treatment, and 16 sessions of CBT were provided.

Results showed an overall significant reduction in SMAST-G scores after treatment, with only 19% (compared to 80%) of people scoring positively for alcohol problems at discharge and follow-up. The treatment programme also reduced prescription medication misuse in 32% of people who were flagged as having problems at baseline. Overall, treatment reduced symptoms of depression.

Alcohol and substance misuse

In this study, patients had a lot of contact with intervention staff, and this in itself may have influenced the outcome. This study indicates that intensity of treatment and multimodal methods tailored to the individual were important. It also demonstrated how such treatment may target other risk factors such as depression, loneliness and social isolation.

Outpatient treatment

The Gerontology Alcohol Project (GAP; USA) pilot programme by Dupree and colleagues (1984) was specifically for people with LO alcohol abusers aged 55 or over. The treatment package included CBT, self-management and education delivered in a group of similarly aged older adults. Results showed that 74% of people who stayed in treatment achieved their goal of abstinence or controlled use, but half of the original group of participants dropped out at the start.

This study demonstrates the importance of identifying barriers to treatment at the outset. Those who stay the full course generally have good outcomes.

Inpatient treatment

Based in the US, this substance abuse treatment (SAT) study by Slaymaker and Owen (2008) followed 67 in-patients who were alcohol dependent. Treatment included individual and group therapy and community activities. Approaches used included CBT, MET, and 12-step groups. Special groups were held to explore challenges of later life including grief, life course transitions, and how to spend leisure time.

Results showed that 71% of patients were abstinent at 6-month follow up, and 60% abstinent at 12 months. Improvements were measured by the Addiction Severity Index (ASI) which was a useful assessment tool for this purpose. Treatment adaptations included: better accessibility for those with poor mobility, slower pace and modifications for sensory or cognitive impairments. This study showed that tailored group treatment addressing triggers to substance misuse are helpful, and focusing on these triggers may result in sustained change.

Efficacy of brief intervention

Brief interventions can be effective in reducing alcohol and substance misuse if delivered appropriately. The Royal College of Psychiatrists (2015, p. 13) suggest three simple ways to deliver brief advice:

1. a sentence or two of feedback based on a person's AUDIT score
2. a sentence or two of feedback, plus an information leaflet
3. five minutes of advice based on FRAMES structure.

Alcohol and substance misuse

The FRAMES model provides an effective structure for brief intervention (Blow and Barry (2012, p. 317):

- **Feedback** is given to the individual about risk (of alcohol and substance misuse).
- **Responsibility** for change is placed with the individual receiving the intervention.
- **Advice** for changing behaviour is given by the clinician.
- **Menu** of alternative options for change is offered.
- **Empathic** and motivational style is used by the intervener.
- **Self-efficacy** or empowerment is promoted.

Personalized feedback about a person's substance use or misuse is superior to general health information in reducing binge episodes, and agreeing on a 'contract' or shared goal can be powerful for brief intervention (Fleming et al., 1999). However, as we have already seen, for people with complex needs, a brief approach is not likely to be enough for significant sustained change.

Reducing relapse

For the purposes of clear terminology, lapse refers to a single occasion 'slip', while relapse refers to return to alcohol or substance abuse (Barrick and Connors, 2002). If a person is currently trying to cut down or stop using substances completely, treatment discussion may involve planning for risky situations where they may lapse, and identifying what factors can trigger a relapse.

Marlatt and Gordon (1978) found that risky situations for older people tend to involve negative emotional states, where alcohol or substances may be used to relieve negative emotion. A step towards productive treatment planning in an older group is to identify high-risk situations, and to discuss motivation to learn new ways to cope with these situations. The treatment approaches previously discussed can directly target these factors.

Pharmacological treatment

There is a lack of evidence for the pharmacological treatment of substance misuse in older people, with this age group mostly excluded from clinical trials. There is no direct evidence on methadone maintenance treatment in older people or for drugs such as naltrexone and buprenorphine. There is a similar absence of evidence for the pharmacological treatment of abstinence from alcohol in older people using drugs such as disulfiram or acamprosate (NICE, 2011a). A community study involving people aged 65–74 on nicotine replacement therapy (NRT) found 29% of participants self-reported smoking cessation at six months (Orleans et al., 1994). There is currently no evidence to

Alcohol and substance misuse

guide clinicians in the use of bupropion and varenicline for smoking cessation in older people.

Driving and substance misuse

In the UK, between 2015 and 2016, 6.8% of people aged 50 or over reported that they had driven while thinking they were over the legal alcohol limit at least once in the last 12 months (Department for Transport, 2016). The proportion of drug driving (driving while thinking they are under the influence of illegal drugs) is lower, with just 0.3% of people aged 50 or over reporting this (compared to 1.9% of people aged 20–24).

At a population level, and compared to a younger group, alcohol-related accidents in older people are still relatively low. For example, in the UK in 2014 there were 290 drink drive accidents involving drivers aged 60 or over, compared to 1,020 in those aged 20–24 (Department for Transport, 2014).

However, the number of older drivers is likely to increase. A report by the Automobile Association estimated that by 2030 more than 90% of men over 70 will be on the road, with 21 million older people driving by 2035 (Automobile Association, 2017).

People who misuse substances who still have a car and a current driving licence should be considered 'high risk'. Driving while intoxicated is dangerous and illegal, and if a person continues to engage in this behaviour, they risk being caught (e.g. legal problems), hurting themselves, or harming others. These complications can interfere with any positive progress they are making in recovery (Royal College of Psychiatrists, 2015).

The following issues should be explored with older patients who present with substance misuse and still drive:

- How often do they drive, and what proportion of these occasions do they drink (or use other substances) and drive?
- At what time of day do they usually drive? It should also be emphasized that a person may still be over the legal limit the morning after heavy drinking. However, fewer retirees may be on the road in the morning as they do not have to attend work. Some people may be aware of when roads are likely to be busy, and avoid driving during this time.
- Do they take other medications that also affect driving ability? Awareness of these risks should be explored.
- Are they aware of the drink drive limit? Can they explain the limit in number of drinks (or drink type)?

- Have they ever been stopped or convicted for drink driving? Those who engaged in this behaviour for a number of years and have never been 'caught' may be more likely to keep doing it (Sykes et al., 2010).
- How do they judge whether they are fit to drive? A person may rely on 'how they feel' rather than number of drinks consumed before getting in the car.

In some cases, a person may need to stop driving, for example, if they lose their license. This may cause profound difficulties, e.g. if they live in a remote rural area, or present a barrier to treatment if they need a car to be able to attend treatment sessions or AA meetings. In these circumstances, a sensitive but realistic discussion of transport options is required.

Developments in policy and practice

The first UK report on substance misuse in older people, *Our Invisible Addicts* (Royal College of Psychiatrists, 2011), made the following recommendations:

- At a policy level, to develop clinical guidelines through care pathways.
- At an educational level, to develop training packages for health professionals.
- At a public health level, to developing a consensus on drinking limits.

The first two recommendations have been taken forward and are discussed in the next section. The third has been subject to increased scrutiny, given the complexity surrounding the lack of a specific 'dose-response' effect from alcohol on health outcomes (Crome et al., 2012). The new guidelines on low-risk drinking are discussed earlier in the chapter.

There has since publication of a good practice commissioning guidance from the National Institute for Health and Care Excellence (NICE, 2011a). This highlighted the need for lower thresholds for high-risk groups (including older people) when commissioning in-patient and residential medically assisted alcohol withdrawal services.

It also included examples of good practice when commissioning for older people, such as community-based interventions, addressing complex needs, equality of access to services, and patient experience. An Information Guide for health and social care professionals was published (Royal College of Psychiatrists, 2015). This guide outlined approaches to assessment, treatment and care that included psychosocial interventions, supporting families and carers, as well as legal and ethical considerations. It also covered specialist approaches to substance misuse, such as emergency physical and psychiatric presentations, managing

Alcohol and substance misuse

withdrawal syndromes, heroin/benzodiazepine misuse in the community, challenges to recovery, and older women with alcohol misuse.

Although the areas of policy and practice have focused largely on alcohol misuse, a later report included illicit drugs, aimed to identify some of the key issues and problems in this area, and make achievable recommendations for change (DrugScope, 2014). A further revision to *Our Invisible Addicts* is currently in preparation, which will also include more recent developments such as the rise in opioid misuse and the potential misuse of gabapentinoid drugs by older people.

Service development for older people with alcohol and other substance misuse

Developing an integrated service for older people with alcohol and other substance misuse requires clinically effective inter-agency working that can minimize harm and improve health and social outcomes. The aims of such a service would be the prevention of alcohol and other substance related mortality (including those with comorbid mental and physical disorders); enhancement of the quality of life of older people and community integration through the provision of high-quality care (Royal College of Psychiatrists, 2015). In addition to mental health service provision, geriatric medicine (Crome et al., 2011), primary care (Rao et al., 2016), social care (Rakshi et al., 2011), the voluntary (third) sector (Holley-Moore and Beach, 2016), local authority (Wilson, 2013), and housing (Giles, 2016) are also key components in enhancing the quality of care for older people with alcohol and other substance misuse.

A key principle in the delivery of non-specialist care within mainstream mental health services is 'making every contact count'. This forms the basis of much of the commissioning for substance misuse services in England (Nelson et al., 2013).

Improving social care is also central to treatment and recovery from substance misuse in older people, where life events such as retirement, bereavement, and social isolation may have a profound impact on social function. Approaches to harm reduction in older people often involve replacing time engaged in substance use with improving social networks and social skills training around refusal of substances in social settings. There is also scope for further social integration, such as attending self-help groups (e.g. Alcoholics Anonymous), increasing family input, encouraging healthy lifestyles and facilitating volunteering activities (Rao, 2015).

One programme providing relapse-prevention and social skills training for older people with alcohol misuse showed higher rates of abstinence compared to the non-completers (Schonfeld et al., 2010).

However, with the complexity in assessment, treatment, and aftercare for older people with alcohol and other substance misuse, there is a need for specialist mental health services that address the needs of older people.

Alcohol and substance misuse

The first specialist dual diagnosis service for older people with alcohol misuse in the UK was developed at the South London and Maudsley NHS Foundation Trust in south east London, UK (Rao and Shanks, 2011).

The initial development of this service was built on the following strategic aims and objectives and continues to be developed with a dual diagnosis working group. This group now includes a consultant old age psychiatrist, nurse consultant lead for dual diagnosis across the Trust, senior Clinical Academic Group Manager for quality, and modern matron and nurse borough leads. The service has the following aims:

- Building on existing good practice (e.g. referral to and from liaison old age psychiatry and addiction psychiatry services);
- Scoping the need for new services and roles (e.g. delivery of in-patient training to meet Commissioning for Quality and Innovation-*CQUIN* outcomes);
- Creating new service options where possible (predominantly home-based assessment and treatment of dual diagnosis by Community Mental Health Teams);
- Developing clinically effective care pathways (Alcohol, benzodiazepines, tobacco and cannabis) (See Box 46.1);
- Promoting robust partnerships with key stakeholders (e.g. service users and carers group);
- Building a skilled workforce (acquiring relevant competencies through dual diagnosis training);
- Establishing robust communication and reporting structures (e.g. serious incidents, as well as rates of screening and brief intervention);
- Promoting health education, prevention and early intervention for service users.

Alcohol and substance misuse

Box 46.1 Care pathway for dual diagnosis

- Aligned to other care pathways for dementia, depression, and personality disorders
- Involves patient, care coordinator, multi-disciplinary team, consultant old age psychiatrists, general practitioner, other medical specialties (e.g. geriatrics), social care, and (where relevant) specialist addictions practitioner
- Comprises screening, assessment, engagement, assessing, and facilitating motivation to change, developing an action plan that incorporates harm reduction and recovery, as well as relapse prevention
- Incorporates a care pathway within risk assessment, care management, and review

Conclusions and future directions

More attention has recently been paid to the issues of substance misuse among older people, but there are still significant gaps in our knowledge about the subject. We need more detailed research about gender differences, including different risk factors for addiction in older women, and barriers to treatment. We need a better understanding of the abuse of prescription medication among older people. Alcohol-related cognitive impairment remains an under-diagnosed and often misunderstood area. And we still have limited information about what treatment works best for older people, with no best practice reviews available for individual therapeutic approaches.

We need to focus on the 'at risk' growing population of 'baby boomers' whose patterns of substance misuse are very different from previous generations. This is likely to mean a greater burden of mental health as well as physical and psychosocial need. It will have implications for exploring substance misuse in a wider variety of prescribed and illicit drugs, as well as finding new solutions to developing integrated care through working with multiple specialties and other agencies.

This can only be achieved by having the evidence base to underpin clinically effective treatment interventions that both reduce harm and improve independence and quality of life.

Older people with intellectual disability

Chapter: Older people with intellectual disability

Author(s): Maria Luisa Hanney, Stephen Tyrer, and Brian Moore

DOI: 10.1093/med/9780198807292.003.0047

Introduction

Older people with intellectual disability (ID) comprise a heterogeneous and clinically complex population to whom little clinical or research interest has been devoted.

Persons with ID and dementia are less likely to receive planned health care than persons with dementia in the general population. They have, however, higher levels of unplanned health care utilization. This clearly indicates that the current support system is not sufficient to meet the challenges of increased longevity among persons with ID (Axmon et al. 2016). The cost of caring for older people with ID makes up a large proportion of healthcare spending in Western Europe. For example, in England older adults with ID comprise about 0.15–0.25% but consume up to 5% of the total personal care budget. It seems very likely that general services for older people will need to prepare themselves for the inclusion

Older people with intellectual disability

of this subgroup of the ageing population. This will have huge implications for future planning of services (Strydom, Romeo et al., 2010).

This chapter reviews the concept and diagnostic criteria for ID and its prevalence in older people, and summarizes the present knowledge about functional psychiatric illness and dementia in this group. A separate section concentrates on issues related to Down's syndrome (DS) and the increased risk of dementia in this group, followed by a section on assessment and management of dementia in ID in general, including pharmacological treatment and end-of-life and best-interest decisions, with reference to relevant best practice guidelines.

Definition and diagnostic criteria for intellectual disability

'Mental retardation' and 'learning disabilities' are terms that have been used to describe a disability characterized by significant limitations in both intellectual functioning and in adaptive behaviour, that is manifest before the age of 18. The term 'Mental Retardation' has been replaced by 'Intellectual Developmental Disorder' in the beta draft of the eleventh edition of the World Health Organization's *International Classification of Disease* (ICD-11) published in 2018 (in use for 2022), and by 'Intellectual Disability (Intellectual Developmental Disorder)' in American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) (APA, 2013). The ICD-11 term has been incorporated in brackets in the DSM-5 schedule to indicate that both classification systems use similar diagnostic criteria.

In both classifications ID forms part of the wider diagnostic category of neurodevelopmental disorders. These are categorized according to severity as mild, moderate, severe, and profound.

A diagnosis of ID has to satisfy three diagnostic criteria:

- i) Significantly sub-average intellectual functioning. This is defined as an Intelligence Quotient (IQ) of 70 or below on an individually administered, standardized, and culturally appropriate IQ test (and for infants, a clinical judgment of significantly sub-average intellectual functioning). By definition, 2.5% of the population fall within this bracket.
- ii) Deficits or impairments in adaptive functioning (skills needed to live in an independent and responsible manner). Deficits in adaptive functioning must be measured using standardized, culturally appropriate tests. Deficit or impairment should be present in at least two of these areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, and health and safety.
- iii) These limitations are evident during childhood or adolescence, before the age of 18 years.

Older people with intellectual disability

Prevalence of intellectual disability in older people

There is no agreed definition of what constitutes 'older' in people with ID. Various age thresholds for the ageing population with ID have been adopted in the literature which range from 40–65 years of age (Jenkins et al., 1994).

Little is known about the prevalence of ID among the general older population. It is estimated that there are 1,198,000 people with ID in England (Emerson, 2011) (approximately 1% of the total population). This figure includes 334,000 individuals with ID over the age of 50 years (37% of the total ID population) and 202,141 over the age of 60 years (22% of the total ID population). It is estimated that a typical GP catchment area of 250,000 population would comprise 2,500 individuals with ID, 925 individuals over the age of 50, and 550 individuals over the age of 60 years.

Approximately 13–20% of the ID population have DS (Hand and Reid 1996) and it has been estimated that there are approximately 40,000 adults with DS in the UK (Wu and Morris, 2013). More than 40% of people with DS in the UK are aged 40 years or older (de Graaf et al. (2011) and one in 10 of these individuals will develop AD over the next 10 years (Livingston and Strydom, 2012). This rate rises to one in three for those who are older than 50 years and more than half for those older than 60 years (Strydom, Shooshtari et al., 2010).

Only a very small number of people with ID are known to services. This is particularly true for older people with ID still being cared for by elderly relatives. These peoples' relatives are from a generation that would have been reluctant to engage with services. Not uncommonly, older people with ID present in crisis when they and/or their own elderly parents develop dementia.

Functional psychiatric disorders in older people with intellectual disability

People with ID of all ages have higher rates of mental ill health than the non-intellectually disabled (Cooper et al., 2007, Hughes-McCormack et al., 2017; Axmon et al., 2017). It is estimated that more than a third of people with ID have associated diagnoses of mental disorders (Pickard et al., 2010). Persons with borderline intellectual disabilities also experience higher rates of mental ill health than the general population, but receive fewer treatments (Cooper and van der Speck, 2009). In a recent study on the prevalence of mental health conditions comparing the population of people with ID with the general population, mental health conditions were reported more often for people with ID than in the general population (Hughes-McCormack et al., 2017). They found that 23.4% of adults (aged 16–64 years) and 27.2% of older adults (aged 65+ years) had mental health conditions compared with 5.3% and 4.5% of people of the same age in the general population, respectively. In this study ID was

Older people with intellectual disability

associated with a mental health disorder with a high odds ratio (OR) = 7.1 (95% CI 6.8-7.3). Hughes-McCormack and colleagues (2017) found that increase in age was also associated with increasing odds of a mental health disorder although this was so only until the age of 64 years. The odds plateaued from that age but remained higher than in the general population. This may be due to the death of people with severe/profound ID who have higher rates of mental disorders relative to people with mild/moderate intellectual disabilities.

Cooper and colleagues (1997) compared the prevalence of psychiatric disorder between a randomly selected younger group of people with ID and a group of identified older people with ID (over 65 years old) in a defined geographical area. In the older group, an additional psychiatric disorder was present in 68.7% of people, compared to 47.9% in the younger group. The higher rates of psychiatric diagnosis in the older group were due mainly to a high rate of dementia of 21.6%, as compared with 2.7% in the younger bracket. This high rate was not accounted for by the presence of DS, as the older group included only 3.7% of people with DS, compared with 28.8% of the younger population. The older group also had higher rates of generalized anxiety disorder (9.0% compared with 5.5%) and depression (6.0% vs 4.1%). The presence of behaviour disorders, pervasive developmental disorders, anxiety disorders, and psychotic disorders was equal in both groups. Schizophrenia/delusional disorders were present in 3% (vs 2.7%) and mania in 0.7% (vs 0.0%). There were no cases of obsessive-compulsive disorder or alcoholism. Behavioural disorder was equal in both groups (14.9% vs 15.1%).

Diagnostic criteria for mental disorders used in the general population (ICD-10 and DSM-5) tend to underestimate the prevalence of mental illness in this population, when compared with the Royal College of Psychiatrists Diagnostic Criteria for Psychiatric Disorders for use with adults with Learning Disabilities (DC-LD) (RCPsych, 2001; Cooper et al., 2007), a supposedly more reliable measure.

Mental ill health has been reported to be less prevalent in adults with DS than for other adults with ID (Cooper and van der Speck, 2009). In a longitudinal cohort study of 168 people with DS (mean age = 41.1 years; range = 16-74 years; standard deviation = 11.8 years), Mantry and colleagues (2008) reported a point prevalence of mental ill health of any type, excluding specific phobias, of 23.7% by clinical diagnosis, 19.9% by DC-LD (RCPsych, 2001), 11.3% by ICD-10 criteria, and 10.8% by DSM-IV-TR criteria. Compared with persons with ID not due to DS, the standardized rate for prevalence of mental illness in people with DS was 0.6 (0.4-0.8), or 0.4 (0.3-0.6) if organic disorders are excluded.

Depression has been reported to be the most common mental health problem in people with DS (Määttä et al., 2006) and is often associated with the presence of dementia (Prasher and Filler, 1995). Detection of depression in DS is problematic as people with DS do not tend to verbalize symptoms of depression and the diagnosis is often inferred from

Older people with intellectual disability

the presence of prominent vegetative symptoms and, on occasions, by auditory hallucinations (Myers and Pueschel, 1991).

Dementia in intellectual disability

Definition and diagnostic criteria for dementia in intellectual disability

There is no definition of dementia that is specific for individuals with ID. The use of the ICD-10 (WHO, 1992) criteria for the diagnosis of dementia in people with ID has been supported in preference to the DSM-IV (APA, 1994), because the ICD-10 criteria place more emphasis on 'non-cognitive' aspects of dementia, which have often been reported to be part of the first signs of dementia in people with ID (Aylward et al., 1997). In 2001, the Royal College of Psychiatrists modified the ICD-10 diagnostic criteria for dementia for use with people with ID in publishing the DC-LD (RCPsych, 2001). However, Strydom and colleagues (2007) examined the validity of the three dementia diagnostic criteria in an epidemiological sample of older adults with ID not due to DS, showing that DSM-IV dementia criteria were more inclusive than DC-LD or ICD-10, and that diagnosis using ICD-10 excluded people with even moderate dementia. It is clear that both schedules are imperfect (Sheehan et al., 2015).

Dementia in the ID population, as in the general population, is a clinical diagnosis that requires the expertise of a clinician with experience in assessing cognitive and functional decline. A recent study by Sheehan and colleagues (2015) compared concurrent validity and reliability of clinicians' diagnoses of dementia against ICD-10 and DSM-IV-TR diagnoses. Validity of clinical diagnoses were also explored by establishing the stability of diagnoses over time. They used clinical data from memory assessments of 85 people with DS, of whom 64 (75.3%) had a diagnosis of dementia. The cases of dementia were presented to expert raters who rated the cases as dementia or no dementia using ICD-10 and DSM-IV-TR criteria, but the raters also rated the cases according to their own clinical judgment. The authors found that the clinicians' judgment corresponded best with clinically diagnosed cases of dementia, identifying 84.4% cases of clinically diagnosed dementia at the time of diagnosis, as opposed to ICD-10 criteria (70.3% of cases) and DSM-IV-TR criteria (56.3% of cases). Over time, the proportion of cases meeting ICD-10 or DSM-IV-TR diagnoses increased, suggesting that experienced clinicians used their clinical knowledge of dementia presentation in DS to diagnose the disorder at an earlier stage than would have been possible had they relied on the descriptions included in the diagnostic systems.

In the beta draft of the ICD-11 there is a specific code for Dementia due to DS, 6E35.8, under 'Dementia due to diseases classified elsewhere'. This is included in the category of 'Neurocognitive Disorders'. This code does not define or give diagnostic criteria for dementia in DS but simply describes it as:

Older people with intellectual disability

Dementia due to Down syndrome, a chromosomal abnormality syndrome, typically associated with Alzheimer disease neuropathological changes. It occurs most commonly after the fourth decade.

Difficulties in the diagnosis of dementia in intellectual disability

Owing to the high rates of physical and mental ill health as well as sensory and mobility impairment in this population, cognitive and functional decline arising from the ageing process can be difficult to distinguish from early signs of dementia.

Given the wide range of abilities in the ID population it is not possible to make a diagnosis of dementia from examining an individual on one occasion. A diagnosis of dementia requires evidence of deterioration in functioning in the individual in question. Longitudinal assessments that document both baseline and present cognitive and behavioural functioning over a period of at least six months is necessary before sufficient information can be obtained to make a confident diagnosis of dementia (Burt and Aylward, 1998).

The clinical picture of decline in cognitive function and behaviour in individuals with mild ID who develop dementia is not dissimilar to that seen in the general population with Alzheimer's disease (AD). However, in people with severe and profound ID, given their extremely limited cognitive and independent functional skills, a diagnosis of dementia is consequently uncertain (Strydom et al., 2009).

To be indicative of dementia, any changes found over time must be greater than those related to normal ageing in adults with ID (Burt and Aylward, 1999). People with ID as a whole tend to age faster and to show signs of 'ageing' earlier than the general population (Jenkins et al., 1994). There is little information regarding the impact of ageing in this population.

Functional ability decreases with age in individuals with ID, but, when examined as a group, functional ability apparently improves in later life. This is very likely an artefact arising because of differential mortality rates, as shorter life expectancy is found in people with more severe learning disabilities and in people with DS (Moss, 1991). Day and Jancar (1994) summarized the extent to which physical disabilities contribute to age-related morbidity in people with ID, as have Haveman and colleagues (2011) more recently. These studies report an increasing prevalence of musculoskeletal, cardiovascular, respiratory, and neoplastic illnesses with age. However, in the case of some disorders (e.g. neoplasia), age-related increases in prevalence are relatively small. Cataract, hearing disorder, diabetes, hypertension, osteoarthritis/arthrosis, and osteoporosis were more strongly associated with advancing age, whereas allergies and epilepsy were negatively associated.

Older people with intellectual disability

Standard cognitive screening tools are inappropriate to use in the ID population as those people with moderate, severe, and profound handicaps will score zero or very low. This is known as the floor effect. It is possible to obtain information from people caring for this population but there is a high turnover of staff in settings where people with ID live and it is often difficult to obtain a reliable informant who has known the individual with ID for long enough to be able to comment on any change in performance.

The assessment of cognitive function in this population is considered in Cognitive tests.

Dementia in people with intellectual disability not due to Down's syndrome

It is established that people with DS tend to develop dementia more often and at an earlier age than the general population. It is generally less well known that people with ID not due to DS also suffer from dementia at higher rates and at an earlier age than those who do not have ID (Thompson, 1951; Tredgold, 1952; Patel et al., 1993; Strydom et al., 2009). Dementia is four times more common in older persons with ID without DS than in the general population (Cooper and Speck, 2009).

Incidence, prevalence, types of dementia, and risk factors

Strydom and colleagues (2013) estimated the incidence rates of dementia from a longitudinal study of dementia in older adults with ID without DS and compared them with general population rates. A total of 222 participants with ID without DS aged 60 years and older were followed up for an average of 2.9 years to identify those who had declined in functional or cognitive abilities. Those who screened positive had a comprehensive assessment for dementia, diagnosed using ICD-10 and DSM-IV criteria. A total of 134 participants who did not have dementia at initial assessment were alive and interviewed at follow-up, and of these 21 (15.7%) were diagnosed with dementia. Overall incidence rate for those aged ≥ 60 was 54.6/1000 person years (95% CI 34.1–82.3). The highest incidence rate (97.8/1000 person years) was in the age group 70–74. The standardized incidence ratio for those aged ≥ 65 was 4.98 (95% CI 1.62–11.67).

Strydom and colleagues in an earlier study in 2009 estimated the prevalence of dementia in people with ID not due to DS in a group of 281 individuals aged 60 years or over using defined diagnostic criteria for 'probable' subtypes of dementia. Overall, prevalence for criteria-defined dementia was 13.1% in those aged 60 years or over and 18.3% in those aged over 65 years. AD, diagnosed using NINCDS-ADRDA criteria (McKhann et al., 1984), was the most common type of dementia, with a prevalence of 8.6% in those of 60 years and over and 12% in those over 65 years. Dementia with Lewy bodies, diagnosed using the McKeith and colleagues (1996) criteria, was the second most common diagnosis, with a prevalence of 5.9% in those of 60 years and over and 7.7% in those over

Older people with intellectual disability

65 years. Frontotemporal dementia, using the McKhann and colleagues (2001) criteria, was 3.2% in those of 60 years and over and 4.2% in those over 65 years and was more common than vascular dementia diagnosed using the NINDS-AIREN criteria (Roman et al., 1993) (2.7% in those of 60 years and over and 3.5% in those over 65 years). Prevalence rates did not differ between mild, moderate, and severe ID groups. Age was a strong risk factor for dementia and was not influenced by gender or ID severity.

Clinical presentation

Despite problems in diagnosing dementia in this group, there are significant measurable differences in several neurocognitive domains between people with ID with and without dementia. Test performance on measures of attention and executive functions, language, memory, and learning have been reported as significantly lower for persons with ID and dementia compared with matched controls of people with ID without dementia (Palmer, 2006).

There is some evidence that the clinical presentation of dementia may differ between people with ID and DS and those with ID due to other causes. Cooper and Prasher (1998) conducted a small study comparing a group of 19 people with DS and dementia, and a group of 26 people with ID from other causes who also had dementia. Maladaptive behaviours and psychiatric symptomatology were assessed in both groups. The group with DS had a higher prevalence of low mood, restlessness and overactivity, disturbed sleep, lack of cooperation, and auditory hallucinations. Aggression occurred with greater frequency in those subjects with ID not due to DS.

Assessment of dementia in people with learning disabilities

The psychiatric assessment of people with ID is complicated, given the potential communication difficulties displayed by this group (Sigelman et al., 1981). In the older person with ID, this is even more difficult as a result of added age-related sensory and cognitive difficulties and often a lack of collateral information from carers who have known the person for a sufficiently long period of time (Holland, 2000).

For most people with ID, the assessment of dementia should follow the same process as in the general population, as recommended in the National Institute for Health and Clinical Excellence and the Social Care Institute for Excellence (NICE/SCIE) guidelines on dementia (2006) and on the Royal College of Psychiatrists and British Psychological Society joint guidance on assessment and management of dementia in LD (2015). The aim is to gather a history and evidence of cognitive and functional decline consistent with a diagnosis of dementia and to exclude any physical or mental/emotional causes.

Older people with intellectual disability

Physical investigations should be performed in the same way as in the general population (Salem et al., 2015). EEG studies show a correlation between cognitive decline and changes in the EEG in people with DS. The changes include absence or a very slow alpha rhythm at the onset of cognitive deterioration (Evenhuis, 1990), decrease in frequency of the dominant occipital activity (Visser et al., 1996; Velikova et al., 2011), and increase in power in the delta and theta bands, with a decrease in beta and alpha power (Angeleri et al., 1997). These changes can also be seen in EEGs of older people with established dementia.

Environmental assessment is important, as many people with ID and a suspected dementia may still be living with their older parents. It is not uncommon for middle-aged people with ID to have become carers for their older parents, who on some occasions may themselves have dementia. Even for those people who are in care, an environmental assessment is essential as the physical environment, the staff, or fellow residents may be unsuitable for residents with dementia.

Cognitive tests

When diagnosing dementia in adults with ID, the focus should be to recognize decline in cognitive and behavioural function relative to premorbid level of functioning. Three types of tests are used to help with the diagnosis of dementia in people within this group: i) those that rely on direct assessment of the individual, ii) those administered to informants, and iii) those that combine direct cognitive tests and informant reports in the form of a test battery. No single test is sufficient to make an adequate assessment and it is recommended that a behavioural assessment, using the Adaptive Behaviour Scale or similar instrument, should be used in conjunction with both subjective and informant-based tests, particularly in those subjects with severe and profound impairment (Elliott-King et al., 2016)

Subject-based assessments

Direct assessment or subject-based tests include the Prudhoe Cognitive Function Test (PCFT) (Kay et al., 2003), The Test for Severe Impairment (TSI) (Albert and Cohen, 1992), the Severe Impairment Battery (SIB) (Saxton et al., 1990), and the Adaptive Behaviour Dementia Questionnaire (ABDQ) (Prasher et al., 2004).

The PCFT covers the major domains of cognitive functioning, which are usually examined when testing or screening normal adults for dementia, i.e., orientation, recall, language, praxis, and calculation, some of which are divided into further subdomains. Administration of the PCFT takes no more than 45 minutes but there are two shorter versions that only take ten minutes to administer and have extremely good correlations (more than 0.97) to the longer version (Tyrer et al., 2010), so the shorter versions are preferred.

Older people with intellectual disability

The PCFT is a highly reliable instrument with excellent temporal stability. Inter-rater and test-retest reliability are both excellent ($ICC = 0.99$ for both) (Margallo-Lana et al., 2003), but there is a floor effect in the more intellectually disabled. It is recommended that a behavioural assessment, using the Adaptive Behaviour Scale or similar instrument, should be used in conjunction with this test, particularly in those subjects with severe and profound impairment (Elliott-King et al., 2016). The PCFT has been validated against The Kaufman Brief Intelligence Test (K-BIT), an instrument that has been utilized widely to assess cognitive abilities in people with intellectual disabilities. Comparison of performance on the long PCFT in 167 subjects with equal representation of mild, moderate, and severe ID showed high correlations between the verbal and performance sections of the K-BIT with correlation coefficients of 0.85 and 0.78, respectively.

The PCFT has face validity in terms of the acceptability of test items to both user and subjects. It also has content validity as the test questions are representative of the skills in the specified domains of the test.

The TSI was originally designed to assess people with severe dementia in the general population. However, it has particular value for those with more severe levels of ID. The test takes approximately 10 minutes and has no significant ceiling or floor effect (Tyrrell et al 2001). It includes assessment of motor performance, language production and comprehension, memory, conceptualization, and general knowledge. Only eight out of the 24 items available require the person to answer a question verbally. The test has good internal consistency ($\alpha = 0.89$) and excellent inter-rater and test-retest reliability ($\rho = 0.97$ and $\rho = 0.98$, respectively). Inter-rater and test-retest reliability are also good among those with severe ID ($\rho = 0.81$ and $\rho = 0.84$, respectively) (Cosgrave et al., 1998). The TSI was designed to assess people with severe dementia in the general population whose MMSE score is <10 out of 30. The test takes approximately ten minutes and the level of difficulty of the TSI is such that most persons with moderate to severe ID should be able to achieve a measurable score unless they are in an advanced stage of dementia.

The SIB was developed to assess a range of cognitive functioning in patients in the general population with severe dementia who are unable to complete standard neuropsychological tests. There have been three versions of the test and a recently published short version. The test has been translated and validated in Korean, Italian, Spanish, and French populations. It relies on direct assessment of the individual and takes into account the specific behavioural and cognitive deficits associated with severe dementia, allowing for non-verbal or partially correct response such as matching. It is brief, taking approximately 30 minutes to administer (15 minutes for the short version). It is composed of simple one-step commands which are presented in conjunction with gestured commands. The SIB is divided into six subscales: attention, orientation, language, memory, visuospatial ability, and construction. There are also

Older people with intellectual disability

brief evaluations of praxis and requests for the patient to respond appropriately when his/her name is called (orientation to name).

The psychometric properties of this scale have been assessed in people with DS with and without dementia. Witts and Elders (1998) concluded that the SIB has a good test/re-test reliability and criterion validity and that in general terms it is suitable for the neuropsychological cognitive assessment of adults with DS.

The Adaptive Behaviour Dementia Questionnaire (ABDQ)

The ABDQ was developed by Prasher, Farook, and Holder in 2004 as a screening questionnaire for dementia in adults with DS. For the development of the ABDQ, one hundred and fifty adults with DS (mean age 44.0 ± 1.46 , range 16-76) were assessed on baseline by review of previously reported intelligence tests, previous level of functioning as determined by review of medical notes, from carer interview and from the mental state examination; severity of the ID was classified using ICD-10 criteria. All persons were followed up on an annual basis as part of ongoing clinical care with detailed reassessments of their physical and mental health, adaptive behaviour, and social needs. Findings for the absence or presence of dementia were compared to changes in the ABS measurements over the five years follow-up to determine which items of the ABS best correlated with deterioration in intellectual functioning and could be subsequently used to develop a screening questionnaire.

The ABDQ is a brief questionnaire with good validity and inter-rater reliability. The ABDQ has been developed from over ten years of research investigating changes in adaptive behaviour in adults with DS. It can be used for all adults with ID irrespective of the severity of ID and dementia. Once the baseline level of independent functioning of a particular person has been established with the full ABS, the ABDQ appears to be a useful instrument for the ongoing assessment of people with DS. It may be most appropriately used in combination with an informant-based schedule,

Informant-based scales

The most widely used informant scales in assessing dementia in this population are the Dementia Questionnaire for People with Learning Disabilities (DLD)—originally called the DMR (Evenhuis et al., 2007), and the Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID) (Deb et al., 2007).

The DLD is an informant-based questionnaire about symptoms of dementia. It consists of 50 items divided in two subcategories: i) cognitive scores and ii) social scores. It is scored by an informant who knows the patient well and covers the person's behaviour over the previous two months. This test was specifically designed for use with people with ID and when used together with standardized tools, it has been useful in providing important information for clinicians assessing dementia in people with ID. The test, however, has some drawbacks. The instrument is

Older people with intellectual disability

less sensitive for assessing individuals with dementia in the severe and profound ranges of ID who may never have been able to perform many of the skills assessed in the questionnaire. Evenhuis (1992) has pointed out that it is difficult to discern sensitivity of the DLD when used with depressed individuals and they recommend the use of additional tools. Elliott-King and colleagues (2016) state that it is necessary to use a scale that rates behaviour when using the DLD as the DLD itself does not cover the full range of factors affected by the dementing process. Although the author reported results for single cross-sectional scores, Evenhuis (1996) recommended that score changes over time should be the most valid criterion, as single assessment cut-off scores could be inaccurate. Cut-off scores for dementia should be used cautiously and in conjunction with information gathered from other neuropsychological instruments.

Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID)

The DSQIID is an observer-rated questionnaire, which is completed by carers of people with DS who have known the individual for some time. It has three parts. The first asks about the 'best' ability the person has or has had. The second contains 43 questions about behaviour or symptoms that are usually associated with dementia in adults with DS. Each item is scored on a four-point scale: 'always has been the case'; 'always, but worse'; 'new symptoms'; and 'does not apply'. Items with a response of 'always been the case' or 'does not apply' are scored 0, those with 'always but worse' or 'new symptom' are scored 1. The third part of the DSQIID contains ten questions, all of which are comparative; for example, 'speaks (signs) less' and 'seems generally more tired'. A response of 'yes' is scored 1 and a response of 'no' is scored 0. Scores from parts 2 and 3 are added to provide a total score.

The 53 items of the DSQIID cover areas such as loss of memory, confusion, loss of skills, social withdrawal, behavioural changes, psychological symptoms, physical symptoms, sleep disturbance, and speech abnormalities. The questionnaire takes 10–15 minutes to administer and has a fixed cut off of 20. It has excellent internal consistency (average $\alpha = 0.91$) as well as inter-rater (ICC = 0.90) and test-retest reliability (ICC = 0.95). However, its fixed cut-off may compromise its usefulness in people with more severe ID or advanced dementia (O'Caoimh and Molloy, 2013).

Deb and colleagues (2007) indicate that to avoid the floor effect, the DSQIID has a scoring system by which only recent changes in behaviour are scored rather than all behaviours, which allows the use of the DSQIID in a cross-sectional context. However, it is probably best used at regular intervals over a period of time to identify the change in score. The DSQIID has been administered to over 800 patients over numerous studies and all found it to be informative (Elliott-King et al., 2016).

Older people with intellectual disability

Communicating the diagnosis to patients and carers

Ideally, every effort should be made to share information with the person with ID and dementia, perhaps recruiting the assistance of a speech and language therapist (SALT) to make the information as 'user friendly' as possible (Royal College of Psychiatrists and British Psychological Society, 2015). However, in practice this is at times not feasible as many people do not have adequate cognitive ability to understand what is being said and such attempts could result in the person becoming distressed.

Because of difficulties in communication with the individual with ID it is very important that carers and family are involved during the assessment process and that information about the outcomes, diagnosis, and care plans are shared with them. Sensitive handling of their own emotional response to the information given will be necessary to maintain their engagement at all stages, particularly at the end-of-life phase.

Dementia in people with Down's syndrome

DS is the commonest cause of early-onset dementia generally and particular attention to the manifestations of dementia in this genetic disorder are considered here.

It is not common for this illness to arise before the age of 50 but Holland and colleagues (2000) found that 40% of those aged over this age had developed dementia. Adults with DS have a high prevalence of AD type dementia and low rates of vascular dementia. They are resilient to atherosclerosis (Ylä-Herttuala et al., 1989) and have low blood pressure and slow pulse (Cooper et al., 2016). While rare, cases of Lewy body dementia and frontotemporal dementia have been reported (Raghavan et al., 1993).

The association between dementia and DS was first scientifically reported by Fraser and Mitchell (1876), well before Alois Alzheimer described the case of the first patient with the disease that later bore his name (Alzheimer, 1907). It was Jervis who in 1948 first clinically described the association between DS and AD (Jervis, 1948).

The reason why dementia occurs more frequently in individuals with DS is still not known definitively. However, it is well-recognized that people with DS have a genetic predisposition to develop this type of dementia due to the triplication of the APP gene on chromosome 21, leading to overproduction and deposition of amyloid beta (A β). Further information on this relationship is covered later in this chapter (see also APP, BACE-1, and BACE-2).

Prevalence

DS is the most commonly identified genetic form of LD and the leading cause of specific birth defects and medical conditions (Sherman et al., 2007). The prevalence of DS for the 16 years and over population in the

Older people with intellectual disability

UK has been reported as 5.9 per 10,000 general population (Mantry et al., 2008). Within this population the prevalence of dementia among adults with DS has been estimated to be approximately 20% after the age of 40 (Janicki and Dalton, 2000) and 45% after the age of 55 (Silverman et al., 1998). After the age of 60, approximately half of individuals with DS have a diagnosis of dementia (Janicki and Dalton, 2000; Margallo-Lana et al., 2007).

A rather more optimistic outlook for this population has been reported by Coppus and colleagues in the Netherlands (2006) in the largest longitudinal study published yet. Their study included 506 people with DS over the age of 45 years who were followed-up for a mean period of 3.3 years. They reported an overall prevalence of dementia of 16.8%. Up to the age of 60, the prevalence of dementia doubled with each five-year interval. From age 45–49, the prevalence was 8.9%, from 50–54, it was 17.7%, from 55–59, it was 32.1%, and from 60 and above, it was 25.6%. The authors argued that the lack of increase in prevalence after the age of 60 may be explained by the increased mortality among older DS patients in comparison with patients without dementia and this belief was supported by the finding that there was no decrease in the incidence of dementia in the age group of 60 and above. In a 15-year follow-up community study of 92 people with DS who had previously been institutionalized, the years at risk for dementia for those aged 45 or under was found to be zero, whereas it reached a maximum of 7.5/100 person years in those aged over 60 years (Margallo-Lana et al., 2007).

Despite greater awareness of the risks of DS, the incidence of births of babies with this condition have barely altered over a ten-year period (Morris and Alberman, 2009).

Life-expectancy and mortality

Life-expectancy of individuals with DS has increased in the last 60 years from 12 years of age in 1949 to nearly 60 today (Penrose, 1949; Bittles and Glasson, 2004). However, life-expectancy in people with DS is still lower than in the general population and remains lower than in people with ID who do not have DS.

Clinical presentation

The clinical presentation of dementia in people with DS is influenced by the severity of handicap. The milder the severity of disability, the closer the symptomatology will be to that seen in the general population with AD.

In this less-severely handicapped population, forgetfulness, impairment of recent memory with relatively intact long-term memory, and confusion are all common, and present early in dementia among adults with DS. A general slowness in activities and speech, language problems, loss of interest in activities, social withdrawal, balance problems, sleep difficulties, and loss of pre-existing skills, along with the emergence of

Older people with intellectual disability

emotional and behavioural problems, are common presentations of dementia among adults with DS (Deb et al., 2007). Some studies have suggested that people with DS tend to have early manifestations of frontal lobe symptomatology rather than memory changes (Ball et al., 2010). This is not surprising, given the brain developmental abnormalities present in people with DS at birth affecting the frontal lobe (Teipel and Hampel, 2006), and the fact that the earliest deposition of A β in the brain of people with DS occurs in the frontal lobe and entorhinal cortex (Azizeh et al., 2000; Nelson et al., 2011).

Among adults with more severe and profound ID, the diagnosis of dementia, in the absence of any measurable cognitive decline, needs to be made on the basis of behavioural changes characteristic of progressive neurodegenerative disease. These include features such as daytime sleepiness, wandering, decreased mobility, onset of epilepsy, increased incontinence (Burt et al., 1992; Margallo-Lana et al., 2007), abnormality of the posture or gait (Lai and Williams, 1989), and rigidity or myoclonic jerks (McVicker et al., 1994). These symptoms support the diagnosis of dementia when cognitive decline cannot be reliably measured.

Cognitive changes associated with dementia in Down's syndrome

As previously described, those people with DS who have mild to moderate handicaps show similar patterns of cognitive impairment when a dementing illness arises to non-handicapped individuals from the general population who develop dementia.

The cognitive profile of people with DS and dementia was recently compared with that of people with AD in the general population by Dick and colleagues (2016) using the Severe Impairment Battery (SIB) (Saxton and Swihart, 1989)). Fifty-one individuals without ID who had moderate to severe dementia and 59 people with DS and dementia were assessed, controlling for gender as well as level of functional ability using a modified version of the Bristol Activities of Daily Living Scale. Overall, the neuropsychological profiles of the higher-functioning individuals within the DS group and individuals with moderate to severe dementia from the general population groups, were very similar to one another, after adjusting for gender and functional impairment, when the total scores and the nine separate domains of the test were compared.

The assessment of cognitive change in the DS population has been covered in the previous section concerned with the assessment of cognition in the ID population. A number of instruments and schedules were covered earlier (see Cognitive tests) and those that have been expressly designed for individuals with DS, e.g. the PCFT and the DSQUID are recommended.

Older people with intellectual disability

Behavioural changes

Behavioural changes are common in people with DS in the early stages of dementia (Määttä et al., 2006). People with DS and dementia tend to display less aggressive behaviour but greater degrees of depression, restlessness, hyperactivity, disturbed sleep, oppositional behaviour, and auditory hallucinations compared to people with ID from other causes who develop dementia. (Cooper and Prasher, 1998). Nonetheless, in comparison with patients with AD, people with DS and dementia have fewer problem behaviours.

Other symptoms often associated with dementia in people with Down's syndrome

Epilepsy

People with DS have a triphasic distribution of epilepsy incidence, with peaks in childhood, early adulthood, and in late middle age (Pueschel et al., 1991). Up to 84% of people with DS and dementia will develop epileptic seizures over time (Puri et al., 2001). These seizures tend to occur early in the course of dementia and respond well to treatment (Gholipour et al., 2017; McCarron et al., 2017). In addition to generalized epileptic seizures, individuals with DS who develop dementia often demonstrate myoclonic seizures, described as Late Onset Myoclonic Epilepsy in Down's Syndrome (LOMEDS) (Möller et al., 2001). LOMEDS is characterized by a progressive deterioration of cognitive function a few years before the onset of the epilepsy, featuring myoclonic as well as generalized tonic-clonic seizures (Li et al., 1995). EEG changes show generalized fast spike-waves or polyspike-waves with or without bilateral myoclonic jerks, especially on wakening. Photo paroxysmal response (11–21 Hz) has also been described as part of LOMEDS (Crespel et al., 2007).

D'Orsi and Specchio (2014) studied the natural history of myoclonic epilepsy associated with dementia in adults with DS. Twelve patients with DS over the age of 40 years with myoclonic epilepsy underwent clinical, neuropsychological, neurophysiological, and neuroradiological studies. Three main phases appeared during the course of the syndrome, which occurred over a short period of time. The first stage was characterized by onset of dementia (mean age: 51 ± 6.6 years), diffuse EEG abnormalities during sleep, and cerebral atrophy determined by neuroimaging. During the second stage, myoclonic epilepsy was manifest (mean age: 51.4 ± 7.2 years) with myoclonic jerks time-locked to diffuse epileptiform abnormalities upon wakening. At the time of the third stage (mean age: 54.8 ± 7.6 years), myoclonic seizures were replaced with non-epileptic myoclonus, and cerebellar signs, severe dementia, and the development of photosensitivity.

Older people with intellectual disability

Dysphagia

There is no published research examining the effect of dementia on drinking, eating, and swallowing in adults with DS (Lazenby, 2008). All degenerative diseases affecting the central nervous system are associated with feeding problems as the disease progresses. People with DS have specific oropharyngeal problems (Hennequin et al., 1999), swallowing dysfunction (Frazier and Friedman 1996), high prevalence of oesophageal motor disorders (Bianca et al., 2002), and increased prevalence of reflux (Wallace, 2007), which increase the risk of dysphagia and aspiration. Progressive dysphagia and frequent choking may be observed in people with DS in the early stages of dementia but are more obvious in the middle stage (Alvarez, 2011). Dysphagia may not be diagnosed until the patient presents with severe weight loss or recurrent respiratory infections.

Motor/gait disorders and falls

When people with DS develop dementia, motor disorders manifest early in the disease but usually become more obvious in the middle and advanced stage of the illness. The symptoms include general motor slowness, difficulty in performing complex motor tasks, e.g. getting in and out of a car, going up and down stairs, negotiating changes in levels e.g. kerbs by pavements, progressive gait disorder, falls, and, in some patients, parkinsonian symptoms (Alvarez, 2011). In the advanced stages patients become bedridden, with little voluntary movement.

There is little research on falls and motor disorders in older people with DS and dementia. Although it has been reported that young people with DS have a lower risk of falling compared with their peers having other types of ID (Finlayson et al., 2010), others have found that increased age on its own is a risk factor for falls generally among the ID population, including people with DS (Cox et al., 2010).

Natural history

There is little research devoted to the natural history of dementia in people with DS. In the 15-year follow-up study of 92 people with DS mentioned in the Prevalence section (Margallo-Lana et al., 2007), the mean age of onset of dementia was 55.5 years (range 45–74) and the mean age of death with dementia was 59.1 ± 9.6 years, with a survival period from onset of dementia until death of 3.5 ± 2.2 , range 1–8 years. The majority of deaths were due to bronchopneumonia. Respiratory tract infection is a common reported cause of death in older people in general, in the general population with AD (Keene et al., 2001), and has previously been reported as a common cause of death of people with DS and dementia (Evenhuis, 1990).

Older people with intellectual disability

Age-related changes in physical health

Adults with DS experience premature age-related health problems (see Esbensen, 2010 for a comprehensive review). Among these, apart from the increased risk for dementia, are skin and hair changes (Madan et al., 2006), early-onset menopause (Seltzer et al., 2001), visual and hearing impairments (McCarron et al., 2005), adult-onset seizure disorder (Menéndez, 2005), thyroid dysfunction (Coleman, 1994), obesity (Melville et al., 2005), sleep apnoea (Resta et al., 2003), testicular cancer (Hasle et al., 2000), musculoskeletal problems such as osteoporosis, osteoarthritis, decreased muscle strength, impaired balance, falls (Dacre and Huskisson, 1988), and mitral valve prolapse (Barnhart and Connolly, 2007). There are conflicting reports about whether people with DS are at increased risk of diabetes type 1 (Haveman et al., 1989; Yang et al., 2002; Hill et al., 2003) and decreased risk of diabetes type 2 (Silverman, 2010).

Adults with DS are at a lower risk than the general population for several medical conditions, including malignant solid tumours (Satgé et al., 1998), cerebrovascular and non-congenital cardiovascular disease (Marino and Pueschel, 1996), and digestive system disease (Glover and Ayub, 2010). They have lower resting heart rates and lower blood pressure than the general population (Prasher, 1994). Hypertension is not common in this population (Kerins et al., 2008). Compared with people with ID not due to DS, they have lower rates of emphysema, fractures, and hypercholesterolaemia (Kerins et al., 2008). While significant respiratory problems are not common (Minihan and Dean, 1990), as mobility declines with age, recurrent pneumonia with incomplete recovery has been found to occur more often than in the general population (Van Allen et al., 1999). This is significant as respiratory illness is a common cause of mortality in adults with DS (Margallo-Lana et al., 2007; Esbensen, 2010).

Age-related cognitive changes

Cognitive decline occurs relatively early in DS and is naturally more common than dementia (Carr and Collins, 2014). Several studies have compared the cognitive profile of older people with DS without dementia to young DS and older people with DS and dementia (Haxby, 1989; Schapiro et al., 1992). These investigations have shown that older people with DS without dementia do not differ from the younger DS groups on tests of overall abilities, such as the Stanford-Binet Test (Terman and Merrill, 1973), tests of attention or language (Schapiro et al., 1992), and immediate verbal memory spans (digit and object pointing spans). Older people with DS without dementia did have lower visuospatial memory span (block tapping) than younger DS subjects. This suggests that there is a greater loss of immediate visuospatial memory compared with immediate verbal memory during the ageing process in DS even in the absence of dementia. Age-related changes in verbal communication in people with DS include a decline in social discourse involving changes in

Older people with intellectual disability

conversational style, literal understanding, and verbal expression in social contexts (Nelson et al., 2001; Couzens et al., 2011).

Other studies looking at measures of attention, executive function, and memory in people with DS without dementia suggest that people with DS over the age of 40 experience an average annual global cognitive decline of 11%, indicating that progressive cognitive decline occurs from midlife onwards, even in the absence of dementia (Margallo-Lana et al., 2003).

Ghezzi and colleagues (2014) in a cross-sectional study of age-related cognitive and adaptive changes of a group of 67 persons with DS without dementia, of different ages (11 to 66 years), found that both neuropsychological function and adaptive skills are lower in adult DS persons over 40 years old, compared to younger ones. In particular, language and working memory skills, frontal lobe function, visuo-spatial abilities, and adaptive behaviour appear to be the more affected domains. A growing deficit in verbal comprehension, along with social isolation, loss of interest and greater fatigue in daily tasks, are the main features found in older, non-demented DS persons evaluated in this study. These signs are the harbingers of incipient dementia.

Age-related changes in functional skills

The literature about age-related changes in functional skills for people with DS without dementia is controversial. Although Esbensen and colleagues (2008) found evidence of age-related change in a longitudinal study over nine years in a group of 150 adults with DS and 240 adults with ID due to other causes, Dressler and colleagues in 2010 detected no major decline in middle adulthood in a study involving 75 individuals with DS without dementia.

Risk factors for development of dementia in Down's syndrome

Age

As in the general population, age is the strongest risk factor influencing the age of onset of dementia in people with DS (Bush and Beail, 2004; cited in Zigman and Lott, 2007).

Gender

The existing literature regarding rates of dementia according to gender shows conflicting results. For example, Schupf and colleagues (1998) reported that, compared with women, men with DS are three times as likely to develop AD. In contrast, Lai and colleagues (1999) found that women were 1.77 times as likely to dement as men at any given point in time ($P = 0.04$).

There does, nevertheless, seem to be a significant relationship between age of onset of menopause and the onset of dementia (Schupf et al., 2006; Coppus et al., 2010) in women with DS. Coppus and colleagues (2010)

Older people with intellectual disability

recently reported that early age at menopause is associated with a 1.8-fold increased risk of dementia.

APP, BACE-1, and BACE-2

APP is expressed at levels that are four- to fivefold higher in DS than in the general population (Beyreuther et al., 1993). A β peptide is generated from APP by sequential action of β secretase amyloid precursor protein cleaving enzymes 1 and 2 (BACE1 and BACE2) and γ secretase. It has been reported that APP C99, the major β secretase product, and A β are increased in DS (Busciglio et al., 2002; Sun et al., 2006). The gene for BACE2 is located on chromosome 21, probably within the obligate region for DS (Korenberg et al., 1990). BACE2 protein levels have been found to be higher in foetal tissue of individuals with DS (Barbiero et al., 2003) and in fibroblasts of adults with DS, compared with controls from the general population (Motonaga et al., 2002; Barbiero et al., 2003). However, the roles of BACE1 and BACE2 in the neuropathogenesis of AD in DS have been questioned (Sun et al., 2006; Cheon et al., 2008). It has been reported that APP overexpression seems to be absent during the development of the DS brain up to weeks 18–19 of gestational age but is expressed in adult DS brains and it has been confirmed that increased gene expression of APP is associated with the diagnosis of dementia (Schupf et al., 2010). The comparable expression of BACE1 and BACE2 in brains of adults with DS during early foetal brain development contradicts the hypothesis that increased β secretase results in (or even underlies) increased production of amyloidogenic A β fragments in people with DS (Cheon et al., 2008).

Apolipoprotein E4

The literature about the effect of apolipoprotein E (apoE) on AD in DS is inconclusive (Coppus et al., 2008). Bálint and colleagues (2000) studied a group of 56 ethnically homogeneous Hungarian people, looking at the apoE distribution in amniotic fluid of 15-week conceptuses with trisomy 21 from a genetic screening programme, thus including those that might have not reached full-term gestation. The authors found no significant difference in the distribution of apoE alleles in the group of trisomy 21 fetuses compared with samples of blood from healthy blood donors in the same geographical area.

It has been reported that E4 allele frequency of older DS patients is about half that of younger ones, suggesting premature death of people with DS of those with this allele (Folin et al., 2003). ApoE2 has been associated with increased longevity and decreased frequency of dementia in the adult population (Royston et al., 1994) but this allele only occurs in less than 2% of the population. As the majority of studies have found that the apoE allele distribution in people with DS is similar to that found in the general population without AD (Hardy et al., 1994; van-Gool et al., 1995)

Older people with intellectual disability

the evidence for a reduced development of dementia in DS subjects possessing this allele is inconclusive because of the low numbers.

Despite the low frequency of apoE4 in earlier studies, several authors (Deb et al., 2000; Coppus et al., 2010; Zigman et al., 2005) have found that on meta-analysis the frequency of apoE4 was higher in adults with dementia compared with adults with DS without dementia, but there was no significant reduction in the frequency of apoE2, although the numbers were small. They concluded that apoE4 influences the age of onset of dementia and mortality risk in DS.

Gene polymorphisms

A gene polymorphism in the prion protein gene has been reported to be associated with earlier decline in intellectual ability in adults with DS (Del Bo et al., 2003). Margallo-Lana and colleagues (2004) reported a 13-year difference in the age at onset of dementia in DS associated with the number of tetranucleotide repeats on intron 7 alleles in the APP gene. The results suggested that APP is an important locus predicting the age at onset of dementia in people with DS.

Atypical karyotypes

Translocations, partial trisomies, and varying degrees of mosaicism are reported to be associated with better survival and lower risk of AD than the full trisomy 21 (Schupf and Sergievsky, 2002). There have been cases reported in the literature of people with DS of advanced age who died showing no signs of cognitive decline. A case of a woman who at 78 years of age was diagnosed with partial trisomy excluding the APP region who died at the age of 83 showing no clinical symptoms of dementia or neuropathological lesions of AD has been reported (Prasher, 1998). Other reports mentioned in the literature include the cases of two women with 25% and 86% trisomy for chromosome 21 who at the ages of 83 and 74, respectively, showed no signs of clinical dementia (Chicoine and McGuire, 1997; W.B. Zigman, personal communication, 2000).

Biomarkers

β-Amyloid peptide levels

People with DS have higher plasma levels of soluble Aβeta peptide (Aβ) levels than individuals in the general population (Mehta et al., 1998).

Jones and colleagues (2009) reported no association between age and plasma Aβ 1–40 and plasma Aβ 1–42 concentrations, nor were plasma Aβ 1–40 and plasma Aβ 1–42 levels found to vary between people with DS with or without dementia. Matsuoka and colleagues (2009) have argued that it is the ratio of plasma Aβ 42/40 rather than absolute levels of the peptides that are important in contributing to the pathophysiology of AD.

Older people with intellectual disability

Changes in A β peptide levels with onset of AD and with the duration of dementia may account for a lack of difference between prevalent cases and individuals without dementia (Prasher et al., 2010).

Results from studies suggest that among adults with DS, decreasing levels of plasma A β_{42} , a decline in the A β_{42} /A β_{40} ratio, or increasing levels of A β_{40} may be sensitive indicators of conversion to AD, possibly reflecting compartmentalization of A β peptides in the brain (Schupf et al., 2010). A more recent investigation has shown that plasma A β levels are closely related to the presence of cerebral amyloid angiopathy, which is strongly associated with the development of dementia in DS (Head et al., 2017).

Telomere shortening

Telomeres, the repeated nucleotides that cap the ends of chromosomes, undergo shortening with each cell division, and therefore serve as markers of a cell's replicative history. Reduction in telomere length may be an indicator of cellular ageing and has been linked to AD in the general population (Panossian et al., 2003).

Jenkins and colleagues in 2006 reported shorter telomere length in T lymphocytes of individuals with DS and AD compared with age-matched paired individuals with DS without dementia. They have reported since then (Jenkins et al., 2010) that people with DS and mild cognitive impairment (MCI-DS) also have shorter telomeres than people with DS without MCI-DS. Furthermore, they demonstrated that light intensity measurements from chromosome 21 exhibited shorter telomeres in adults with DS with either dementia or MCI-DS compared to ageing per se. The authors suggested that chromosome 21 measurements appeared to be especially promising for use as a biomarker because of the lack of overlap in the distribution of telomere measurement scores between normal ageing, mild cognitive impairment, and dementia in individuals with DS. In a more recent study Jenkins and colleagues (2016) found consistent shortening of telomere length in five individuals with DS as they declined cognitively.

Neuroanatomical features in dementia

Neuropathology in ID

People with DS have smaller brains than individuals in the general population, and their brain size reduces with age and declines further with the onset of dementia (Schapiro et al., 1989). Macroscopic abnormalities in the brains of people with DS described in the literature have been summarized by Lubec and Engidawork (2002) as small, rounded, and foreshortened, with a steep rise of the occipital lobes and narrowing of the superior temporal gyri.

Older people with intellectual disability

The principal neuropathological features in AD dementia are the formation of senile amyloid plaques (SP) and neurofibrillary tangles (NFTs), AD neuropathology develops in many individuals with ID not due to DS. In a post-mortem series, Malamud (1972) reported no evidence of AD pathology among adults in this population for people under the age of 40 and a prevalence of 14% in individuals over 40 years old. Barcikowska and colleagues (1989) reported a prevalence of AD neuropathology in 31% in people with ID not due to DS who were over 65 years of age at the time of death.

Popovitch and colleagues (1990) examined the brains of 385 adults aged 23–90 years with ID without DS, metabolic disorder, or hydrocephalus. The presence of one or more NFTs and/or neuritic plaques (NP) was observed in 63.4% of all cases and varied with age. Recommended age-specific quantitative criteria for the diagnosis of AD (Khachaturian, 1985) were met in 9.5% of those cases below 50 years of age, 54.2% between 50 and 65, 70% between 66 and 75, and 87% of the cases greater than 75 years of age. However, in most cases the NP did not have a neuritic component containing paired helical filaments, and substantial numbers of NFT were seen in the frontal cortex, contrasting with results reported in the literature for the general population. The number of NP per square millimetre consistently increased with age for all areas examined, with the largest age-associated increases in density seen in frontal and temporal regions. In contrast, NFT density increased with age only within hippocampus and parahippocampal gyrus, but not in the neocortex.

In a study of similar individuals, Silverman and colleagues (1993) reported statistical independence of regional amyloid plaque and NFT densities although NP lesions within the neocortex were more diffusely distributed across regions for older cases compared to younger cases. Interestingly, no similar age-associated change in the topography of NFT was observed.

Neuropathology in DS

The majority of people with DS have senile plaques in their brains by the age of 40. However, the relationship between plaque count and dementia is poor; there is a much more robust correlation of the presence and severity of dementia with neurofibrillary tangle count (Margallo-Lana et al., 2007). Head and Lott (2004) suggest that there may be additional provocative factors in the development of dementia (e.g. apoE genotype, gender, individual differences in A β deposition) acting in parallel with compensatory events that would maintain brain function despite the accumulation of AD pathology. Such compensatory events reported in people with DS include neuronal growth response (spouting) in the hippocampus and frontal cortex at ages immediately before the development of full-blown AD pathology (Head et al., 2003, 2007; Ohara et al., 1999). This compensatory growth responses may occur in DS prior to extensive AD pathology and may be one mechanism underlying

Older people with intellectual disability

observations in PET studies of hypermetabolism in the entorhinal cortex of individuals with DS (Haier et al., 2003, 2008; Zigman and Lott, 2007).

In addition to the formation of SPs and NFTs there is evidence of cerebral amyloid angiopathy (CAA) in DS. This is because in DS there is overexpression of chromosome 21, leading to increased amyloid precursor protein (APP) production, which then leads to abnormal amyloid deposits. When the soluble protein tau is hyperphosphorylated the internal structure of the cell is deranged due to destabilization of microtubules; NFTs result, and cell death may occur. Enzymes such as dual specificity tyrosine-phosphorylation-regulated kinase 1A coded by *DYRK1a* gene and the DS critical region RCAN21 ('Regulator of Calcineurin') (Davies et al. 1998) are encoded on chromosome 21 and they play a role in tau formation. The pattern of NFT formation in DS follows the hierarchical pattern observed in AD (first layer II of the entorhinal cortex, followed by the hippocampus, and then the neocortex). SP deposition may commence in people with DS during adolescence, and NFTs appear later as the person ages (Mann and Esiri, 1989). It is the appearance of NFT deposits that induces AD symptoms despite the early presence of SP (Armstrong, 1994; Margallo-Lana et al., 2007).

Although Mann (2006) considers that the pathological changes that arise in DS and in AD are similar, later authors disagree (Nelson et al., 2011) and recent writers support the contention that the neuropathology of DS and AD are different (Ballard et al., 2016). It has been proposed that CAA should be increased in DS because the extra copy of APP leads to increased beta-amyloid peptide (A β) accumulation. CAA in DS was indeed found in significantly higher frequencies in brains of individuals with DS compared to sporadic AD and controls (Head et al., 2017). Hypertension and arteriosclerotic changes occurred commonly in those with sporadic AD whereas atherosclerosis and sclerosis of the smaller arterioles were rare in the cases with DS. The seminal role of A β accumulation in DS suggests a different mechanism of cell loss in this disease. This finding is supported by evidence that PET scanning of DS subjects has confirmed that amyloid deposition occurs before the onset of dementia and tau accumulation correlates with cognitive decline (Rafii et al., 2017; Fortea et al., 2020).

Other processes that may influence the development of dementia in DS are being investigated, in the search for new therapeutic interventions. Oxidative processes, mediated by mitochondria, may lead to protein damage and cognitive difficulties. Senile plaques and NFTs provoke an inflammatory response from microglia, which may lead to cellular damage. White matter changes have been reported in the younger adults with DS. White matter pathology may increase the risk of AD in non-DS individuals. Many of these processes are currently under investigation.

Neuroimaging

Older people with intellectual disability

Interested readers are referred to Beacher and Murphy (2006) and Schaer and Eliez (2007) for reviews on the subject. Compared with age matched non-ID controls without dementia, individuals with DS have a significantly greater age-related reduction in the volume of frontal, temporal and parietal lobes, and a significantly greater age-related increase in volume of peripheral cerebrospinal fluid (Beacher et al., 2010).

Brain computerized tomography scan studies on people with DS and dementia have reported changes similar to those seen in the general population with AD, including an increased degree of brain atrophy (Schapiro et al., 1992) and medial temporal atrophy (Ikeda and Arai, 2002). Studies using voxel-based morphometric (VBM) MRI scans (automated, observer-independent technique) of people with DS (White et al., 2003) support findings seen on volumetric MRI scans (Beacher et al., 2009). In a study of 27 people with DS without dementia (mean age 44.1 years) Teipel and colleagues (2004) found that the regional gray matter volume was decreased with advancing age in parietal, frontal, occipital, temporal, and parahippocampal regions. Gray matter volume was relatively preserved in subcortical nuclei, periventricular regions, the basal surface of the brain (bilateral orbitofrontal and anterior temporal areas) and the anterior cingulate gyrus. These findings suggest grey matter reductions in allocortex and association neocortex in the predementia stage of DS.

It is uncertain whether VBM offers a more accurate description of brain anatomy in DS than traditional techniques, as VBM includes statistical modelling assumptions that may not apply to populations known to have marked abnormalities in brain anatomy (Beacher and Murphy, 2006).

Functional neuroimaging using positron emission tomography (PET) measurements of fibrillar β amyloid ($A\beta$) burden and reductions in regional PET measurements of the cerebral metabolic rate for glucose (CMRgl) have been used in several studies in DS with and without dementia. People with DS and dementia have shown deficits in regional cerebral blood flow and glucose consumption, and regional pattern of fibrillary $A\beta$ deposition similar to that observed in late-onset AD and in additional frontal regions. (Sabbagh et al., 2015, 2011; Landt et al., 2011; Nelson et al., 2011).

Treatment

There is a lack of evidence for both pharmacological and psychological treatment of dementia in people with ID (Sheehan et al. 2015).

Pharmacological treatment: Cognitive enhancers

Despite a poor evidence base (Ballard et al., 2016) cholinesterase inhibitors are approved for the treatment of people with dementia in DS in the UK. The National Institute for Health and Care Excellence (NICE) has published a clinical evidence statement on pharmacological

Older people with intellectual disability

management of mental health problems in people with ID and dementia (NICE, 2016). They found that there was moderate quality evidence suggesting donepezil may be effective in treating cognitive decline and increasing adaptive behaviour in people with DS who do not yet have dementia (Kondoh et al., 2011; Prasher et al., 2002). There was little evidence supporting the use of memantine in the DS population (Boada et al., 2012; Hanney et al., 2012). A Cochrane review of the evidence was even less supportive, and Livingstone and colleagues (2015) concluded that, 'due to the low quality of the body of evidence, it is difficult to draw conclusions about the effectiveness of any pharmacological intervention for cognitive decline in people with DS'.

Other psychotropic medication

The use of psychotropic medication in people with ID and dementia should follow the same principles as those used in the general population, but with consideration that this group may be unusually sensitive to some medication as a result of reduced drug metabolism, reduced drug clearance, and reduced plasma protein binding. It is considered good practice when treating people with ID to start medication at a lower dose and to make increments at a lower rate than for the general population.

Depression is often associated with dementia in people with ID (Coppus et al., 2006). Selective serotonin reuptake inhibitors (SSRIs) are preferred in this population.

Sleep disturbance appears to be as common in people with ID and dementia (Espie, 2000) as in the general population with dementia (Vitiello and Borson, 2001). Some patients respond well to small doses of trazodone, despite the fact that this drug is not licensed for this indication. The dose ranges from 25 mg to 150 mg at night.

The drugs used for the treatment of epilepsy do not differ greatly from those used in younger people with ID. Sodium valproate is widely used, and the newer drug, levetiracetam, has benefits; senile myoclonic epilepsy in DS responds well to it (Aller-Alvarez et al., 2017; Vignoli et al., 2011). For the treatment of status epilepticus, NICE (2004) suggests the use of buccal midazolam, a short-acting benzodiazepine, at a dosage of 5–10 mg as an alternative to rectal diazepam. In people with DS, a lower dose of 2.5mg is preferable to avoid over-sedation. Buccal midazolam is unlicensed in the UK.

Psychological and psychosocial treatments

A mixture of nonspecific psychosocial interventions, such as reducing environmental demands, simplifying routines, and minimizing avoidable changes, would intuitively appear appropriate in the care of people with ID and dementia. Unfortunately, there are no studies evaluating the effectiveness of these interventions in people with ID and dementia (Royal College of Psychiatrists and British Psychological Society, 2015). If problem behaviours arise in the course of dementia in ID guidance is

Older people with intellectual disability

given on assessment and intervention (Royal College of Psychiatrists, 2007).

Practical considerations

To move or not to move

Janicki and Dalton (1998) argued that, wherever possible, people with ID and dementia should stay in their usual place of residence, 'dying in place', with the necessary adaptations to meet the person's increasing health needs, including provision of palliative care (Thompson and Wright, 2001). If this is not possible, then they should be transferred to a residence within an ID service, 'referral in', with the last preferred option being a 'referral out' of ID services when the person is transferred to services for older people. However, persons with ID may have been placed in a residence when they were young without considering their long-term needs. Not uncommonly, these placements cannot be adapted to suit the requirements of a person with dementia. Given the lack of provision of specialist placements for people with dementia within ID services, many of these people end up on an emergency placement or in a general nursing home.

Compared with older people with ID not due to DS, ageing adults with DS encounter more relocations, and are more likely to have their final placement for end-of-life care in a nursing home (Patti et al., 2010)

End-of-life decisions

End-of-life decisions are made in between one quarter and one half of people with ID (Lohiya et al., 2002; Wagemans et al., 2010). This figure is similar in those of normal intelligence (van der Maas, 1997). The prevalence and nature of end-of-life decisions was investigated in a Dutch study of medical files of people with ID who died between January 2002 and July 2007 (Wagemans et al., 2010). The authors found that one or more end-of-life decisions were taken in over half of the deaths in that period, but the family had been involved in decision-making in only half of the cases. They also found no information in the medical notes about the process of end-of-life planning and no evidence that any of the people with ID were consulted in taking an end-of-life decision. The wishes of people with ID are often unknown because of lack of mental capacity. In these cases, a decision should be made according to what others consider are the best interests of the person (Mental Capacity Act, Department for Constitutional Affairs, 2005). It is recommended that a formal discussion involving carers, the GP, family, and advocates, should take place to determine what are thought to be the best interests of the person before the person with ID dies (Lohiya et al., 2002).

The Department of Health (2008) End of Life Strategy provides best-practice examples for management of people with ID and dementia towards the end of their lives. Recently the International Summit on Intellectual Disability and Dementia produced a report (Watchman et al.,

2017) on end-of-life care in advanced dementia. The report recommended that palliative care providers should be informed about such cases and adults with ID should be consulted early on in their advance care planning (McCallion et al., 2017).

Introduction

The importance of enquiring about sleep patterns was recognized by Hippocrates as early as 400 BCE when he wrote 'sleep and watchfulness, both of them when immoderate, constitute disease'. Unfortunately, many medical students and doctors-in-training receive little or no training in sleep medicine (Stores, 2007). Sleep disorders, remain largely unrecognized, under-diagnosed, and under-treated (Stores, 2007, Rosenberg, 2015).

This vital physiological process occupies a third of our adult lives and disrupted sleep has immediate and long-term consequences on physical and mental health. For the old age psychiatrist, two of the most important functions of sleep remain regulation of normal affect and normal

Sleep and circadian rhythm disorders

cognition—not only just simple attention and vigilance, but also the key role of memory consolidation and new learning (Cellini, 2017).

There is also emerging evidence that sleep, acting via the glymphatic system, is vital for the clearance of toxic protein aggregates from the brain (Tarasoff-Conway et al., 2015). In humans, disruption of slow-wave sleep has been shown to increase cerebrospinal fluid (CSF) antibody levels (Ju et al., 2017), providing support for the hypothesis that sleep disruption may perpetuate the neurodegenerative cascade (Wu and Swaab, 2007).

Primary sleep disorders are common with the prevalence of these disorders increasing with age. These include sleep related breathing disorders, restless legs syndrome (RLS), periodic limb movements of sleep (PLMS), circadian rhythm disorders, and parasomnias such as REM sleep behaviour disorder (RBD). Sleep disturbance may also be a result of medical and psychiatric comorbidities, as well as polypharmacy.

Sleep disturbance commonly occurs in psychiatric disorders and is often regarded as a secondary phenomenon that will improve following treatment of the underlying psychiatric disorder. Insomnia has been shown to be a risk factor for subsequent development of depression (Pigeon et al., 2017). There is often a tendency to attribute sleep disturbance in those with mental health problems to the psychiatric diagnosis or the psychotropic medication, rather than as a distinct and treatable set of disorders.

Sleep disturbance is common in patients with dementia, with a prevalence of 24.5% reported in a sample of patients with mild to moderate Alzheimer's disease (AD) (Moran et al., 2005). In neurodegenerative disorders, the development of a significant sleep disturbance is often the reason for a patient to enter residential care (Pollak and Perlick, 1991; Bianchetti et al., 1995). The association between sleep and dementia is bidirectional: abnormal amyloid and tau deposition may affect the structure and functioning of brain networks mediating sleep (Ju et al., 2014; Holth et al., 2017) and impair the production and release of melatonin (Ju et al., 2014); and sleep disturbances may perpetuate the neurodegenerative cascade (Wu and Swaab, 2007). However, treatment of sleep disorders in the field of dementia remain challenging: hypnotic medications are commonly used, but evidence for efficacy is lacking and limited by side effects (Forlenza et al., 2017). Melatonin and nonpharmacological interventions like light therapy have not yet demonstrated efficiency in clinical trials (Kinnunen et al., 2017). Nursing homes pose a particular challenge for sleep: limited daytime sunlight exposure, night-time noise, nursing practices, and low physical activity also contribute to sleep disruption.

This chapter provides the tools to identify and treat patients presenting with signs or symptoms associated with poor sleep.

Sleep and circadian rhythm disorders

The anatomy and neurochemistry of sleep and wakefulness

The control of sleep and wakefulness is a complex process that involves an interplay between various brain regions and neurotransmitter systems. Sleep is controlled by two distinct but overlapping neuronal circuits (Borbely, 1987; Borbely, 1982; Daan et al., 1984). The homeostat drives an increasing pressure to sleep after every hour awake and the circadian rhythm drives alertness in the day and sleep at night (Borbely & Achermann 1999; Borbely et al., 2016). Once a threshold in the pressure to sleep is achieved that is appropriate for the phase in the circadian rhythm, sleep ensues (Fig. 48.1).

Fig. 48.1

The two-process sleep model. Process S represents the homeostatic process to sleep, which increases with the duration of time spent awake. Process C represents the circadian rhythm. The two processes interact to determine the gating of sleep: the greater the difference between Process S and Process C, the higher the sleep pressure, which is typically when sleep ensues.

Adapted with permission from Borbély, A.A., et al. The two-process model of sleep regulation: a reappraisal. *Two-Process model*, 25(2): 131-143. Copyright © 2016 European Sleep Research Society. <https://doi.org/10.1111/jsr.12371>.

The neural circuits mediating sleep remain far from being completely understood but can be grouped into four systems: the wakefulness-promoting system, the non-REM sleep promoting system, the REM sleep promoting system, and the hypocretin/orexin system which maintains wakefulness and suppresses REM sleep. These systems interact with the circadian pacemaker located within the suprachiasmatic nucleus (SCN) and a sleep homeostatic system. Readers are referred to these excellent reviews written on this subject (Scammell et al., 2017; Saper and Fuller, 2017; Weber and Dan, 2016).

Circadian rhythm generator

The internal circadian clock is highly conserved throughout evolution and modulates all cellular processes, physiology, and behaviour, including the sleep-wake cycle (Bell-Pedersen et al., 2005). The SCN is the site of the internal clock and coordinates and regulates a network of cellular clocks

Sleep and circadian rhythm disorders

throughout the body (Mohawk et al., 2012). The SCN itself keeps time via a group of 'clock genes', which also serve as transcription factors for other genes, thereby influencing physiological processes (Duffield, 2003; Wilking et al., 2013).

The most powerful timekeeper or 'zeitgeber' to regulate the SCN is light intensity which is detected via the intrinsically photosensitive retinal ganglion cell (ipRGC) containing the photopigment melanopsin. These cells have direct projections to the SCN and the intergeniculate leaflet via the retinohypothalamic tract and optic tract respectively. The SCN then makes further connections to the ventrolateral preoptic nucleus (VLPO) and the pineal gland.

In humans, blue light is particularly effective at activating the melanopsin photopigment and thereby suppressing melatonin production. Photo-entrainment of the circadian rhythms thus occurs: with sunlight exposure suppressing melatonin release and darkness promoting melatonin release. Other than light, other physiological signals also act as 'zeitgebers' or timekeepers including physical activity, temperature, and body position.

Wakefulness-promoting systems

The wakefulness-promoting system includes the cholinergic cell groups located at the basal forebrain, parabrachial nucleus, pedunculo pontine and laterodorsal tegmental nuclei, and the monoaminergic regions (locus coeruleus, dorsal and median raphe, ventral tegmental area, and tuberomammillary nucleus), which produce noradrenaline, serotonin, dopamine, and histamine, respectively. These are collectively termed as the ascending reticular system and project to the thalamus and throughout the cortex to cause wakefulness.

NREM sleep-promoting systems

The NREM sleep-promoting systems include the GABAergic and galanin secreting cell groups (ventrolateral preoptic area, median preoptic nucleus, basal forebrain, parabrachial nucleus), which inhibit the wake-promoting neurons in the caudal hypothalamus and the brainstem, and project widely to the cortex to promote sleep.

REM sleep-promoting systems

The pons is the site of REM sleep generation. The cholinergic pedunculo pontine and laterodorsal tegmental nuclei (collectively known as REM-on nuclei) project to the REM-off nuclei in the brainstem. Glutamatergic neurons located in the sublaterodorsal nucleus produce muscle atonia by exciting GABAergic/glycinergic neurons in the ventromedial medulla and spinal cord that in turn hyperpolarize motor neurons.

Sleep and circadian rhythm disorders

The hypocretin/orexin system

Hypocretin 1 and 2, which are also known as orexin A and B, are neuropeptides secreted from the lateral hypothalamus. In the 'flip-flop switch model', hypocretin has been proposed to act to by stabilizing sleep-wake transitions (Saper et al., 2001, 2005).

Influence of psychotropic medications on sleep and sleep disorders

The major neurotransmitter systems, involved in the maintenance and wakefulness and sleep and the medications exerting therapeutic and side effects on these systems are as summarized in Table 48.1.

Sleep and circadian rhythm disorders

Table 48.1 Major neurotransmitter systems involved in the maintenance of wakefulness and sleep, and drugs exerting therapeutic and side effects on these systems.

Major nuclei	Histamine TMN	Serotonin Raphe nucleus	NA Locus coeruleus	Dopamine Mesencepha lon, substantia nigra pars compacta	ACh LDT-PPT, nucleus Meynert	Glutamate Reticular formation	GABA VLPO	Melatonin Pineal gland
Function	Arousal system (via hypothalamus forebrain)				Thalamocorti cal arousal system		Sleep induction	Circadian rhythms
Wakefulness	+++	+++	+++	+++	+++	+++	0	0
Slow wave sleep	+	+	+		+	+	+++	+++
REM sleep	0	0	0		+++	0	+++	+++
Agonist drugs	Low-dose doxepin	SSRI, SNRI e.g. venlafaxine		Amphetamine , L-dopa, dopamine agonists, methylphenid ate	ChEI		Benzodiazepi ne, Z- hypnotics (nonbenzodia zepines), ethanol	Melatonin ramelteon agomelatine

Sleep and circadian rhythm disorders

Antagonist drugs	Antihistamines Pitolisant (inverse agonist)		Prazosin	Neuroleptics	Scopolamine, atropine, TCA	Ketamine, memantine	Flumazenil	

ACh, Acetylcholine; 5-HT, 5-hydroxytryptamine; GABA, gamma-aminobutyric acid; NA, noradrenaline; TMN, tuberomammillary nuclei; LDT-PPT, laterodorsal tegmental and pedunculopontine tegmental nuclei; VLPO, ventrolateral preoptic area; SSRI, selective serotonin reuptake inhibitors; ChEI, cholinesterase inhibitors; REM, rapid eye movement sleep; SNRI, Serotonin-norepinephrine reuptake inhibitor; TCA, tricyclic antidepressants.

+++ , high activity; ++ , intermediate activity; + , low activity; 0 , no activity.

Sleep and circadian rhythm disorders

Psychotropic medications with their broad range of effects on various CNS neurotransmitters can commonly cause either insomnia or daytime sedation as common side effects (Doghramji and Jangro, 2016).

Antidepressants modulate various monoamine transmitters and also interact with histamine and muscarinic cholinergic receptors. Depending on their specific pharmacological profile, antidepressants have differential effects on sleep. Selective serotonin reuptake inhibitors (SSRIs), serotonin-noradrenaline reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs) and the activating tricyclic antidepressants all tend to cause deterioration in sleep quality. SSRIs commonly cause treatment-related insomnia at initiation. (Thompson, 2002) The sedating antidepressants, trazodone and mirtazapine, decrease sleep latency and increase slow-wave sleep due to their antagonistic action on the 5HT₂ receptors; with mirtazapine having additional H₁ receptor antagonism. The tertiary amine tricyclic antidepressants (e.g. amitriptyline) tend to cause sedation, whereas the secondary amine tricyclic antidepressants (nortriptyline) tend to be more activating. Doxepin is a highly selective H₁ antagonist with effective sedation with fewer side effects compared to other tricyclic antidepressants and it has been approved by the FDA for the treatment of insomnia.

Wakefulness and the sleep stages

The different stages of sleep and wakefulness are defined by specific electroencephalogram (EEG), electro-oculogram (EOG) and electromyogram (EMG) features on polysomnography, such that we are either awake or alternate between non-rapid eye movement (NREM) or rapid eye movement sleep (REM) at approximately 90–120-minute cycles (Fig. 48.2). NREM sleep is further subdivided into light NREM sleep (N1 and N2) and deep NREM sleep (N3) which is also termed as slow-wave sleep. Sleep stages are scored according to standardized criteria (Berry et al., 2015).

Sleep and circadian rhythm disorders

Fig. 48.2

The sleep hypnogram. The sleep hypnogram in a young adult: sleep stages over a typical night as determined by polysomnography. During adult life, at night we cycle between non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep approximately every 90–120 minutes. REM sleep typically occurs > 90 minutes into the night and NREM sleep is divided into three stages; N1, N2, and N3. N3 is often known as slow wave sleep (SWS). The normal young adult will wake two to four times during the night although may not be aware of this. Most adults will have four to five cycles of REM sleep, although dream recall is highly variable and few patients recall four to five distinct cycles of dreaming. Age-related physiological changes in the sleep architecture that are typically observed in older compared to younger adults include: delayed time to sleep onset, fragmented sleep with frequent awakenings, and early morning awakenings with decreased time spent in the deeper stages of sleep.

During wakefulness, the EEG typically shows low-amplitude and high-frequency activity predominantly in the alpha range (7–14Hz) with a variable amount of muscle activity detected on EMG.

NREM sleep is characterized by slower EEG frequencies in the delta (0–4Hz) and theta (4–7Hz) ranges with decreases in muscle tone. N1 sleep is a brief transition state characterized by drowsiness and slow rolling eye movements. N2 sleep is characterized by the presence of sleep spindles and K complexes. N3 sleep is dominated by high-amplitude delta activity.

REM sleep is associated with most of our emotional dream content and has EEG appearances similar to that of the awake state with additional theta activity. Complete paralysis of postural muscle activity occurs. During REM sleep, rapid bursts of fast saccadic eye movements occur.

Sleep stages normally transition from N1, N2, to N3 sleep, followed by a period of REM sleep before cycling back to NREM sleep 4–6 times during a night. Through the course of the night, REM sleep episodes become longer.

Sleep and circadian rhythm disorders

Numerous physiological changes in sleep occur as part of normal ageing. Total sleep time decreases: younger people average 8.9 hours of sleep which decreases to an average of 7.4 hours in older people (Klerman and Dijk, 2008). Sleep architecture is altered with an increased proportion of time spent in the lighter stages of sleep. There is also increasing sleep fragmentation and increased time to fall asleep in healthy older adults with and without sleep complaints (Gooneratne and Vitiello, 2014), with a tendency to phase advance by 30 minutes earlier a decade from the third decade onwards (Skeldon et al., 2016). Daytime napping, night-time arousals, and recalled awakenings become more common. Ageing is associated with an increase in apnoea-hypopnoea index (AHI) and decreases in oxygen saturation (Moraes et al., 2014). However, it is important to recognize that, although normal ageing results in changes in sleep, this should be distinguished from sleep complaints, which are indicative of an underlying sleep disorder.

Current classification of sleep disorders

Sleep disorders are classified into one or more of four categories: hypersomnia, insomnia, circadian rhythm disorder, and parasomnia. Common evening and night time disorders also include restless legs syndrome (RLS) and associated periodic limb movements of sleep (PLMS).

The most recent International Classification of Sleep Disorder, 3rd Edition (ICSD-3) was revised in 2014 and has been used for the diagnostic criteria discussed here (Medicine, 2014). DSM-5 diagnostic classifications have been listed where relevant.

How to assess a patient for a sleep problem—taking a sleep history

Given the value placed on the history taking within psychiatry, a sleep history should be routine. Many sleep disorders can be accurately diagnosed by history alone.

Simple screening questions will often help to identify the type of sleep problem with which you are dealing (see Box 48.1 for a suggested proforma). Thereafter, specific sleep problems are best characterized by a more thorough history if needed. A collateral history from the bed partner is very helpful to determine the presence of snoring or breathing abnormalities, the characteristic pattern of periodic limb movements of sleep, sleepwalking, or other parasomnia. It is important to ask about the duration and course of symptoms.

Box 48.1 Recommended questions for a sleep history

Sleep and circadian rhythm disorders

1. Do you snore heavily? Has anyone witnessed prolonged pauses in breathing (apnoeas)?

For typical obstructive sleep apnoea the snoring is very loud, often heard outside the bedroom door, sometimes by neighbours, the pauses are typically 20–30 seconds rather than brief <5–10 seconds, a snort or a start at the end of apnoea is characteristic.

2. Do you have unpleasant tingling or discomfort in the legs, which makes you need to kick or to move? Is it worse in the evenings, is it helped by moving? (restless in the body rather than a racing mind)

Everybody needs to be asked specifically about restless legs as people can find it hard to describe the dysaesthesia 'wriggly, itchy, worms under the skin'. Bed partners can be asked about the infuriatingly regular kicks that may wake them but not the patient—every 20–30 seconds is typical.

3. What drugs do you take and when do you take them?

Including the dose and timing of caffeine/alcohol and nicotine. Consider over the counter medication that might affect sleep.

Short-acting painkillers, sedative opiates, adrenergic drugs that exacerbate insomnia such as inhalers or some nasal sprays, counting the cups of coffee or tea, are all important.

4. Take me through your typical 24 hours—describing the sleep/wake pattern over a day.

Particularly helpful for those with sleep restriction, circadian rhythm disorder, and insomnia.

5. Do you nap during the day—if so, when, and for how long?

Can you get through the day without sleeping and examples of when they might sleep can help to distinguish fatigue from true hypersomnia, few of us would sleep in the middle of a conversation or with food in our mouths.

6. Do you have any history of nightmares, acting out of dreams, sleepwalking out of the bedroom? If so, at what time of night do things tend to happen?

Typically, the first cycle of REM sleep starts 90 minutes into the night, so REM parasomnias are more likely in the second half of the night. NREM parasomnias can occur within the first hour of sleep.

Comorbid medical or psychiatric disorders and the occurrence of chronic pain should be noted, and their relationship with the onset of the sleep problem should be explored. A list of prescribed and over-the-counter medications, as well as the timing of medications should be obtained.

Sleep and circadian rhythm disorders

Patients may develop sleep-related side effects as a result of not taking medications at the prescribed timings. In the elderly with unexplained sleepiness, special attention should be paid to nocturia as it could be the only clue to previously undiagnosed obstructive sleep apnoea.

Discussing the patient's expectations of normal sleep is a fundamental part of treatment in insomnia disorder. For those with significant daytime sleepiness, driving safety should be discussed. The American Academy of Sleep Medicine (AASM) recommend asking 'have you had crashes, near misses or claims on insurance in the last year?'; people who are aware of nodding off at the wheel or have modified driving behaviour have been shown to be at higher risk of accidents (Ghosh et al., 2012).

To further assess a patient's sleep, one of the simplest and cost-effective diagnostic test is a sleep diary kept for at least two weeks. Fig. **48.3** shows two examples of sleep diaries.

Sleep and circadian rhythm disorders

Fig. 48.3

Sleep and circadian rhythm disorders

Sleep diaries. The patient should be instructed to complete the diary once a day, typically in the morning and think about their best estimate of the night. Lights out, lights on, and night-time awakenings should be noted. Any daytime naps should be noted and their estimate of total sleep time in hours. Daytime activities such as meals, exercise, caffeine intake, and alcohol consumption can be noted in some diaries. Ideally the diary should be completed for two weeks. Diary 1. Insomnia disorder where time in bed is far longer than time perceived asleep, both difficulty initiating and maintaining sleep is seen without day time naps. The variability among nights is seen with occasional good nights of prolonged sleep. Diary 2. Delayed sleep phase syndrome in a 23-year-old male who had this sleep pattern since the age of 15. Despite getting into bed early, the pattern is of falling asleep typically between 2.30am and 4am but waking well after 11am with few night awakenings. The estimated total sleep time is far greater than for the patient with insomnia.

There has been a dramatic increase in the use of commercial accelerometers as lifestyle gadgets. As of 2016, more than 80 sleep-tracking apps and sensors were available on the market of which only a small number have since been approved by the US Food and Drug Administration (FDA) or recommended by the NHS Apps Library (Shelgikar et al., 2016). Overall, these devices lack standardization and generally underestimate waking and overestimate sleep efficiency compared to conventional polysomnography (Shelgikar et al., 2016). Paradoxically, the frequent checking of such devices can exacerbate insomnia. However, voice recorder or smart phone video data which can capture sleeptalking, parasomnia, or snoring can be helpful.

Screening questionnaires—which scales to use?

The Epworth Sleepiness Scale (ESS) is a widely used validated questionnaire to assess daytime sleepiness as self-rated over the prior month (Johns, 1991). Patients are asked to estimate their chances of actually dozing or napping in a series of listed situations. Advantages of the score include speed and simplicity for the patient. Critics point out that it correlates poorly with more objective measures of sleep in the laboratory (Fong et al., 2005) and does not predict driving safety. The normal range within the original study was 4–9, and many people with typical insomnia score 0 or 1, while a score of over 10 is taken as daytime sleepiness. One advantage of the score is to then assess any subsequent intervention for sleepiness.

Another widely used screening tool is the Pittsburgh Sleep Quality Inventory (Buysse et al., 1989). Seven questions ask about time in bed, time taken to fall asleep, and satisfaction with sleep. The scoring system gives a single score with above 5 indicating some form of sleep disturbance and people scoring above 10 having more severe sleep disturbance.

Sleep and circadian rhythm disorders

The Insomnia Severity Index is quick and easy to complete, and it is more often used to assess both severity and improvement after therapy with scores ranging from 0–24 (Bastien et al., 2001).

Insomnia disorder

Insomnia disorder is defined as difficulty falling asleep, difficulty staying asleep, and subsequent daytime distress and impaired functioning.

Earlier diagnostic criteria for insomnia emphasized a distinction between ‘primary’ and ‘secondary’ insomnia. With the increasing recognition that medical and psychiatric disorders are often comorbid (Ohayon, 2002; Riemann, 2007), the most recently revised ICD-10 and DSM-5 diagnostic criteria for insomnia have now merged these previously distinct diagnostic entities into the single entity of Insomnia Disorder.

Numerous epidemiological studies have shown an association between reduced sleep duration with adverse medical and psychiatric outcomes: including a greater risk of cardiovascular disease (Gami et al., 2013; Sabanayagam and Shankar, 2010; Ayas et al., 2003) and increased risk of the subsequent development of depression (Baglioni et al., 2011; Ellis et al., 2014).

Insomnia remains the commonest sleep disorder in primary care, with at least 10% of the population affected (Morin et al., 2006). Increasing age is a risk factor for insomnia due to both accumulating comorbidities as well as age-related physiological changes in sleep.

Assessment

The diagnosis is typically made on the basis of the history, alongside sleep diaries. It is important to exclude common mimics. Typically, ESSs are low, in the range of 0–2. High ESSs should prompt screening for other secondary causes of insomnia. In older patients, at least 10% will have RLS and 20% will have obstructive sleep apnoea (OSA).

Polysomnography is generally unhelpful unless a secondary cause of insomnia is suspected such as OSA. It is surprisingly difficult to distinguish between isolated insomnia disorder and insomnia disorder with comorbid OSA (Lichstein et al., 2013). Another common mimic is circadian rhythm disorder, where patients perceive difficulty initiating sleep with delayed sleep phase, but in fact then stay asleep well.

The cornerstone of both diagnosis and therapy is recording of sleep diaries, where a typical pattern of far more time in bed awake than asleep is usually seen. The sleep efficiency (total sleep time/time in bed) can be calculated. Normal sleep typically has a sleep efficiency of over 85%, whereas patients with severe insomnia often have sleep efficiency less than 50%. Fatigue rather than daytime sleepiness is usually described. A hypervigilant phenotype is typical with a description of a ‘racing mind’ that finds it hard to switch off. A common model of causation includes:

Sleep and circadian rhythm disorders

predisposing factors; a precipitating trigger; and subsequent perpetuating or maladaptive behaviours that worsen rather than improve sleep and disrupt both the normal homeostatic and circadian drivers to sleep (Spielman et al., 1987).

The history should include questions about the typical 24-hour pattern but also about the environment and bedroom itself. Review of the prescription list for all potentially stimulant medications is required, and an assessment of mood is also needed. It is common to hear the patient catastrophize about the impact of poor sleep upon work and driving, but there is often a mismatch between perceived performance and more objective assessments. The prior and current use of sleeping tablets needs to be documented as these in themselves can be contributing to some of the daytime fatigue.

Treatment of insomnia

Although newer pharmacological therapies with more specific mechanisms of action have been developed, the recently published guidelines by the European Sleep Research Society (ESRS), American College of Physicians, and AASM have again emphasized the role of cognitive behaviour therapy for insomnia (CBTi) as the first line treatment for insomnia where available, with pharmacological therapies considered only as second line treatments (Riemann et al., 2017, Qaseem et al., 2016, Sateia et al., 2017). These guidelines are broadly aligned in their recommendations. Recommendations from the European guidelines for the pharmacological treatment of insomnia are presented in Box 48.2 (Riemann et al., 2017)

Cognitive behavioural therapy

CBTi has been shown to be an effective treatment for older patients as well as patients with other comorbidities. Obviously, the presence of significant cognitive impairment precludes the use of CBTi and pharmacological therapies are typically used instead. CBTi has been shown in randomized control trials to result in sustained benefits and was superior to benzodiazepine therapy when assessed 6–12 months after treatment discontinuation (Mitchell et al., 2012; Morin et al., 2009). The more widespread use of CBTi has been limited by the lack of local service provision. However, recent studies on internet-based CBTi have been promising, showing similar efficacy to traditional forms of CBTi (Zachariae et al., 2016; Seyffert et al., 2016).

CBTi is a set of techniques that strengthen the bed–sleep association, realign the homeostatic mechanisms and circadian rhythm, and decrease anxiety and rumination about sleep. Sleep hygiene measures represent only part of the techniques used in CBTi, and their use in isolation is ineffective for the treatment of insomnia (Morgenthaler et al., 2006). CBTi would typically include: sleep hygiene, sleep restriction, stimulus control, cognitive therapy and relaxation therapy. Exercise was not

Sleep and circadian rhythm disorders

emphasized in the original CBTi regimes, although recent research has highlighted its positive impact on sleep (Chennaoui et al., 2015).

Sleep restriction is the cornerstone of treatment in CBTi. Using a sleep diary, the average sleep duration is obtained, which is then used to restrict the time that the patient can spend in bed in order to achieve a high sleep efficiency. Patients are instructed to maintain strict schedules to wake up at the same time throughout the week. The time permitted in bed is then progressively increased.

Pharmacological treatments

Pharmacological therapies are recommended as second line therapy for the treatment of Insomnia Disorder (Riemann et al., 2017; Qaseem et al., 2016). In the elderly population, the risk-benefit ratio should be carefully considered (Schroeck et al., 2016). Major drug classes used to treat insomnia include the benzodiazepines, non-benzodiazepine receptor agonists ('Z-drugs'), antidepressants, antipsychotics, antihistamines, and phytotherapeutics, as well as the newer drugs such as melatonin receptor agonists and orexin receptor antagonists. The evidence for the use of these medications for the treatment of insomnia has been reviewed by the ESRS and the AASM (Riemann et al., 2017; Sateia et al., 2017). Despite recent excitement over the availability of agents with more selective modes of action, the evidence of long-term benefit for these therapies remains weak. There is a marked disparity between the number of medications obtaining FDA approval and those recommended for use by the AASM (Sateia et al., 2017).

Sleep and circadian rhythm disorders

Box 48.2 Pharmacological therapies recommended for the treatment of insomnia

Recommended drug classes for the short-term (≤ 4 weeks) treatment of insomnia when CBT-I is not effective or not available:

- Benzodiazepines
- Non-benzodiazepine receptor agonists
- Sedating antidepressants

Drug classes NOT recommended for the treatment of insomnia:

- Antihistamines
- Antipsychotics
- Melatonin
- Phytotherapy
- Valerian
- Other complementary therapies

Source: data from Riemann, D., Baglioni, C., Bassetti, C. et al. 2017. European guideline for the diagnosis and treatment of insomnia. *Journal of Sleep Research*, 26(6): 675–700.

At present, hypnotics are approved for only for short-term (two to four weeks) treatment of insomnia. Benzodiazepine use is still common in the elderly population (Olfson et al., 2015). Use of benzodiazepines in the older population is associated with confusion, psychomotor impairment, falls, and daytime fatigue (Glass et al., 2005). Although improvements in sleep quality, total sleeping time, and reduced arousal are observed, the overall risks often outweigh the benefits (Glass et al., 2005). A meta-analysis of 45 randomized clinical trials showed that benzodiazepine use reduced sleep onset latency by just over four minutes (Holbrook et al., 2000). Furthermore, the placebo effect of medications in insomnia trials cannot be ignored (Winkler and Rief, 2015). There is a widely held perception among physicians that intermittent prescription of hypnotics reduces side effects but this view is not supported by any randomized controlled trials.

Benzodiazepines act via binding to the gamma-aminobutyric acid (GABA) receptors. The choice of benzodiazepine depends on their different pharmacokinetics: drugs with a short half-life are used to treat sleep onset insomnia, and drugs with a longer half-life are used to treat sleep maintenance insomnia (Schroek et al., 2016).

Sleep and circadian rhythm disorders

The non-benzodiazepine receptor agonists ('Z-drugs') were developed with the aim of avoiding the side effects of benzodiazepines and act by binding more selectively to the GABA(A) receptor alpha 1 subunits. Although they have a better safety profile, observational studies have shown that they are associated with adverse cognitive outcomes, sleep walking, fractures, and serious injury (Schroek et al., 2016).

Sedating antidepressants have weak evidence for benefit, with tolerance developing quickly: low-dose doxepin is recommended only for sleep maintenance and trazodone is not recommended by the American Guidelines (Sateia et al., 2017). However, trazodone, which lacks anticholinergic activity and has a more favourable side effect profile compared to benzodiazepines, has been useful in community-dwelling patients with AD (Camargos et al., 2014). Doxepin is used more commonly as an anti-insomnia drug in the US. At low doses, doxepin has high affinity for the histamine H1 receptors with few side effects, so it could be useful in older people (Krystal et al., 2010). However, clinical effects are mainly on sleep maintenance and not sleep initiation (Yeung et al., 2015).

Antihistamines and antipsychotics are not recommended for the treatment of insomnia (Riemann et al., 2017; Sateia et al., 2017).

Melatonin acts on the melatonin receptors, which are highly expressed in the suprachiasmatic nucleus. Newer drugs acting on this pathway include ramelteon (Kato et al., 2005), a MT1/MT2 melatonin receptor agonist, and agomelatine. Melatonin and ramelteon have been shown to reduce sleep onset latency. However, their overall benefits are modest and the evidence for their use in insomnia is limited (Riemann et al., 2017). In the American Guidelines, ramelteon has a short half-life and is recommended for sleep onset insomnia but there is no convincing role for melatonin (Sateia et al., 2017).

Suvorexant, a reversible antagonist at the orexin receptors A and B, has been recently licensed for use in the US. Benefits so far have been modest, with a meta-analysis showing that it resulted in a modest decrease in sleep latency by 6.4 minutes (Kuriyama and Tabata, 2017). It has only been recommended for the treatment of sleep maintenance insomnia in the American Guidelines (Sateia et al., 2017).

Sleep-related breathing disorders

The sleep-disordered breathing (SDB) disorders include OSA, central sleep apnoea (CSA), sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder.

A diagnosis of SDB is made when more than five apnoeas or hypopnoeas are present per hour of sleep (AHI >5 events/hour). The diagnosis of OSA and CSA is then made depending whether the majority of events are classified as obstructive or central.

Sleep and circadian rhythm disorders

Obstructive sleep apnoea

OSA is by far the most common cause of significant daytime sleepiness in individuals over the age of 50. Unfortunately, the disorder is often overlooked despite having an excellent therapy with continuous positive airways pressure (CPAP) (McDaid et al., 2009).

Untreated OSA is associated with significant morbidity and mortality. Severe OSA is associated with hypertension, atherosclerosis, atrial fibrillation, and an increased risk of stroke (Lavie et al., 2000; Zhou et al., 2017; Wang et al., 2013; Zhang et al., 2015). Epidemiological studies suggest that the presence of SDB is associated with an increased risk of developing subsequent cognitive impairment (Leng et al., 2017), and could potentially be a modifiable risk factor for dementia (Liguori et al., 2017).

The biggest risk factors are male sex and increasing age. At particular risk are those over the age of 50 with obesity and increased neck circumference (>17 inches). In the Wisconsin Sleep Study Cohort, mild OSA (AHI >5) was present in 43% of men and 28% of women aged 50–70 years of age, with moderate to severe OSA in 17% of men and 9% of women. (Peppard et al., 2013). In institutionalized patients with dementia, the reported prevalence of OSA is extremely high, with 70% meeting the diagnostic criteria for mild OSA, and almost half the cohort having severe OSA with an AHI ≥ 20 (Ancoli-Israel et al., 1991).

Psychiatry patients have particular risk factors for sleep apnoea with reported higher rates of 20–50% (Benca et al., 1992; Anderson et al., 2012). Variable ascertainment and selection bias make interpretation of such studies challenging but there is most evidence for increased rates in major depressive disorder and in those with elevated body mass index (BMI) (Gupta and Simpson, 2015).

Assessment

History from the bed partner is helpful. Spouses are often aware of loud snoring and pauses in breathing. It is rare for the patient themselves to be aware of the apnoeas or to have a perception of choking. Although snoring is common in OSA, snoring in itself is not specific for the diagnosis.

The typical OSA history includes progressively troublesome sleepiness and awaking unrefreshed. Mild morning headache is common. Clues for those who live alone include a dry, sore throat in the morning, nocturia, awaking unrefreshed, vivid dreams, and night-time sweating alongside daytime sleepiness.

The clinical presentation of OSA in the older patient can be atypical. It is important to recognize that at least 20% of patients with OSA are not overweight. Compared to younger patients with similar disease severity, older patients with SDB tend to have a lower BMI and neck

Sleep and circadian rhythm disorders

circumference (Chung et al., 2009). Although excessive daytime sleepiness (EDS) is frequently reported, a significant proportion of patients with OSA do not have EDS. There is an age-related reduction between SDB and the symptoms of sleepiness, with older patients reporting a lesser severity of sleepiness compared to younger patients with similar disease severity (Morrell et al., 2012). Neuropsychiatric symptoms, including cognitive impairment and affective disorders, can be a presenting feature of OSA. On polysomnography, age-related increases in AHI and decreases in oxygen saturation occur. For example, in one study in a large population-based sample, average AHI in individuals aged 55–59 ranged from 11.1 ± 14.2 ; increasing to 21.9 ± 20.5 in individuals aged 75–80 (Moraes et al., 2014). Mild SDB is common in the older people, and it remains unclear whether elderly patients without significant symptoms require treatment.

Nocturia is a common geriatric syndrome traditionally regarded as a symptom of lower urinary tract disorders, but the diverse aetiology including that of sleep disorders is now recognized (Dani et al., 2016). In elderly patients with unexplained sleepiness and no other medical comorbidities to cause nocturia, attention should be paid to nocturia itself, which may sometimes be the only clinical clue to previously undiagnosed OSA.

It is also worth mentioning chronic fatigue syndrome, which is a diagnosis of exclusion. Sleep disorders must be excluded prior to the diagnosis and OSA is a common mimic (Gotts et al., 2013, Mariman et al., 2013).

The STOPBang is a particularly helpful short screening tool for those at high risk of OSA (Chung et al., 2008). Higher scores in the range of 5–8 have a high sensitivity of over 90% for moderate OSA, and low scores in the range of less than 3 have a high negative predictive value for OSA. The ESS is also helpful as a measure of baseline functional impairment and to assess treatment response.

People with suspected OSA should be referred for further investigations and typically within the UK this would involve a domiciliary sleep study, which measures a limited number of parameters, including airflow, nasal pressure, respiratory effort, ECG, and oxygen saturation, rather than in-patient polysomnography. An AHI score of over 5 is regarded as abnormal, but if it is greater than 15 (moderate) or 30 (severe) then symptomatic sleepiness is far more likely to occur.

Treatment

CPAP is first line therapy for the treatment of OSA. Other lifestyle changes that should be instituted include weight loss, avoidance of alcohol and other sedatives, and adopting non-supine sleep positions. Weight loss on its own can result in improvements of OSA severity; however, improvement to normal levels of AHI (<5) only occurs in a minority of patients.

Sleep and circadian rhythm disorders

CPAP acts as a pneumatic splint to keep the oropharynx open. CPAP therapy significantly improves quality of life, daytime sleepiness, mood, and cognitive impairment. Improving sleep probably has an impact upon affective disorders, although further large RCTs are needed to demonstrate this robustly (Wells et al., 2007).

In older patients with OSA, CPAP results in beneficial effects on cardiovascular mortality, stroke incidence, and stroke mortality (McMillan and Morrell, 2016). CPAP adherence is not affected by advancing age. Even in patients with AD, adherence to CPAP treatment can be achieved (Ayalon et al., 2006) and treatment may slow down cognitive decline in AD (Troussiere et al., 2014).

Alternative treatments to CPAP include (Lorenzi-Filho et al., 2017): oral appliances that advance the mandible, upper airway stimulation of the hypoglossal nerve, nasal expiratory positive airway pressure (EPAP), the Winx device (a mouthpiece sited within the oral cavity and connected to an external console to generate a negative pressure), and oropharyngeal exercises. These alternative therapies are less effective, but may be useful in patients who cannot tolerate CPAP.

Symptomatic OSA is notifiable to the driving licence authorities but patients typically can restart driving when compliant with treatment.

Central sleep apnoea

CSA refers to repeated pauses in both respiratory effort and airflow during sleep. This can result either from ventilatory instability or depression of brainstem respiratory centres or chemoreceptors.

In older people, CSA is encountered in the presence of heart failure, prior stroke, neurodegeneration, and use of sedative medications, in particular opiates and hypnotics. Chronic opioid use places individuals at a greater risk of developing CSA, and to a lesser extent, OSA (Filiatrault et al., 2016). Relevant studies have suggested that the prevalence of sleep disordered breathing could be as high as 70–85% in patients taking opioids (Mogri et al., 2008; Correa et al., 2015).

People taking over 200mg of morphine or an equivalent dose are at the greatest risk, in particular if this is in combination with benzodiazepines. While people with chronic pain typically complain of bad sleep, this is mostly attributed to the pain itself, rather than considering apnoeas secondary to opioid use as a possible cause.

Assessment

Unlike patients with OSA, many with CSA do not complain of EDS. To diagnose CSA, a respiratory sleep study or polysomnography is necessary to demonstrate the lack of ventilatory effort that characterizes this disorder.

Sleep and circadian rhythm disorders

Treatment

There are currently no evidence-based treatments for the management of CSA in patients with heart failure (Khayat and Abraham, 2016). Recent interest in the potential role of adaptive servo-ventilation (ASV) has declined with the publication of a large randomized control trial that showed that treatment resulted in increased cardiovascular mortality (Cowie et al., 2016). There is some limited evidence for benefit in opioid-induced CSA but cessation of medication is clearly the best option if possible (Van Ryswyk and Antic, 2016).

Circadian rhythm disorders

There are six distinct circadian rhythm disorders currently defined by ICSD-3. The circadian rhythm disorders are caused by misalignment of the period of sleep and they are characterized by a relatively normal length of sleep time and quality of sleep but occurring out of step with societal norms.

These disorders include:

- Advance sleep-wake phase syndrome
- Delayed sleep-wake phase syndrome
- Irregular sleep-wake rhythm disorder
- Shift work disorder
- Jet lag circadian rhythm disorder
- Non-24 sleep-wake syndrome

There is an increasing recognition of the relatively high frequency of circadian rhythm disorders occurring in psychiatric patients (Abbott et al., 2015), with a delayed sleep-wake phase syndrome and non-24-hour sleep-wake syndrome in particular being associated with psychiatric comorbidity (Reid et al., 2012). Of the circadian rhythm disorders, the advanced sleep-wake phase syndrome and irregular sleep-wake syndrome are most commonly encountered by old age psychiatrists.

Assessment

The diagnosis of the various circadian rhythm disorders relies principally on the clinical history where the bedtime, falling asleep, and wake times are determined. In advanced neurodegenerative disease, a caregiver history is often helpful.

Actigraphy and sleep diaries are helpful for confirming the diagnosis and determining the optimal timing of melatonin treatment if required.

Advanced sleep-wake phase syndrome

The circadian rhythm tends to advance with increasing age, with the advanced sleep-wake phase syndrome being probably the most common

Sleep and circadian rhythm disorders

circadian rhythm disorder in older adults (Martin et al., 2006). Although psychiatric comorbidity is less common in advanced sleep-wake phase syndrome than in the delayed sleep-wake phase syndrome, a careful history should allow the early morning awakenings of advanced sleep-wake phase syndrome to be distinguished from early morning awakenings typical of major depressive disorders.

Patients typically fall asleep from 6 to 9pm, with a normal duration of six to eight hours of sleep before awakening in the early morning between 2 and 5am.

Treatment

The AASM 2015 clinical practice guidelines recommends treatment with bright light therapy in the evenings for the treatment of advanced sleep-wake phase syndrome (Auger et al., 2015).

Delayed sleep-wake phase syndrome

It is rare for the isolated delayed sleep-wake phase syndrome to present late in life, hence restless legs, depression, or chronic insomnia should be excluded. The disorder typically presents in teenage years with patients who fall asleep and wake far later than the societal norm, causing associated daytime dysfunction. The diagnosis can be made on the history alone, alongside well completed sleep diaries (Fig. 48.3, see Diary 2). For many the key question is 'if you were allowed to sleep when you wanted, would you sleep well?' The quality of sleep is typically good but patients tend to fall asleep between 3 and 4 am and then struggle to wake in the morning. Those woken early may have daytime sleepiness.

Treatment

In older patients where there is no societal pressure to wake at fixed times for work, treatment may not be required.

The AASM 2015 clinical practice guidelines recommend precisely timed melatonin in adult patients with delayed sleep-wake phase syndrome (Auger et al., 2015). Melatonin in conjunction with bright light therapy delivered one hour prior to the habitual waking time may be more effective than either therapy alone (Burke et al., 2013). Chronotherapy, whereby the sleeping time is advanced further until the desired sleeping time is achieved, may be helpful in highly motivated patients.

Irregular sleep-wake rhythm disorder

Irregular sleep-wake rhythm disorder is characterized by the loss of a distinctive sleep-wake pattern and is commonly encountered in schizophrenia, neurodegenerative disorders and institutionalized patients. Caregivers typically report frequent daytime napping, and patients may complain of either night-time insomnia or EDS. Sleep and

Sleep and circadian rhythm disorders

wake episodes are fragmented across the 24-hour cycle. However, the total sleep time may be normal for age.

Treatment

Clinical practice guidelines from the AASM recommend the use of light therapy in elderly patients with dementia with irregular sleep wake rhythm disorder (Auger et al., 2015). In institutional settings, 'mixed modality treatment', which consists of various interventions including: keeping individuals out of the bed during the daytime, light daytime physical activity, morning bright light exposure, a structured bedtime routine, and minimization of night time noise, has been shown to result in decreases in daytime sleep and improvements in night time sleep. Melatonin has not shown to be of benefit, and the use of other sleep-promoting agents is discouraged (Auger et al., 2015).

Excessive daytime sleepiness or hypersomnia

Hypersomnia affects up to 15% of the adult population with around 5% severely affected and describing functional impairment (Ohayon et al., 2002).

The differential diagnoses of EDS are wide. Potential causes of EDS include:

- Too little sleep (e.g. sleep restriction)
- Poor-quality sleep (e.g. sleep apnoea, restless legs, external triggers)
- Hypersomnia (e.g. medication, medical comorbidities, narcolepsy, idiopathic hypersomnia)
- Circadian rhythm disorder (e.g. shift work (>40), delayed sleep phase (teens and 20s))

As mentioned previously, obstructive sleep apnoea is a common diagnosis in older people, with a new diagnosis of narcolepsy and idiopathic hypersomnia being far less common. EDS might be attributable to previous head trauma: this is most commonly transient for the first three to six months after injury but, if it persists, other causes should be screened for (Gardani et al., 2015).

The cause of hypersomnolence tends to be multifactorial in older patients as a result of neurodegenerative disorders (Bhat and Chokroverty, 2017), comorbid medical and psychiatric disorders, sleep disturbances, and medication side effects.

In patients with psychiatric comorbidities, hypersomnolence is common, particularly in major depressive disorders, and it can be difficult to reliably differentiate hypersomnolence resulting from the underlying psychiatric disorder from the side effects of medications or hypersomnolence related to other causes. Barateau and colleagues (2017)

Sleep and circadian rhythm disorders

provide a helpful diagnostic and treatment algorithm in the evaluation of hypersomnia in this patient population.

Assessment

The diagnosis is based on a detailed sleep history and completion of sleep diaries, including information on the episodes of subjective sleepiness, number and duration of naps, and episodes of 'sleep attacks'. The ESS is helpful to determine the severity of sleepiness. Objective measures such as actigraphy can be useful in institutionalized individuals.

In older patients, a full polysomnography is recommended to exclude other sleep disorders and also to document an adequate duration of sleep prior to the performance of the Multiple Sleep Latency Test, which can identify sleep-onset rapid eye movements and short sleep latencies. The Maintenance of Wakefulness Test can be used to monitor treatment.

Treatment

Treatment of hypersomnia is focused on treatment of the underlying cause. Behavioural measures such as a structured schedule with fixed bed and wake times, regular exercise, restriction of daytime naps, and bright light exposure are helpful in improving sleep.

Although there are a number of different alerting agents such as modafinil, armodafinil, dexamphetamine, and methylphenidate available for the treatment of hypersomnia (Takenoshita and Nishino, 2017), concerns about cardiovascular risk, drug interactions, and abuse potential limit the use of these medications, particularly in older people.

Parasomnias: 'things that go bump in the night'

Described as 'undesirable physical and/or experiential phenomena accompanying sleep,' parasomnias can involve complex and occasionally prolonged motor acts, such as walking, eating, texting, and even driving a car. Parasomnias are broadly divided into those occurring in NREM sleep and those occurring in REM sleep.

Parasomnias are common in psychiatric disorders, with reported prevalences reaching almost 40% for nightmares, 20% for sleep paralysis, and 10% for sleep-related eating disorders and sleepwalking (Waters et al., 2017). REM sleep behaviour disorder (RBD) typically manifests in the older population and is the focus of this section.

REM sleep behaviour disorder (RBD)

In normal REM sleep, a powerful, descending, glutaminergic signal from the brainstem inhibits the spinal motor neurons, resulting in muscle atonia (Luppi et al., 2013). In RBD, a progressive degeneration of this inhibitory brainstem control results in the loss of normal REM atonia, resulting in dream enactment behaviour alongside vivid and often violent dream content. Behaviours commonly observed include shouting, kicking,

Sleep and circadian rhythm disorders

and punching. Events are typically violent, but a range of milder behaviours are also recognized (Rodriguez et al., 2017). RBD typically occurs in the second half of the night. Up to 70% of patients will cause injury to themselves or their bed partner.

The condition predominantly affects older men with a reported prevalence of at least 1% (Chiu et al., 2000, Kang et al., 2013). RBD was first described in 1986 in a small series of elderly men (Schenck et al., 1986). In fact, there were reports of selective brain stem lesions in cats causing oneiric or dreamlike behaviours in animal models as long ago as 1967 (Mouret et al., 1967).

RBD is traditionally classified into idiopathic or secondary forms. Secondary RBD can be caused by a neurodegenerative disorder, particularly the synucleinopathies; a structural lesion; antidepressants, in particular the SSRIs and SNRIs (Lee et al., 2016, McCarter et al., 2015); beta-blockers; and alcohol withdrawal. Discontinuation of the antidepressant may result in clinical and polysomnographic resolution of RBD. However, RBD has also been reported to persist and antidepressants may simply unmask individuals with a latent neurodegeneration.

There is increasing debate whether true idiopathic RBD exists with an increasing recognition of the strong association between RBD and the subsequent development of neurodegenerative disease, particularly the synucleinopathies, such as Parkinson's disease, dementia with Lewy bodies, and multiple system atrophy, with 91% developing one of these conditions over 14 years of follow up (Iranzo et al., 2013).

Assessment

The diagnosis of probable RBD can be made with a positive history of dream enactment or complex motor behaviours occurring from sleep. Patients are often unaware of these behaviours unless injury has occurred, so therefore a collateral history is essential. In RBD, it is typical to obtain a history of the behaviours beginning insidiously and infrequently as limb jerks and sleep talking before progressing to become nightly or near nightly violent events.

A number of validated screening questionnaires are available to help make a diagnosis of probable RBD. However, these questionnaires are unable to distinguish RBD from other NREM parasomnias, sleep apnoea, and nocturnal confusion. Occasionally, severe OSA can cause strikingly vivid dreams and agitated arousals termed as 'pseudo-RBD', hence a diagnostic polysomnography should be performed in patients who have other features to suggest OSA. To make a definite diagnosis of RBD, polysomnography is required to identify the excessive EMG activity that occurs in REM sleep (REM sleep without atonia, RSWA; see Fig. **48.4**).

Sleep and circadian rhythm disorders

Fig. 48.4

In-patient video polysomnography in a patient with REM sleep behaviour disorder. In this in-patient video polysomnography, eye movements in the two electro-oculogram traces (E1, E2) are displayed in the two top traces where large amplitude rapid eye movements characteristic of REM sleep are observed. Electroencephalography (EEG) traces are displayed in the next eight traces (O2, C3, C4, F3, F4, M1, M2, and O2), which show low-voltage desynchronized EEG activity that is observed in REM sleep. Chin movements are displayed in the bottom three chin EMG traces (ChinL, ChinR, and ChinA). In normal REM sleep, REM atonia occurs and the Chin EMG activity should be reduced. However, in this patient with REM sleep behaviour disorder (RBD), phasic bursts of increased muscle activity are seen during REM sleep. This is abnormal and reflects the loss of normal REM atonia in RBD.

Treatment

There is debate as to how and when patients with idiopathic RBD should be counselled on their future risk of developing a neurodegenerative disorder, but many patients are aware of associations with RBD so this is often part of the consultation.

Behavioural interventions to ensure a safe sleeping environment should be implemented to prevent injury to the patient or their bed partner. If comorbid OSA is present, treatment of OSA often improves RBD. Medications known to exacerbate RBD should be discontinued where possible.

There are no licensed therapies for RBD but clonazepam has been regarded as the first line treatment for RBD. It has no effect on RSWA but usually suppresses RBD behaviours in most patients. A lack of response should prompt the clinician to re-evaluate the diagnosis of RBD. The use of clonazepam is contraindicated in comorbid OSA. Common side effects, including sedation, falls, confusion, cognitive impairment, and respiratory depression, often limit dose escalation and so this drug should be used cautiously (Anderson and Shneerson, 2009).

Sleep and circadian rhythm disorders

Melatonin has been used as a second-line therapy and demonstrated effectiveness when evaluated in one small randomized blinded cross-over trial (Kunz and Mahlberg, 2010). Unlike clonazepam, melatonin is able to restore normal REM atonia. Melatonin also tends to be better tolerated with a better adverse effect profile than clonazepam, with similar efficacy although there are no head-to-head trials (McCarter et al., 2013). The effective dose range is 2-12mg, with a recent large case series showing benefit at an average of 6mg (McCarter et al., 2013). Other recently developed melatonin receptor agonists such as ramelteon and agomelatine have only been studied in small numbers of patients with inconsistent results so far (Jung and St Louis, 2016).

In patients for whom RBD remains refractory, occasional case reports have described that rivastigmine and sodium oxybate may be effective (Di Giacopo et al., 2012; Moghadam et al., 2017).

Sleep-related movement disorders: restless legs syndrome and periodic limb movements of sleep

RLS is underdiagnosed in older patients. The disorder is characterized by an urge to move the body in order to relieve uncomfortable sensations that typically occur in the legs. The urge to move is prominent during periods of inactivity and tends to be worse in the evenings. Symptoms can be episodic or wax and wane, and not all patients have sleep disturbance. However, people with moderate or severe symptoms may have considerable sleep disturbance.

RLS has a female predominance (Berger et al., 2004). The prevalence ranges from approximately 4-15% and is more common in the Caucasian population. At least 50% will have a family history. In older people, estimates of the prevalence of RLS have ranged from 6 to 37% (Beaulieu-Bonneau and Hudon, 2009; Guarnieri et al., 2012). Late onset RLS (defined as onset >45 years) tends to have a more rapid onset and progression to a continuous syndrome (Allen and Earley, 1996).

Although several studies have suggested that RLS could be associated with a wide variety of medical disorders, in fact only end-stage renal disease and iron deficiency have a strong association with RLS (Trenkwalder et al., 2016). High caffeine intake, smoking, excess alcohol, and exercise close to bed time can exacerbate RLS. Comorbid depression and anxiety are common in RLS (Mackie and Winkelman, 2015). Several psychotropic medications exacerbate symptoms, particularly those that deplete dopamine as well as some antidepressants and melatonin. Among antidepressants, mirtazapine, SSRIs, and SNRIs are more likely to worsen RLS, whereas bupropion and sedative antidepressants such as trazodone and doxepin do not have this effect (Kolla et al., 2017; Mackie and Winkelman, 2015).

PLMS is a closely related disorder whereby involuntary limb movements occur during wake or sleep but typically in the first half of the night. They

Sleep and circadian rhythm disorders

overlap with RLS but can be an isolated phenomenon. Patients (or a frustrated bed partner) can describe these strikingly periodic limb movements which typically consist of a brief, triple flexion movement of the toe, foot, and ankle with an interval of 20–30 seconds before the next movement occurs. PLMS are present in 80% of patients with RLS (Montplaisir et al., 1997), but are not specific and can be found in other conditions.

Assessment

The diagnosis of RLS is based on the clinical history. Patients can find it difficult to describe the sensations, and often use terms such as ‘creeping, itchy, fidgety, crawling’. The discomfort is felt deep within the limbs. Pacing and walking are seen in more severe cases. Other parts of the body can be affected, such as the back and less commonly the arms. Unlike people affected by the pain of arthritis or peripheral neuropathy, those with RLS are better or symptom free when walking.

Many disorders are commonly confused for RLS: these include neuropathy, akathisia, myalgia, venous stasis, leg oedema, arthritis, leg cramps, positional discomfort, and habitual leg tapping. Excluding these disorders is now formally incorporated as one of the five mandatory diagnostic criteria for RLS (Allen et al., 2014).

Ferritin levels should be checked in all patients, as values below 75ng/ml are often associated with RLS.

Further tests to confirm the diagnosis include using polysomnography to record the typical periodic limb movements with both limb EMG and video. This also helps to exclude other or additional causes of sleep disturbance, such as OSA. Some units have access to lower limb foot actigraphy that can be used over two or three nights at home to record a periodic limb movement index.

Treatment

Drug treatment should be initiated only when symptoms interfere with sleep, quality of life, and functioning. In patients with low levels of ferritin (<75ng/ml), iron replacement can improve symptoms.

Nonpharmacological interventions include sleep hygiene measures and avoidance of caffeine and nicotine close to bedtime.

Until recently, low-dose dopamine agonists were used as the first-line treatment of RLS, and ropinirole, pramipexole, and the rotigotine patch are all licensed for use. Treatment is typically very effective, but augmentation can occur in up to 60% of patients (Silver et al., 2011, Lipford and Silber, 2012), in which patients develop earlier onset and increased severity of symptoms over time. Impulse control disorders also develop in a significant minority.

Sleep and circadian rhythm disorders

Recent guidelines published by the IRLSSG/EURLSSG/RLSF have now recommended that the alpha-2-delta ligands (gabapentin enacarbil, gabapentin, and pregabalin) should be used as the first-line therapy (Garcia-Borreguero et al., 2016).

In the situation where dopaminergic therapies are still required for symptom control, only the lowest possible dose for the shortest duration should be used.

As dopamine agonists are associated with the development of impulse control disorders, these should be actively screened for.

Conclusions

Sleep changes with age, but sleep disorders cannot be considered to be part of normal ageing. They are commonly associated with mental or physical disorders, pain, and neurodegenerative disease. Polypharmacy can further contribute to sleep problems. An in-depth clinical history is the key to diagnosis. Sleep disorders are under-recognized and nonpharmacological treatment strategies are underused. Patients need to be informed about the physiological changes of sleep with normal ageing and the principles of sleep hygiene, such as more physical activity and less napping during daytime, and the restriction of alcohol, coffee, and nicotine in the evening hours. The most common sleep disorders in older age are insomnia, obstructive sleep apnoea, RLS, and REM sleep behaviour disorder. Most management strategies include pharmacological and nonpharmacological treatment strategies.

Additional helpful information can be found in comprehensive textbooks for sleep medicine (Kryger, 2010; Chokroverty, 2017) or on the websites of the World Federation of Sleep Research and Sleep Medicine Societies (<http://www.wfsrms.org>), which also include links to other national organizations such as the AASM (<http://www.aasmnet.org>).

The effects of ageing on personality

Chapter: The effects of ageing on personality

Author(s): Bob Woods and Gill Windle

DOI: 10.1093/med/9780198807292.003.0049

Introduction

In the twenty-first century, mental health can no longer simply be viewed as the *absence* of mental illness. In later life, and indeed across the lifespan, the aim of the commissioners of mental health services is to enhance wellbeing and quality of life as well as to promote good mental health (e.g. Age Concern England, 2006). For clinicians working directly with older people, the question may often arise as to the extent to which the older person's current state of wellbeing (or ill-being) reflects more the person's life-long attitudes, coping style, and personality, rather than the current circumstances and context.

Such questions are fuelled by research demonstrating that there is in fact a *positive* relationship between increasing age and subjective wellbeing, despite the influence of apparent 'risk factors' in older age such as bereavement, ill-health, etc., which would be expected to have a cumulative negative effect on wellbeing. Many older people encounter

The effects of ageing on personality

difficult life circumstances in later life; how is it that most older people maintain or improve wellbeing when life appears to be so difficult? For example, Siedlecki and colleagues (2008) examined factors associated with wellbeing in 818 people aged from 18 to 94. Wellbeing was greatest in the oldest age group, and was predicted by personality factors such as neuroticism, not by health status. This stability of wellbeing in the face of accumulating adversity has been termed the 'wellbeing paradox' (Staudinger, 2000) or the 'satisfaction paradox' (Diener et al., 1999) and the consistent identification of this across many studies, populations, and measures suggests that it is probably not simply a methodological artefact.

This chapter examines the interactive effects of personality and ageing. Although the title of the chapter may suggest a one-way direction of influence of ageing on personality, it is now recognized that personality characteristics may provide a valuable resource, with a demonstrable impact on outcomes in health and wellbeing. This chapter explores the role of personality and the self as a source of psychological resilience in relation to ageing and wellbeing. It describes how the self is able to maintain continuity and stability and to change adaptively. Diener and colleagues (1999) suggest that the maintenance of wellbeing across the life span demonstrates the ability of the person to adapt positively to a wide range of conditions, highlighting the role of the individual in achieving a sense of wellbeing in older age. We thus discuss a dynamic interaction between personality and ageing, which must also take into account that 'ageing' itself is not a unitary process, but covers a range of influences that change, often variably, over time.

The chapter also considers whether personality does change as people age, or whether it remains stable across the lifespan. According to Allemand and colleagues (2007, pp. 323-4), 'many people have the impression that older adults are, in general, more rigid, stubborn, resigned, and conscientious than younger adults.' Of course, such stereotypes may confound differences between birth cohorts with the effects of the passage of time. Early theories, developed from the perspective of psychoanalysis, provided detailed accounts of personality development during childhood and adolescence, but did not appear to conceive that personality could continue to develop during adulthood and accordingly had nothing to say about personality development in older age. More recent approaches suggest that personality can show elements of both change and consistency across the life course. This chapter presents some of the theory and research relating to personality and ageing. It considers personality as a range of traits and resources, i.e. the characteristics or qualities within the individual that predispose the person to behave in characteristic ways across a range of situations. Knowledge of a person's personality profile helps to predict how the person will behave in any given situation, but there will, of course, be many other factors that influence the interaction between person and environment. Staudinger (2015) describes the multidimensional nature of

The effects of ageing on personality

ageing: 'human development and aging are the result of the continuous interaction between biological influences, sociocultural influences, and the decisions and competencies as well as beliefs and attributions of the developing individual himself or herself' (p. 188).

As cognitive impairment and dementia are seen as a particular challenge to adaptation in older people, the chapter concludes with reference to the impact of dementia on personality and, likewise, the impact of personality on the presentation of the person with dementia.

Personality across the lifespan

The 'Big Five' five-factor model has emerged as the predominant trait model of personality (Digman, 1990), and has been described as offering a meta-theoretical framework of personality (McCrae and Costa, 1996). The five factors included in this model are:

1. Neuroticism, including anxiety and vulnerability vs emotional stability
2. Extraversion, including warmth, gregariousness and activity vs introversion
3. Openness to experience, including broad-minded values and aesthetics
4. Agreeableness, including altruism, modesty, and trust vs ruthless and hostile
5. Conscientiousness, including competence, goal-directedness, self-discipline, and self-control

These factors form a crucial part of the self-concept. With its origins in psychometrics and the study of individual differences, the five-factor model represents a scientific approach to the study of personality. It is derived from factor analyses of descriptions of personality that were obtained through self-report methods and observer ratings that have been extensively validated. Each trait represents a tendency to behave in a particular way, with individuals varying in the extent to which they show each trait. It is the consensus on this model that has underpinned the revival of research on personality development over the lifespan.

Based on evidence from longitudinal and cross-sectional research, using a personality measure that evaluates these five traits (the NEO-PI), it had been previously argued that there is little or no change in personality after the age of 30, despite the varied experiences that occur over the life course (Costa and McCrae, 1992; 1994; 1997). 'Individual differences in personality traits are extremely stable in adults, even over periods of as long as three decades' (McCrae, 2002, p. 309). A longitudinal study, with 684 participants aged 17–76 undertaking three personality assessments over a period averaging 20 years, concluded that 'personality stability plateaus early in adulthood' (Terracciano et al., 2010). Such findings have been related to the proposition that personality traits are biologically determined, with environmental and secular influences seen as less

The effects of ageing on personality

important. An alternative, less-researched, view highlights plasticity in personality, as in other areas of development, reflecting the potential for age-related changes to be modified (Staudinger, 2015). In considering personality stability and change, it is important to note that there are at least three forms of stability that are being discussed: changes in the absolute *level* of scores; changes in the *rank order* of individuals (consistency); and changes in the *structure* of personality (Staudinger, 2005).

The *structure* of the five-factor model does appear to be replicable across age-groups (Allemand et al., 2007) with similar age-trends identified across diverse cultures. McCrae and colleagues (2005) used observer ratings of personality across 50 different cultures. The raters were college students and those being rated were college age (18–21) or adult (40–98); however, the mean age of the adult group was relatively young at 49.9 years. They found that the five-factor model of personality was consistent cross-culturally, providing further support for the argument that personality development is independent of life experiences.

Similarly, the evidence for stability of *rank order* of individuals is relatively strong in mid-life. Roberts and DelVecchio (2000) conducted a meta-analysis of relevant studies, indicating that stability plateaued in the 50–73-year-old age group, but it is noteworthy that there were no studies included with age groups older than this. Subsequent studies including older people in their samples have produced mixed results. Mottus and colleagues (2012) concluded there was rank order stability on the five factors in longitudinal analyses of two cohorts, one aged 69 initially, followed for three years; the other aged 81 initially and reassessed six years later. Lucas and Donnellan (2011) report analyses of a large German longitudinal sample, including over 9,000 adults aged 49–84, indicating lower rank order stability in the older groups for all five of the NEO traits. Specht and colleagues (2011) report analyses from the same study, replicating an inverted U-shaped curve for rank order stability, with the peak between the ages of 40 and 60, for all the traits except conscientiousness, the stability of which continued to increase with age. Similar findings of lower stability in later life are reported from samples in New Zealand (Milojev and Sibley, 2017) and Australia (Wortman et al., 2012), but with different traits showing higher stability (agreeableness in New Zealand; extraversion and conscientiousness in Australia).

Greater variation in later life is a classic gerontological finding, with heterogeneity typically attributed to the wide range and increasing diversity of life events experienced across the life span. For example, Allemand and colleagues (2013) state ‘individual differences in change reflect the plurality and diversity of life experiences individuals can encounter in adulthood such as getting married or getting fired from job, retirement, or physical and cognitive decline in later adulthood.’ Terracciano and colleagues (2018) have identified a potential major influence on the reductions in rank order stability noted in most, but not all, studies involving older people. They analysed data from nearly 10,000

The effects of ageing on personality

people, aged 50–96, assessed twice, with a four-year interval, on the Big Five personality traits. The results indicated once again that there was a progressive reduction in rank order stability with advancing age. However, when the results for those with cognitive impairment and dementia were analysed separately, it was evident that stability was especially low in this group, perhaps reflecting personality changes in dementia discussed later in this chapter. Among those without cognitive impairment or dementia, there was no evidence of lowered rank order stability with age. They conclude that the observed lower rank order stability of personality traits with increasing age is attributable to cognitive impairment and dementia, not age per se.

There is a large body of evidence that indicates that changes in mean *levels* of personality traits may occur beyond the age of 30 (Roberts et al., 2006). Here we focus on changes in later life, where data are now available from several large-scale studies, incorporating both cross-sectional and longitudinal analyses.

Extraversion

Almost all studies show a reduction with age in extraversion, especially in older cohorts (e.g. Specht et al., 2011; Lucas and Donnellan, 2011; Wortman et al., 2012; Kandler et al., 2015) and towards the end of life (Wagner et al., 2016). In a sample aged 80 and over, Berg and Johansson (2014) reported that this decline was related to hearing impairment. Where longitudinal studies have shown increases in extraversion, this has been with younger samples (aged 60–69) and/or over shorter periods. For example, Mottus and colleagues (2012) report decreased extraversion over a six-year period in a cohort initially aged 81, but a small increase in a younger cohort (aged initially 69) over a briefer, three-year period.

Agreeableness

Across the life span, large cross-sectional studies indicate higher levels of agreeableness in mid- and later life (e.g. Donnellan and Lucas, 2008). However, longitudinal analyses in later life generally show a reduction in agreeableness over time (Specht et al., 2011; Lucas and Donnellan, 2011; Wortman et al., 2012). Mottus and colleagues (2012) report a gender difference, with decreased agreeableness over time in females (but not males) in both their young-old and old-old cohorts.

Conscientiousness

In cross-sectional analyses, this trait increases from adolescence, before plateauing around the age of 50 or so (Donnellan and Lucas, 2008), with some studies showing older cohorts having higher levels still (e.g. Specht et al., 2011; Wortman et al., 2012). However, most longitudinal analyses in later life show reduced conscientiousness over time (Specht et al., 2011; Lucas and Donnellan, 2011; Wortman et al., 2012; Mottus et al., 2012; Kandler et al., 2015).

The effects of ageing on personality

Neuroticism

Donnellan and Lucas (2008) report discrepant age trends from two large cross-sectional samples. In a UK sample, consistent with other findings, neuroticism decreased with age; in Germany, it appeared to increase. Longitudinal analyses also produce mixed results; decreases in neuroticism are most often reported (e.g. Allemand et al., 2007; Allemand et al., 2008; Wortman et al., 2012; Mueller et al., 2016; Milojev and Sibley, 2017). However, Kandler and colleagues (2015) report increased neuroticism over time and Wagner et al. (2016) report increased neuroticism especially towards the end of life.

Openness

There appears to be a reduction in openness in later life, after a period of stability in mid-life (Donnellan and Lucas, 2008). This pattern is supported by most longitudinal analyses (Specht et al., 2011; Lucas and Donnellan, 2011; Mottus et al., 2012; Wortman et al., 2012). Wagner and colleagues (2016) report openness decreasing over time or towards the end of life.

Other triggers

Despite many differences between studies in samples and methods, there do appear to be distinct normative changes in personality beyond the original age of 30 previously suggested by Costa and McCrae, demonstrating that there is no specific age at which personality traits stop changing—development continues. In later life, reductions in absolute levels of extraversion, openness, and conscientiousness may be observed. Although agreeableness may be higher than in younger cohorts, it too may reduce over time. Neuroticism generally—but not in every sample—appears lower in later life.

In contrast to the notion that personality is biologically determined, Roberts and colleagues (2006) argue that, across the lifespan, some of the changes between and within cohorts could be affected by aspects of the environment. This is supported by Specht and colleagues (2011), who suggest changes in old age were partly attributable to social demands and experiences, and by Kandler and colleagues (2015), who relate individual differences in change to environmental sources, indicating plasticity in later life. This plasticity is evident in studies where an increase in openness in older people has been identified following cognitive training interventions (Jackson et al., 2012; Staudinger, 2015).

Wrzus and Roberts (2017) have proposed the 'TESSERA' framework, where personality development arises from processes of association and reflection concerning repeated short-term sequences of Triggering situations, Expectancies, States/State Expressions, and ReActions. Triggers might occur resulting from social, environmental, or health-related losses, with heterogeneity occurring as individuals experience these triggers at different times, or not at all. They suggest that further

The effects of ageing on personality

diversity results from less fixed social role expectations in later life, and from cognitive impairment affecting the reflective and associative processes that ultimately drive personality change.

Other factors may also lead to differences; for example, Allemand and colleagues (2008) suggest that reductions in neuroticism in later life may reflect a survivor effect, with those lower in neuroticism perhaps living longer. The changing context of later life is also likely to be an influence. Billstedt and colleagues (2013) demonstrate a clear cohort effect, comparing the scores of people aged 75 and over on the Eysenck Personality Inventory in 1976–1977 with those of people of the same age in 2005–2006. They report an increase in extraversion and a reduction in social desirability bias, suggesting a more independent-minded, outward-looking cohort than 30 years previously. Neuroticism levels, on the other hand, did not differ between the cohorts, presumably less influenced by the environmental and social context.

In summary, there is increasing acceptance that both change and stability in personality occur in later life (Allemand et al., 2013), and there is clearly a need to recognize the interaction of genetic and environmental influences. Measures of personality traits are, of course, designed to show stability, so considering other aspects of the self may help to understand more fully the subtle ways in which people change—in order, perhaps, to maintain their stability.

Lifespan development

The lifespan development perspective offers a theoretical framework which acknowledges that personality may develop from an interaction with both biology and the environment. This approach enables the ‘normal’ changes that occur due to the passage of time to be understood as part of ‘the ageing process’, by recognizing that ageing is influenced by earlier aspects of the life course (Baltes et al., 1980). Accordingly, human development continues throughout the entire lifespan, with old age being just another developmental phase. Baltes and Baltes (1990) summarized this psychological perspective on lifespan development into seven propositions about the nature of human ageing:

1. There are major differences between normal, pathological, and optimal ageing.
2. The course of ageing demonstrates much inter-individual variability (heterogeneity).
3. There is much latent reserve capacity in older age.
4. There is an age associated limitation to the range of reserve capacity.
5. Age-related decline in some aspects of cognitive functioning (speed, etc.) can be compensated by pragmatic knowledge (intelligence, reasoning).
6. The balance between gains and losses becomes less positive with increasing age.

The effects of ageing on personality

7. In old age the self remains resilient.

Underpinning these propositions are three sets of influences. The first set—normative age-graded influences—are those which have a relatively strong relationship with chronological age in terms of their onset and duration. These include biological maturation and age-related socialization, such as the family life cycle, education, and occupation. They are normative, in that the timing and duration are similar across individuals.

The second set of influences—normative history graded—are biological or environmental influences that occur in similar ways to most members of a specific population cohort. Examples of these influences would be wars or epidemics, or experiencing with one's age-peers a significant event or sequence of events in history.

The final set of influences—non-normative life events—occur independent of age or history, and their occurrence tends to be specific to the individual. These include factors such as unemployment, illness, winning a lottery, divorce, bereavement, institutionalization, or relocation. The 'joint impact of influences of the three types, mediated through the developing individual, accounts for the nature of lifespan development, for its regularity, and also for its differential properties in terms of inter-individual differences, multi-directionality and multi-dimensionality' (Baltes et al., 1980, p. 76).

The lifespan developmental perspective of ageing and its seven propositions offer a comprehensive picture of ageing, encompassing decline, change, stability, and growth, reflecting the three sets of influences on ageing described previously. They also emphasize the considerable variability and flexibility of older age, described as 'differential ageing' (e.g. Baltes et al., 1999).

Erikson's life-cycle model of personality development

Typically, developmental models with their roots in psychoanalysis focused on infancy, childhood and adolescence, with scarcely a nod towards adulthood. Erikson's Eight Stage Model of the Life Cycle stood out because it viewed personality development as continuing throughout the whole life cycle from childhood to old age (Erikson, 1963, see Table 49.1). This model describes how individuals may accomplish each life phase, emphasizing how the self/personality/identity develops in stages and results in fulfilment, and proposes that there is a biological predisposition to adapt at each of these distinct stages of the life cycle. It may be described as an interactional model of personality and environment, with the developing individual being affected by societal demands and requirements.

Table 49.1 Erikson's Eight Stages of the Life Cycle.

The effects of ageing on personality

Conflicting issues	Emerging value	Life period
1. Basic trust versus mistrust	Hope	Infancy
2. Autonomy versus shame and doubt	Will	Early childhood
3. Initiative versus guilt	Purpose	Play age
4. Industry versus inferiority	Competence	School age
5. Identity versus identity (role) confusion	Fidelity	Adolescence
6. Intimacy versus isolation	Love	Young adulthood
7. Generativity versus stagnation	Care	Maturity
8. Integrity versus despair (and disgust)	Wisdom	Old age

Source: data from Erikson. E. (1963). *Childhood and Society*. Harmondsworth: Penguin.

These eight periods of the life cycle originate in childhood. At each stage there is a conflict between two forces, and if development is to be successful, the conflict needs to be resolved in order to obtain an emerging human strength. The eighth (and originally final) stage is characterized by an evaluation of life, involving looking back and assessing whether it was a meaningful experience. Acceptance of life is crucial for achieving a sense of integrity or wholeness, with wisdom being the successful outcome. Alternatively, this review of life could lead to a conclusion that life was unproductive and meaningless, thereby resulting in despair.

Erikson's model was later extended by his widow, Joan (Erikson, 1998), to include a ninth stage of 'gerotranscendence' (Brown and Lowis, 2003). This draws in part on work by Tornstam (1992) and appears to have been prompted by the experience of both Joan and Erik Erikson in living well into their 80s. Gerotranscendence refers to an acceptance of the proximity of death without fear, a sense of release from material stresses, an enjoyment of quiet reflection, reduced self-centredness, and a positive disengagement. For Tornstam, this was a forward-looking process, associated with wisdom and with continued life satisfaction. Erikson

The effects of ageing on personality

(1998) associates the path to gerotranscendence with re-engagement with the negative poles of the previous eight stages; for example, the older person may have to confront their mistrust of their own abilities to remain independent, or their sense of inferiority in not being able to continue with previous roles. There is a strong sense of the spiritual, in its broadest meaning, in this proposed developmental stage.

Erikson's theory fits well with the proposition of the 'resilient self' of Baltes and Baltes (1990) and that older age can be accompanied by the acquisition of new behaviours important for ageing (Baltes et al., 1980). In terms of Erikson's stages, the continuing development of the self across the lifespan and the ultimate achievement of wisdom provide some explanation for the maintenance and growth of wellbeing in older age.

There is some empirical support for this claim. Ardel (2000) examined the benefits of wisdom in older age, with wisdom operationalized as cognitive, affective, and reflective personality qualities. Wisdom outweighed the contribution of objective conditions to the prediction of life satisfaction, and Ardel (1997) showed that wisdom had a higher impact on life satisfaction in old age than physical health, income, socioeconomic status, physical environment, or the extent of social relationships. Thus, the still-developing personality exerted a strong influence on wellbeing in later life.

Erikson's stage model introduces some important aspects of ageing. It reflects the continuous development of the self. It highlights the process of adaptation, which is achieved through tackling and resolving the conflicting issues at each life stage. Implicit in the model is the potential for earlier developmental tasks that are not completely resolved to re-surface at later points of the life cycle. For example, the person whose sense of inferiority is managed by additional investment in industriousness, in keeping busy and active, becomes vulnerable when retirement leads to a loss of purpose, or physical health problems enforce inactivity. Or the person who learned in infancy that others cannot be trusted finds dependency on others difficult to countenance, even though the support of others may clearly be required. Adaptation is crucial and is dependent upon how the factors that might either constrain or enhance the ability to reach full potential are negotiated. The emphasis on the development of the self in this life cycle theory also highlights the important role that inner psychological resources central to the self might play in successfully negotiating conflicting issues and achieving wellbeing.

Psychological resources in later life

Psychological resources central to the self are increasingly recognized as important in adaptation, development, and wellbeing in later life (Ryff, 2014). These psychological resources have a variety of labels, including self-efficacy, self-esteem, self-acceptance, environmental mastery, and sense of control. Resilience is increasingly being used (loosely) as a

The effects of ageing on personality

general term for these 'self' resources, which all reflect an inner strength that allows the person to assimilate changes and losses, and to find ways of coping and managing the situation and their own response to it, without threatening their sense of self-worth. More extensive changes or difficulties may require an accommodation of the self-concept, but those who age successfully maintain a strong core sense of self. In line with this, continuity theory (Atchley, 1989) argues that learning how to best adapt to change continues across the lifespan, and that wellbeing is achieved through adaptive choices that maintain the continuity of the self, while dealing with age-associated changes. Stability in older age then results from the active and ongoing interplay an individual has with their environment.

This section explores these resources in more depth and outlines five psychological resources important to ageing (self-esteem, perceived control, self-efficacy/competence, self-acceptance, and resilience). It discusses evidence for the relationship of each with age and presents their importance across a range of outcomes.

Self-esteem

Self-esteem refers to the person's evaluation of his/her self-worth, derived from values, goals, and aspirations (Rosenberg, 1979). Self-esteem features in research as an outcome measure, an intervening variable and as a resource to draw on when confronted with certain situations, although Orth and colleagues (2015) consider it should be seen as a personality trait.

Cross-sequential analyses of several large samples using the standard measure of self-esteem (the Rosenberg self-esteem scale) across the lifespan show consistently a curvilinear relationship between self-esteem and age (Orth et al., 2012; Orth et al., 2015). Self-esteem increases from adolescence to middle adulthood, reaching a peak at about age 50 years, and then decreases into later life. Although Orth and colleagues (2012; 2015) suggest that there is stability across cohorts, Twenge and colleagues (2017), re-analysing data from one of the samples, identified higher levels of self-esteem in later birth cohorts.

The association of self-esteem with a variety of other variables emerges from Orth and colleagues' (2012; 2015) analyses. Mood and affect, relationships, health, and work satisfaction all correlate with self-esteem.

Perceived control

Possessing a sense of control enables individuals to regulate and direct events, to participate actively in life, and to be independent and have self-responsibility (Wallhagen, 1998). As older adults seek to maintain control when facing losses associated with older age (Baltes, 1996; Fung, Carstensen and Lutz, 1999), control could be regarded as an important psychological resource in older age.

The effects of ageing on personality

The locus of control theory was proposed by Rotter (1966). Individuals with an 'internal locus of control' believe they have control over their successes and failures, while those who believe that their lives are controlled by other, external forces such as luck, fate, or the behaviour of another person are said to have an 'external locus of control'. Research findings support the beneficial effect of an internal sense of control in older people; for example, it is associated with less physical disability in women recovering from surgery for fractured neck of femur (Shaw et al., 2003) and predicts better life satisfaction in frail older people (Abu-Bader et al., 2002).

Age and gender differences in personal control have been reported, with older women having lower perceived control than men. This gender gap was greater among older people than in younger comparisons (Ross and Mirowsky, 2002). Mirowsky (1995) examined perceived control across an age range of 18 to 85. In the 18–50 age range it remained high, but declined with increasing age, with the oldest age groups having the lowest score. In a longitudinal study of adults aged initially 64–85, over a five-year period, perceived control decreased significantly, with changes associated with increased neuroticism and reduced conscientiousness (Kandler et al., 2015).

Schulz and Heckhausen (1996, 1998) distinguish two types of control: primary and secondary. Primary control refers to the immediate environment: changes are made by influencing the external world. Secondary control is based within the individual: the self is the source of change, the person adjusting to the situation, adapting goals and expectations. Both types of control are thought to assist in favourable development across the lifespan but have different paths. Primary control is most prominent in infancy and adolescence, with a peak around the age of 40–50 years, then a gradual decline into later life. Secondary control starts later in life, with a steady increase into older age (Magai, 2001; McAdams and Olson, 2010). The change from primary to secondary control across the lifespan may enable greater regulatory control of emotion and wellbeing, providing a valuable resource in older age. The two types of control need to be assessed differently, perhaps explaining why some earlier studies did not show a decline of perceived control in later life (e.g. Lachman and Weaver, 1998). Some measures may reflect secondary control more than others.

Perceived control emerges from longitudinal studies as both a precursor and an outcome of health and social support across adulthood and later life. Perceived control predicts later health and social support, but perceived control is also greater where initially health is better and more social support is available (Gerstorf et al., 2010). Infurna and colleagues (2011) report similar findings but add life satisfaction to the list of related variables involved in this positive feedback loop. Interestingly, these associations appear not to be greatly influenced by age, despite health arguably becoming much more of a salient issue.

The effects of ageing on personality

Self-efficacy/competence

The concept of competence can be thought of as covering three broad domains: the range and level of skills, personal belief about abilities (efficacy and mastery), and the adaptive fit between skills and environmental demands (Baltes et al., 1993). Personal efficacy/self-efficacy (Bandura, 1997) encompasses the belief that success can be achieved in what we want to do. It is also regarded as an evaluation based on a sense of competence (Dietz, 1996). A strong sense of efficacy increases the likelihood of a successful outcome, by affecting performance and intentions (Bandura, 1997). Estimates of predicted success or failure are derived from memories of the effects of previous activities; previous experiences of success or failure will determine whether the person believes they are *personally* capable—or not—of achieving a desirable outcome. Crucially, beliefs concerning personal efficacy influence thought patterns and subsequent performance.

Personal competence underlies the adaptive behaviour that is central to the person-environment transaction model (Lawton, 1989). This theory proposes that the person and the environment are joint determinants of behaviour and subsequent wellbeing. For example, older people with decreased physical functioning may need to draw on their resources and adapt their behavioural competence to the level of environmental demands experienced, in order to maintain positive subjective wellbeing (Lawton, 1989). Demands can come from a diverse range of environmental areas: interpersonal, suprapersonal, social, and physical. In this context, competence is an evaluative, cognitive process where the demands of the situation influence an individual's sense of efficacy (Wallhagen, 1998).

Welch and West (1995) describe how according to self-efficacy theory, older age is generally considered to be a time where the potential for positive effective behaviour is reduced. Negative stereotypes of ageing lead to cognitive changes being interpreted as failures and changes in physical functioning can make negotiating the physical environment difficult. Trouillet and colleagues (2009) identified little age-difference in self-efficacy in adults aged between 22 and 88. Problem-solving coping was predicted by self-efficacy and social support, but not by age—although their older sample tended to report having less social support.

In addition to measures of general self-efficacy, domain-specific measures are often used, examining self-efficacy in a specific context. In terms of the memory domain, levels of perceived memory efficacy were found to predict the extent of improvement in memory performance in both young and older adults after training in mnemonic aids (Rebok and Balcerak, 1989). Stephan and colleagues (2011) reported that higher memory self-efficacy was related to higher life satisfaction and subjective health and to lower subjective age in a sample of older people aged 60 and over. Thus, people who regarded themselves as younger than their chronological age had more confidence in their memory and enjoyed

The effects of ageing on personality

greater life satisfaction. An Italian study of adults aged 20–80 found that self-efficacy for positive affect, empathy, and social self-efficacy declined as age increased, although there were gender differences, with increased self-efficacy for negative affect across the age cohorts for females (Capara et al., 2003).

Self-acceptance

Ryff and Singer (1996) describe self-acceptance as a key dimension of positive psychological functioning, viewing it as an aspect of self-actualization, maturity, and optimal functioning emphasizing the acceptance of current and past life. It makes possible the maintenance of self-esteem when dealing with some of the less desirable aspects of personal life (Keyes and Waterman, 2004). Self-acceptance is crucial for achieving a sense of integrity, which is the final stage of Erikson's model of the life cycle.

Self-acceptance has been found to remain consistent across young, midlife, and older aged cohorts (Ryff and Singer, 1996), with males reporting significantly higher self-acceptance than females (Capara et al., 2003). The positive relationship between self-acceptance and subjective wellbeing in older adults is seen as enabling an acceptance of age-related changes (Ranzijn and Luszcz, 1999).

Resilience

The concept of resilience derived from the observation that people can still function positively although exposed to substantial stressors and risks, and recover quickly from set-backs (Rutter, 1995). Resilience can be viewed as the opposite to vulnerability, encompassing personal competences across cognitive, emotional, and social domains (Tizard and Clarke, 1992). Psychological resilience is thought to be important in late life as a component of successful psychosocial adjustment (Wagnild and Young, 1993) and Pruchno and colleagues (2015) suggest that successful ageing could be viewed as a pattern of resiliency across the lifespan.

A conceptual analysis of resilience (Windle, 2011) identified three necessary requirements for resilience: a significant adversity or risk; the presence of assets or resources to offset the effects of the adversity; and positive adaptation or the avoidance of a negative outcome.

Resilience was then defined as 'the process of effectively negotiating, adapting to, or managing significant sources of stress or trauma. Assets and resources within the individual, their life and environment facilitate this capacity for adaptation and 'bouncing back' in the face of adversity. Across the life course, the experience of resilience will vary' (Windle, 2011).

Although resilience can be defined, its measurement has proved challenging (Windle et al., 2011). Hardy and colleagues (2004) proposed that in older people, a positive response to a stressful life event is

The effects of ageing on personality

indicative of a resilient process. For example, Netuveli and colleagues (2008) defined resilience as 'bouncing back' from adversity; in a longitudinal survey, those exposed to adversity (e.g. bereavement or functional limitation) who after a year had returned to their pre-exposure level of psychological distress were identified as resilient. However, the conceptualization of resilience as the response to the stressful event has its limitations, in that it cannot be measured in the absence of a significant adversity.

The examination of resilience as an internal personality resource provides the opportunity to address this limitation, and a number of questionnaire measures have been developed. Rutter (1987) described resilient individuals as possessing self-efficacy, self-esteem, and a range of problem-solving skills. Others describe resilient individuals as possessing personal competence and acceptance of self and life (Wagnild and Young, 1993). These personality resources are thought to protect individuals in the face of adversity and lead to positive adaptive behaviour by acting as a protective 'buffer' (Rutter, 1987) or as compensatory factors that directly influence outcomes (Masten, 1999). In this context, resilience could be viewed as an 'umbrella' term for such psychological resources which are central to the self. Windle and colleagues (2008) provided some support for this, in that they identified a single common higher-order factor underlying self-esteem, personal competence (self-efficacy), and perceived control in a large sample of 1847 people aged between 50 and 90. Scores on this 'resilience' variable were lower in this cross-sectional survey in those aged 70 and above, with the highest scores in those age 60–69 (Windle et al., 2009). However, caution is needed in interpreting age differences in resilience scores, given the complexity of the construct and its measurement, and the potential differences in demands on resilience at different points in the life-course.

The importance of psychological resources to wellbeing

Research that has examined the influence that psychological resources have on wellbeing finds that they can have an intervening effect. They can increase the possibility of positive changes in health behaviours and wellbeing (Wells and Kendig, 1999), or can limit the potential negative influences on wellbeing of risk factors associated with ageing (Windle and Woods, 2004). In the latter study, a representative sample of 420 people aged 70 and above (mean age 78) were interviewed. Physical health limitations, loneliness, housing difficulties, and being widowed or divorced were related to lower levels of life satisfaction. However, the person's sense of environmental mastery mitigated the effects on life satisfaction of both physical health limitations and housing difficulties, and, to a lesser extent, of loneliness. In other words, having a strong sense of environmental mastery reduced the impact of the difficult circumstances the older person was experiencing.

The effects of ageing on personality

Self-efficacy has been found to buffer the impact of cancer on depressive symptoms in people aged 55–85 (Bisschop et al., 2004) and to diminish the negative impact of impaired functional capacity on depressive symptoms (Knipscheer et al., 2000). Self-efficacy probably influences the coping processes that people require when faced with problematic situations, and their subsequent choice of adaptive strategies (Slangen-de Kort et al., 2001). Reductions in perceived control over a five-year period have been related to reductions in wellbeing in older people initially aged 64–85 (Kandler et al., 2015).

Windle and colleagues (2009) found evidence for the protective effects of psychological resilience on wellbeing in the presence of ill health, but the relationship was slightly different in different age cohorts. In those aged 60–69 years, higher levels of psychological resilience were associated with high wellbeing whatever the level of ill health. For those aged 70–79 and 80–90 years, psychological resilience again provided an advantage overall, but for those with high levels of resilience there remained an association of ill health with lower wellbeing. In a sample of over 10,000 people aged 51–98, Manning and colleagues (2014) found that, over a two-year period, resilience protected against the negative impact of chronic disability in later life on day-to-day functioning. Not only did people with higher scores on their resilience measure have lower levels of disability, but also resilience buffered the effects of the onset of a new chronic condition in relation to subsequent disability.

The beneficial effects of such resources in older age may then be a key factor for wellbeing. Resources such as mastery, self-esteem, and optimism may be conceptualized as part of the core of the reserve capacity that provides a basis of resilience in older age (Gallo et al., 2005). These mechanisms of personal agency can help to give meaning to many external pressures, so that they can be dealt with successfully, with positive ageing being the outcome for those who are able to respond with resilience to the accumulating adversities across the lifespan (Pruchno et al., 2015).

The theory of selective optimization with compensation

The potential regulatory effect on wellbeing of the resilient self can be partially explained through the theory of Selective Optimization with Compensation (SOC, see Fig. **49.1**). The theory describes three processes which may be used in adaptation to changes occurring in later life.

The effects of ageing on personality

Fig. 49.1

The theory of Selective Optimization with Compensation, which describes three processes that may be used to adapt to changes occurring in later life.

Reproduced with permission from Baltes, P. B. & Baltes, M. M. (1990). Psychological perspectives on successful aging: The model of selective optimisation with compensation. In P. B. Baltes, and M. M. Baltes, (Eds.), *Successful aging: Perspectives from the behavioural sciences*. Cambridge: Cambridge University Press. Copyright (c) 1990 Cambridge University Press.

Selection implies an adjustment of expectations to permit personal control and satisfaction (Baltes and Baltes, 1990). It involves choosing goals, life domains, or life tasks. Selection may require a restriction to fewer domains of functioning due to new responsibilities and stresses—described as elective selection—or it may occur as a consequence or in anticipation of losses in certain areas of life, such as personal or environmental resources (loss-based selection). It may also refer to the avoidance of one domain, or a restriction of tasks or goals in one or more domains. Selection can also involve new goals, such as environmental changes (e.g. moving house due to difficulties with the current home) or a more passive type of adjustment (such as not climbing the stairs) (Baltes and Carstensen, 1999). Compensation and optimization provide the ability to maintain or even enhance chosen goals (Baltes and Carstensen, 1999). *Optimization* of behaviour occurs when losses are minimized and gains maximized and is the desired *outcome* of the SOC process. The methods a person has for achieving their goals are refined and perfected (Baltes and Carstensen, 1999). *Compensation* is required when skills and capacity are reduced below the level required for adequate functioning. In order to maintain or even optimize that prior functioning, a present skill may be adapted into a new behaviour, or new means sought to retain that functioning (Baltes and Carstensen, 1999). Freund (2008) reviews empirical studies that have provided evidence for the importance of the SOC model in understanding how individuals manage their resources and achieve their goals.

According to Herzog and Markus (1999) the theoretical perspective of the self system can assist in understanding such processes. They state that:

The effects of ageing on personality

the domains and dimensions that define the self provide the basis of selectivity, determining where time and energy will be invested, where efficacy and control (or the lack of it) will be experienced, what will be planned for, what will be compensated for, what will be discounted or ignored, and ultimately how individual lives accrue meaning and structure (p. 228).

In other words, the self can provide context and meaning, which, in turn, is developed from a view of the self from the past, present, and future perspectives. This process of self-reference can maintain a positive self-concept. In relation to ageing, how individuals react to changing roles and life events is dependent upon mediation by the self-concept (Markus and Herzog, 1991). The concept of resilience may then represent positive functioning across the diverse range of resources that characterize the self.

Personality and dementia

If personality can indeed be thought of as showing continuity over the lifespan, with individuals showing remarkable capacity to adapt and cope with difficult life circumstances, what are the effects of a dementia on personality, and does the person's personality influence the way in which dementia presents? McCrae (2002) suggests that 'the most dramatic and best-documented changes in personality are those associated with changes in the brain, attributable to Alzheimer's disease (AD) or to traumatic brain injury'.

Is personality a risk factor for dementia?

In recent years, a wide variety of potential risk factors have been examined in relation to their association with the development of a dementia later in life. In the psychological domain, most attention has been given to the potential for 'cognitive reserve' to delay the onset of dementia, with factors such as education and engagement in cognitively stimulating activities and pursuits thought to build an additional resource upon which to draw. Maercker and Forstmeier (2012) have extended this concept, under the title of 'motivational reserve', which encompasses aspects of how cognitive resources are used and developed, in terms, for example, of a sense of purpose (Boyle et al., 2010) and drive.

This broader view of psychological risk factors is now supported by a number of studies that highlight the role of various of the major personality traits in relation to predicting both cognitive decline in later life and the incidence of dementia. In reviewing the literature relating to cognitive function and cognitive decline in later life, Curtis and colleagues (2015) highlight the protective effect of higher levels of conscientiousness with respect to cognitive decline, although unrelated to level of cognitive function per se. Openness shows the opposite pattern, higher levels being positively associated with cognitive ability, but not with less decline. Neuroticism also appears to be related to aspects of

The effects of ageing on personality

cognitive function. Luchetti and colleagues (2015) provide results from a large-scale longitudinal study, along with a meta-analysis of five other prospective studies, in which nearly 14,000 older people, with a mean age of 68.8 years, were followed up for four years. The association between higher neuroticism and lower conscientiousness and cognitive decline were evident in both the meta-analysis and the large follow-up study. In the latter, there was also evidence that higher openness was associated with less decline in memory performance.

Low and colleagues (2013) reviewed studies examining the association between personality and incidence of dementia; they included 15 studies in a meta-analysis and concluded that conscientiousness reduced risk of developing dementia, while neuroticism increased risk. Extraversion and agreeableness showed no association with dementia, but the evidence for the protective effect of openness was inconclusive. Terracciano and colleagues (2014) reviewed evidence from five prospective studies, with similar results, although there was again a more tentative suggestion that openness, along with agreeableness, might have a protective role. They also reported results from a follow-up of up to 22 years of 1,671 participants in the Baltimore Longitudinal Study of Aging, and identified that the risk of developing a dementia was increased considerably for those with high neuroticism and for those with low conscientiousness scores.

More recently, Terracciano and colleagues (2017), following over 10,000 people for up to eight years, provide further support for the association of neuroticism and low conscientiousness with the development of both dementia and of milder levels of cognitive impairment. Lower agreeableness was also associated with greater risk of developing dementia. The personality risk factors for dementia incidence remained significant even after controlling for other common dementia risk factors such as education, age, diabetes, and hypertension.

The question arises as to why aspects of personality might be related to cognitive decline and to dementia incidence. Terracciano and colleagues (2014) suggested that part of the explanation could be the association between personality and lifestyle, with low conscientiousness and high neuroticism being linked with obesity, inactivity, and smoking, all risk factors for dementia. They point out that high neuroticism is associated with depression, another established risk factor (e.g. Wilson et al., 2004). However, as noted, this research group subsequently reported that the link between personality and dementia incidence remained after controlling for a number of these risk factors (Terracciano et al., 2017).

In a report of 309 participants who had undertaken frequent cognitive assessments in longitudinal studies, who had died (mean age 87.6 years), and whose brains had been examined at post-mortem, Wilson and colleagues (2015) were able to examine trajectories of cognitive decline, for an average of 10.7 years prior to the person's death. They identified that, on average three years before death, there was a period of steeper

The effects of ageing on personality

cognitive decline much more pronounced than the gradual decline in preceding years. Higher conscientiousness (assessed at baseline) was associated with slower terminal decline, but not with the gradual decline preceding this. This effect remained after taking into account the extent of neuropathological changes evident at post-mortem. This suggests that high conscientiousness may contribute to cognitive reserve, influencing the degree of impairment arising from a given extent of neuropathological change. A similar conclusion may be drawn from Terracciano and colleagues (2013) analysis of a cohort of 111 people evaluated for Alzheimer pathology at post-mortem. They describe a 'resilient personality profile', including higher conscientiousness and lower neuroticism, as self-reported on average 15 years previously, associated with a greater probability of remaining clinically asymptomatic in the presence of Alzheimer-type neuropathology.

Segerstrom (2018) discusses several possible pathways for the personality/incident dementia linkage, focusing on AD specifically. These include a common 'cause', such as a gene; personality predisposing the person to AD risk, through health behaviours; personality affecting the appearance or severity of AD, as perhaps with cognitive reserve, a 'pathoplastic' effect, or resilience to neuropathology; and personality change (towards lower conscientiousness and/or higher neuroticism) forming part of the AD spectrum, occurring decades prior to a diagnosis being made. Distinguishing these potential mechanisms will not be easy, but Segerstrom concludes that predisposition and/or a pathoplastic effect appear most promising.

Does dementia change personality?

In evaluating personality change in people with dementia, researchers must usually rely on a relative completing two personality inventories, one for how the person is now, and one for a period well before the onset of the condition. This involves two assumptions; firstly, that proxy reports of personality can be reliable and valid; and secondly, that retrospective accounts can be accurate, and not influenced by the dementia-related changes, or by the relative's experience of care-giving. The reliability and validity of the proxy version of the NEO-PI scale has been well documented (McCrae and Costa, 2003). Evidence for the second assumption is provided by Strauss and colleagues (1993), who report ratings of 22 people with AD by two informants (the main caregiver and another relative or friend), showing substantial agreement between the raters, both in comparative rankings and in absolute level on the NEO-PI scale.

A number of studies have used the NEO scale, placing the results in the context of contemporary personality research. Robins-Wahlin and Byrne (2011) report a systematic review of such studies. They identified nine studies, with a total of 291 participants, with the individual studies being relatively small in size (range 19–50). The findings were consistent across studies; a major increase in neuroticism and decrease in

The effects of ageing on personality

conscientiousness were identified (of the order of 1–2 and 2–3 standard deviations, respectively). The other factors—extraversion, openness and agreeableness—all showed consistent reductions across studies also. The findings fit well with those regarding personality factors predicting dementia reviewed earlier.

These findings on change between pre-morbid and current personality as rated retrospectively by an informant are broadly supported by studies where the current personality ratings of people with dementia have been compared with a control group of similar age but without dementia. A meta-analysis of such studies has been reported by D'Iorio and colleagues (2018), including ten studies. People with AD had significantly higher levels of informant-rated neuroticism, and lower levels of conscientiousness, openness, agreeableness, and extraversion than comparison groups. The results were similar where people with AD had rated their own personality, except that they reported similar levels of conscientiousness and agreeableness to the comparison groups.

Several studies have begun to explore whether the reported personality changes are specific to AD, or are a more general feature of neurodegenerative disorders. For example, Torrente and colleagues (2014) report changes in informant ratings of personality (current vs ten years ago), in a mixed sample of 50 patients. The changes were broadly similar for people with diagnoses of AD, primary progressive aphasia (PPA) and behavioural-variant frontotemporal dementia (bv-FTD). The exception to the pattern of higher neuroticism, lower conscientiousness, and lower extraversion was for bv-FTD, where no change in neuroticism was noted. Lykou and colleagues (2013) report similar results for a small sample (total 42) of people with AD, mild cognitive impairment, and bv-FTD, with the latter group showing reduced neuroticism compared with the pre-morbid rating.

Although more research is needed, the robustness of the personality changes reported and consistent findings across studies and samples suggests that they may reflect adaptation to neurodegeneration, as well as the potential for resilience to the effects of neuropathology discussed previously. Thus, the reduction in extraversion may reflect the withdrawal from social contact and social roles typically seen in dementia; the reduced (informant-rated) conscientiousness may arise from difficulty in maintaining previous standards in view of the cognitive impairment; and the increased neuroticism may reflect the presence of increased uncertainty and vulnerability for the person with dementia. In bv-FTD, plausibly the specific neuropathology provides some protection from these worries and concerns.

In contrast to these consistent changes in personality, evidence is emerging of stability in self-concept (Clare et al., 2012). The Tennessee Self Concept Scale (short-form) was completed by 95 people with early-stage dementia in the MIDAS study, and scores were consistent with normative values and distribution. Over a 20-month period, scores did not

The effects of ageing on personality

change significantly, although there was a downward trend. Lower self-concept scores were related to higher scores on depression and anxiety scales and on a memory test; potentially, those with better memory are more able to recall and recognize the changes occurring. Discrepancies with a carer's rating of the person's self-concept on the same scale were small, and were predicted by level of caregiver distress. Maintaining self-concept appeared to be important for the maintenance of quality of life in this sample.

Does personality influence dementia presentation?

Kitwood (1997) included pre-morbid personality as one of the variables influencing dementia presentation, and there is some evidence that personality variables influence quality of life of people living with dementia. For example, higher self-reported conscientiousness as well as a more positive self-concept were associated with better quality of life as rated by the person with dementia in the MIDAS study (Woods et al., 2014). The relationship of conscientiousness to quality of life was explained in part by the associations between conscientiousness and self-concept and with lower depressed mood.

There has also been interest in whether behaviour that challenges in dementia may relate to pre-morbid personality traits. In other words, do certain personality traits lead to the person with dementia being more vulnerable to experiencing distress and interpersonal difficulties. Osborne and colleagues (2010a) conducted a systematic review of this relationship and identified 18 eligible studies involving 1,417 people with dementia where the studies had made use of a comprehensive pre-morbid personality assessment. They report that 72% of the studies reviewed did find a significant relationship between pre-morbid personality and behaviour. Pre-morbid neuroticism was related, perhaps unsurprisingly, to mood, but also to aggression and overall behavioural problems. There were also suggestions that those who were rated as less agreeable in earlier life were more likely to be aggressive and those who were rated as having been extraverted were less likely to wander.

Other studies, not included in Osborne and colleagues' review, provide mixed support for the overall findings. Whall and colleagues (2008) report a small but significant association between lower pre-morbid agreeableness and aggression during a shower bath, but Beck and colleagues (2011) report that *higher* pre-morbid agreeableness was related to (non-aggressive) persistent vocalization. This is a timely reminder that the factors underlying different types of challenging behaviour may well be different. Pocnet and colleagues (2013) failed to identify a relationship between pre-morbid personality and behavioural problems in people in the early stages of AD. They point out that personality does typically change as dementia develops (as mentioned previously), and at the same time behavioural problems may well develop, but that any causal relationship between the two is likely to be complex.

The effects of ageing on personality

Sutin and colleagues (2018) report analyses of data from a large population study (the Health and Retirement Study), identifying 1,988 participants who had shown cognitive impairment before death, and who had completed a self-report personality measure up to eight years previously. An informant was asked whether a number of behavioural problems had occurred during the last year of the person's life. Higher levels of self-reported neuroticism were associated with a number of problems at the end of life, including depression, hallucinations, wandering off, not being able to be left alone, and uncontrolled temper. These associations were evident irrespective of age, gender, race, or education. Lower conscientiousness was associated with a higher risk of needing someone constantly with the person and with getting lost in familiar places, but was associated with fewer symptoms overall. Agreeableness was associated with less risk of getting lost and extraversion with depression, whereas openness was not associated with any of the behavioural problems included. Although there are advantages to self-report personality ratings, the relatively brief period between the personality rating and the occurrence, if any, of the behavioural problems makes it difficult to be certain to what extent the associations reported relate to life-long traits as opposed to changes in personality related to dementia and its prodromal period.

There has been some considerable interest in the effect of the attachment style of the person with dementia on their behaviour and adjustment (e.g. Miesen, 1993). Attachment style in adulthood is thought to reflect early experiences of parenting, with typically three main styles identified: secure; insecure-ambivalent; and insecure-avoidant. These styles provide a basis for personality traits such as neuroticism, extraversion, and agreeableness.

Magai and colleagues (1997) report results from a group of 27 people with mid to late dementia. Relatives rated lifelong attachment style, and ratings of the person's current emotional state were made by family, care staff, and independent observers. People with dementia rated as having a secure attachment style appeared to show greater positive affect, whereas ratings of pre-morbid hostility were related to ratings of current anger, disgust, and contempt. In a much larger sample of 168 people with mid to late dementia, Magai and Cohen (1998) found that people who were rated by relatives as insecure-ambivalent had increased levels of depression and anxiety. Those rated as insecure-avoidant had higher levels of activity disturbance and paranoid symptoms. Caregivers of people rated as having secure attachment styles reported less overall burden than caregivers of people with dementia who had life-long insecure attachment styles. Browne and Shlosberg (2005), in a sample of 53 people with dementia living in care homes, found that those rated as having life-long insecure-avoidant attachment styles showed more overt attachment behaviours (e.g. following staff, clinging onto visitors) than those rated as securely attached. However, Osborne and colleagues (2010b) report that 'parent fixation' was greater in people with dementia

The effects of ageing on personality

rated as having *lower* levels of insecure anxious (ambivalent) attachment. Parent fixation, defined as the belief that one or other parent was still alive, was also more common in those who were rated as having higher pre-morbid levels of conscientiousness. Neither attachment style nor pre-morbid personality predicted the presence of behavioural consequences of such a belief, such as calling out for a parent or seeking to return to the parental home.

In summary, it appears that there is some evidence that aspects of current and pre-morbid personality are related to the current quality of life, emotional state, and behaviour of the person with dementia, but the precise nature of the relationship needs further exploration. Given that ratings of pre-morbid personality often rely on family members as informants, using other informants for current function is essential to avoid spurious associations that reflect the impact of caregiving rather than an accurate appraisal.

Conclusions

This chapter firstly presented the debate regarding stability and change in personality across the lifespan, especially in relation to the 'Big Five' five-factor model. There is much evidence, in general, for continuity and consistency, but some changes are widely accepted, such as reduced neuroticism and greater conscientiousness. Lifespan developmental models emphasize that change may well be required to maintain stability in the face of changing external and internal circumstances and events, and Erikson's model provides a broad-brush approach, identifying a developmental task specific to later life, reflecting the potential for continued growth.

The model of selective optimization with compensation indicates how individuals can deal with ageing and the age-related tendencies for increased losses and fewer gains, making use of regulatory processes (Baltes, 1993). It has been proposed that the regulation of subjective wellbeing can occur through psychological resources that promote adaptation to adverse situations (Smith et al., 1999; Staudinger et al., 1999). Continuity theory would imply that a lifetime accumulation of experience would aid the development of a resilient self over the years, and this could explain how the self might be the link between various domains of life and wellbeing. Resilience is presented as a concept that captures the reality of development into later life, where the self faces many difficulties, losses, and threats, and yet seeks to maintain wellbeing. Research that has examined the role of resources such as mastery, self-esteem, optimism, and perceptions of social support and social conflict has conceptualized these resources as the core of reserve capacity that provides a resilient basis in older age (Gallo et al., 2005). Although the literature points to the importance of these psychological resources in older age, it is less clear about the maintenance of these resources in the oldest cohorts. The psychological resources that underpin resilience may

The effects of ageing on personality

provide the basis for the maintenance of wellbeing in older age, but it may be that there is an optimal time for their benefit.

In the context of dementia, evidence is emerging of consistent personality changes, especially relating to increased neuroticism and reduced conscientiousness. However, the picture is less clear with respect to the association of pre-morbid personality and current behaviour, except perhaps in relation to neuroticism and depression/anxiety. There is great scope for further work exploring the self in dementia, and the influence of factors such as resilience in this most demanding of challenges.

Finally, Hooker (2002) describes a three-level model of personality, of which the first two have been the main focus of this chapter. Level I relates to traits, as in the five-factor model; Level II includes self-regulatory processes, such as self-efficacy and control processes. Level III reflects the person's life story and is seen in activities with a social component such as remembering, reminiscence, and story-telling. It is also at the heart of Erikson's eighth stage, where the person's life review can enable meaning and coherence to be found in the varied experiences of a life lived. Hooker suggests that 'personality is most clearly revealed in later life', and it is ultimately in the person's life story narrative that the richness and meaning of the individual's personality can be discerned. Personality measures are rarely used in clinical practice (in the UK at least), but careful listening to the person's life story may well, ultimately, be far more informative than a profile of scores from an assessment battery, however useful they may be in a research context.

Sexuality in older age

Chapter: Sexuality in older age

Author(s): Sharron Hinchliff and Bianca Fileborn

DOI: 10.1093/med/9780198807292.003.0050

Introduction

Sexuality is a central part of human life, and remains important across the life-course (Carpenter and DeLamater, 2012). However, sexual activity and late adulthood have typically been positioned as incompatible in public discourses. The deeply entrenched view of the sexless older person has been repeated and reinforced, often unintentionally, in various ways over the past 100 years. For example, Western medical regimes of knowledge, through their focus on treating disease, position old bodies as dysfunctional bodies in decline, including sexual decline. Furthermore, public policy relevant to sexual health has tended to promote ageism through the neglect of older adults in key policy documents such as the UK *National Sexual Health Strategy* (Department of Health, 2001). In wider society, and popular media in particular, a reluctance to pair sexual agency with older adults serves to reinforce the view that sex is the preserve of the young (Gill, 2008). The combined force of these powerful

Sexuality in older age

discourses and highly visible messages in Western societies has meant that later life sexuality has seldom been acknowledged.

However, over the past 30 years this has started to change. The sexual agency of older adults and their sexual health and wellbeing needs are now being recognized. Research in the area of older age sexuality has grown during this time, and there is now consistent evidence that sexual activity is important to the quality of life of many older adults. Sexual activity and satisfaction have been acknowledged for their benefits to wellbeing and physical health in older age (DeLamater, 2012; Træen et al., 2017a). And many people aged 60 and older (78% of women and 91% of men) consider sexual activity as important to their sense of wellbeing (Ferris, Smith et al., 2008) (more later). Nonetheless, health professionals can find it difficult to communicate about sexual matters with their patients. This chapter discusses the numerous reasons for this, and ageism is a major factor.

Ageism is pervasive and taken for granted, and has been described as being more socially condoned in Western societies than racism and sexism (North and Fiske 2012). Ageism can be exacerbated when older age intersects with other social categories such as sexual orientation, gender identity, socioeconomic position, and race/ethnic group. Older adults can face multiple stigma and being part of a marginalized group can have significant consequences as members not only lose power, but also face other inequalities (Calasanti and Slevin, 2006). According to the World Health Organization, sexuality encompasses 'sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction' and is 'experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles and relationships'. So, when older age is coupled with sexuality, which is highly politicized and 'subject to power relations in both the private and public domains' (Heidari, 2015, p. 1), older adults can experience discrimination on a number of intersecting levels.

The majority of research on ageing and sexuality is conducted in high- and middle-income countries, which creates a bias in the evidence base. Where possible, we have included evidence from non-Western countries, but recognize that our chapter is predominantly Western focused. Similarly, the literature is biased towards those who are heterosexual and cisgender. So, we recommend caution when applying the literature in this chapter to those with non-binary gender identities and diverse sexual orientations.

We have included guidance to help professionals to be aware of sexuality issues that may affect their patients, as well as suggestions to help them open a dialogue. This guidance is suitable for patients of any sexual orientation. We have described our 'Three Ps' framework: Privacy, Permission, and Practice, which provides practical advice on talking to patients about sex, including how to start the conversation, and ways to facilitate comfort for both the patient and health professional. Many

Sexuality in older age

professionals carry their biases into their work, and are often unaware that these biases influence the way they respond to other people. For this reason, we have included an activity aimed at helping professionals explore their own practice and awareness of sexuality issues. But first, we discuss the key areas in the field of older adults and sexuality, starting with sex in later life, the sexual rights of older adults, sexual health, sexual violence, sexual communication and consent, sexual difficulties, and the barriers that older adults and health professionals face when communicating about sex in a healthcare context.

Sex in later life—a snapshot

Contrary to the stereotype that older adults are ‘asexual’ or no longer interested in sex, a growing body of research evidence suggests that many older individuals remain sexually active (Fileborn et al., 2015a; Fileborn et al., 2015b; Gott, 2001; Gott and Hinchliff, 2003; Gott et al., 2004; Minichiello et al., 2004). Although rates of sexual activity decline as we age, and particularly as we enter ‘deeper’ older age (Field et al., 2013; Karraker and DeLamater, 2013; Lindau et al., 2007; Schick et al., 2010), it is clear that many continue to engage in a diverse array of sexual practices across the life-course. U.S.-based research by Herbenick and colleagues (2010), with a nationally-representative sample of adults up to age 94, found that 53.5% of 60–69-year-old men, and 42.9% of men aged 70 and older, had vaginal intercourse in the past 12 months. 34.3% of 60–69-year-old men, and 24.3% of men aged 70+, reported performing oral sex on a woman. For older women, 23.4% of 60–69-year olds, and 6.8% of those in the 70+ category respectively reported having vaginal intercourse in the past 12 months. Women in these age groups were slightly more likely to report receiving oral sex from a male partner in the past 12 months, with 24.8% of women age 60–69, and 7.8% of women 70+ having done so.

The extent to which older adults are viewed as sexually active also depends on how we define ‘sex’, with older adults themselves tending to define sex in a broad way (Fileborn et al., 2016a; Gott, 2005; Helmes and Chapman, 2012; Karraker and DeLamater, 2013; Sandberg, 2013b; Trudel et al., 2014). U.S.-based research, for example, found that those in their 50s and older were more likely to have engaged in masturbation, rather than partnered sexual activity, in the past 12 months (Herbenick et al., 2010). Trudel and colleagues (2014, p. e45) further argued that older adults’ sexual desire may be better understood as ‘a characteristic of wanting more varied sexual activities with less genital activity, less based on performance, and could be characterized by persisted interest in sexuality in a broad sense’. As such, studies which focus on penetrative sex may underestimate the extent and richness of older adults’ sexual lives (Minichiello et al., 2004).

Research has consistently illustrated that sex in later life is highly gendered, with men reporting greater levels of sexual interest and activity, and placing a higher level of importance on sex, in comparison to

Sexuality in older age

women (Bergstrom-Walan and Nielsen, 1990; DeLamater and Koepsel, 2015; Karraker and DeLamater, 2013; Lindau et al., 2007; Minichiello, Plummer and Loxton, 2000, 2004). The reasons for this gendered disparity appear to relate largely to gendered norms regarding the acceptability of sexual desire and expression, the decrease in availability of sexual partners for heterosexual women as they age, and heterosexual women tending to partner with men who are older than them (Berdychevsky and Nimrod, 2016; DeLamater, 2012; DeLamater and Sill, 2005; Gott, 2001; Karraker and DeLamater, 2013; Lindau et al., 2007; Schick et al., 2010).

What shapes rates of sexual activity in later life?

Continued participation in consensual sexual activity, broadly defined, has been associated with a range of benefits (DeLamater, 2012), including an increased sense of wellbeing (Berdychevsky and Nimrod, 2016), better physical and psychological health outcomes (DeLamater, 2012; DeLamater and Koepsel, 2015; Gott and Hinchliff, 2003), physical pleasure and enjoyment (Berdychevsky and Nimrod, 2016; Fileborn et al., 2016a; Weeks, 2002), strengthened relationships, and enhanced intimacy (Berdychevsky and Nimrod, 2016; Fileborn et al., 2016a; Heiman et al., 2011; Trudel et al., 2014; Weeks, 2002). However, poor health is associated with reduced sexual activity (Field et al., 2013; Karraker and DeLamater, 2013; Lindau et al., 2007), and it is unclear whether sexual activity directly contributes towards 'good' health and wellbeing, or whether those who are already healthy are more likely to have sex.

Reduced interest or participation in sexual activity is associated with a range of complex factors that extend beyond simplistic biological and functional decline models of sexuality (DeLamater and Still, 2005; Hinchliff, Gott and Ingleton, 2010; Gott, 2005; Minichiello, Plummer and Loxton, 2004). For example, older adults may reprioritize the importance of sex in their lives upon the loss of a partner or the onset of significant health issues (Gott, 2005). DeLamater and Sill (2005) proposed that we should take what they term a 'biopsychosocial' model of sexuality in later life. They argue that sexual desire and function are shaped by a range of complex, intertwining factors including (DeLamater and Sill, 2005, p. 138; see also DeLamater, 2012):

- Biological: such as good or poor physical health, hormone levels, use of medications, and physiological function of our sexual organs as we age;
- Psychological: such as depression and other mental health challenges, our learned attitudes towards and beliefs about sex and sex in later life (for example, adhering to the belief that sex in later life is 'inappropriate'; see also Weeks, 2002), and the information or education we have received about sex and sexuality, and;
- Social: such as having a sexual partner, relationship duration, relationship quality and satisfaction (with those who are more satisfied

with their relationships reporting higher levels of sexual activity), and socio-economic status

Sex can be an important part of older adults' lives and sense of identity (Berdychevsky and Nimrod, 2016; Fileborn et al., 2016a). However, this is not to say that older individuals express themselves sexually in the same ways as their younger counterparts, or that there is no change in sexual function, desire, or identity (Trudel et al., 2014). Rather, it is to acknowledge that these changes do not result in older adults' sexual lives and sexual expression being 'less than' those of younger people (Fileborn et al., 2016a; Sandberg 2013a; Trudel et al., 2014). It is likewise important to recognize and acknowledge the diversity in older adults' desires and experiences: some individuals may indeed lose interest in sex as they come into later life (De Lamater and Sill, 2005; Karraker and DeLamater, 2013; Lindau et al., 2007). Older heterosexual women, for example, can express a sense of relief at no longer having penetrative sex (Berdychevsky and Nimrod, 2016; Fileborn et al., 2015a). Thus, in recognizing the rights of older individuals to remain sexually active, we must simultaneously acknowledge and respect their rights to *not* engage in sexual activity. Additionally, partnered sexual encounters should be mutually desired and consented to, and we address the emergent issue of sexual violence against older adults and sexual consent later in this chapter.

Shifting relationship contexts

In understanding the sexual lives of contemporary older adults, it is vital to consider the changing social and cultural contexts in which their sexual and romantic relationships are taking place. 'Baby Boomers'—those born in the decades following the Second World War—are commonly heralded as approaching sex and ageing differently to earlier generations, challenging pre-established norms of an asexual later life (Adams et al., 2003; Bourne and Minichiello, 2009; Fileborn et al., 2015a,b; Gott, 2006; Kirkman, Dickson-Swift and Fox, 2015). Within the Anglophone West, many of those coming into later life lived through the sexual revolution of the 1960s and gay and lesbian rights movement of the following decades, witnessed substantive changes to sexual norms and the acceptability of casual sex and sex outside of marriage, further aided by the development of reproductive technologies such as the oral contraceptive pill (Fileborn et al., 2015a; Gott, 2005; Kontula and Haavio-Mannila, 2009; Lyons et al., 2015; Nash et al., 2015; Smith et al., 2010). The introduction of no-fault divorce, and shifting acceptability of repartnering after the end of a marriage or death of a spouse likewise opened up opportunities for sexual and romantic relationships later in life (Bateson, Weisberg, McCaffery and Luscombe 2012; DeLamater, 2012; Gott, 2006; Nash et al., 2015; Smith et al., 2010). Developments such as online dating have revolutionized the process of meeting new romantic and sexual partners, and older individuals are embracing their use

Sexuality in older age

(Adams et al., 2003; Bateson et al., 2012; Malta, 2007; Malta and Farquharson, 2014).

Relationship styles and structures are likewise shifting. There is evidence to suggest, for example, that older adults are engaging in casual dating to a greater extent than their predecessors (Sears-Roberts Alterovitz and Mendelsohn, 2011). Some older women are also remaining single by choice, unwilling to (re)enter into new heterosexual relationships particularly where they may be expected to take up traditional gender roles based on 'wife' or 'carer' (Fileborn et al., 2015a,b). Others are 'living apart together', where couples form long-term relationships while maintaining independent living arrangements. Qualitative Australian research has documented older individuals engaging in what might be considered 'non-traditional' relationship styles (Kirkman et al., 2015). This includes 'friends-with benefits relationships', in which 'people have a friendship which includes a sexual relationship that is repeated or ongoing, yet do not live together or call themselves a couple' (Kirkman et al., 2015, p. 267), and open or non-monogamous relationships. Conversely, couples may divorce or separate yet remain living together, and this can again shift the sexual and power dynamics of the relationship. While evidence for these innovative relationship styles is largely based on small-scale qualitative research, it is nonetheless clear that sexual and romantic relationship arrangements are changing. We can no longer assume that heterosexual, monogamous marriage for life is the 'norm'.

Together, these significant social, cultural, legal, and technological advances have arguably increased both the acceptability of, and opportunities for, engaging in new romantic and sexual relationships in later life. These changes have also put the sexual health and wellbeing of older cohorts on the agenda, perhaps for the first time. As we outline in this chapter, it is becoming increasingly apparent that the sexual health and wellbeing of older adults must be included in health practice and policy.

The sexual rights of older adults

The increasing recognition of the sexual agency and sexual expression of older adults, alongside broader societal awareness of gender identity and sexual orientation, has prompted calls for the sexual rights of older adults to be acknowledged and met. Research on the sexual health and sexual wellbeing of older adults has been slowly growing. And research that explores sexual orientation in older age, and its connection with healthcare, is beginning to thrive (see, for example, Barrett et al., 2015). Such work is helping to shape the sexual rights arena, even though very few attempts, in research and practice, have focused specifically on the topic of the sexual rights of older adults.

Sexuality in older age

One reason for this may be because sexual rights have been considered predominantly in relation to young people. Traditionally, sexual rights have been promoted as a young person's issue because of the reproductive focus of public health. The umbrella of 'sexual and reproductive health' has excluded anyone who sits outside of this (narrow) definition, including those in same-sex relationships, and those deemed to be passed reproductive age. While young people are certainly more at risk of unintended pregnancies, and of acquiring a sexually transmitted infection (STI), older adults have been stereotyped as people who are not sexually active, and certainly not people who take sexual risks (we challenge this view later in the chapter). Assumptions such as these have worked to prevent progress in the area of the sexual rights of older adults.

Viewing sexual rights solely within the context of young people reflects the neglect of older adults from the area of sexual health overall. It is as though issues related to sexuality simply do not matter to older adults, or do not have relevance to their health and healthcare. However, this has started to shift and sexual rights have begun to be applied broadly. The influence of activist groups with an interest in the rights of marginalized groups, e.g. lesbian, gay, transgender, intersex, have played a role in helping to shape the sexual rights agenda away from a narrow reproductive focus. The sexual rights of older adults are beginning to be taken seriously, and a clear sexual rights agenda is being set by those who work with older adults and who can transform the service provision landscape.

In 2018, Barrett and Hinchliff proposed a sexual rights framework for older adults based on the Declaration of Sexual Rights from the World Association for Sexual Health. The framework connects fully with human rights, emphasizes empowerment, acknowledges diversity, and recognizes sexual pleasure (Barrett and Hinchliff, 2018). It has 15 key domains (Box 50.1).

Box 50.1 Sexual rights framework for older adults

The right to:

1. Equality and non-discrimination
2. Life, liberty, and security
3. Autonomy and bodily integrity
4. To be free from torture and cruel, inhuman, or degrading treatment or punishment
5. To be free from all forms of violence and coercion
6. Privacy
7. The highest attainable standard of health, including sexual health
8. Enjoy the benefits of scientific progress and its application

Sexuality in older age

9. Information
10. Education and the right to comprehensive sexuality education
11. Enter, form, and dissolve marriage and other similar types of relationships
12. Freedom of thought, opinion, and expression
13. Freedom of association and peaceful assembly
14. Participation in public and political life
15. Access to justice, remedies, and redress

A sexual rights framework is required because not all who work in aged care, including health professionals and service providers, are aware that sexual rights can and should be applied to older adults. In these instances, unintentional violations of sexual rights can occur. The framework, when applied in professional practice, will ensure that older adults are treated with dignity and respect, and are able to contribute towards informed decisions about their health and wellbeing. It will help to address inequalities in practice and service provision. Applying a rights-based framework to practice and service delivery can therefore help to promote awareness among staff, and to improve health services. Education that is built on a sexual rights framework can improve patient outcomes, and may be of particular relevance to the psychiatric context with regard to helping to prevent sexual risk behaviours (discussed further on).

Research in the area of older adults' sexualities has identified key recurring themes: invisibility, silencing, prejudice, discrimination, and lack of awareness and understanding from professionals (see Barrett and Hinchliff, 2018). A key obstacle to promoting the sexual rights of older adults, and ensuring that accessible and appropriate support is available, is the resistance to sexual rights per se across the world (Scientific and Technical Advisory Group and Gender Rights Advisory Panel, 2017). This is confounded by the current lack of a specific human rights convention for older adults. But a sexual rights framework for older adults is necessary and desperately required. Ageist attitudes and behaviours can affect *all* aspects of health and social care, with potentially damaging consequences.

Key Points

- Older adults have sexual rights.
- A sexual rights framework protects people from prejudice and discrimination.
- Service delivery and practice that employ a sexual rights framework will see better patient outcomes.

Sexual health and sexually transmitted infections in later life

Being older should not prevent clinicians from considering STIs in their patient group. While many are aware that people with severe mental illness can engage in sexual risk-taking, and thus high diagnoses of STIs are made (De Hert et al., 2011; Hallett and Rees, 2017), there may be less awareness that STIs are increasingly diagnosed in older age groups. STIs are on the rise among older individuals across Western countries including the US, Canada, the UK, and Australia (Bodley-Tickell et al., 2008; Minichiello et al., 2012; Spring, 2015). STI surveillance reports show that, although older adults face a considerably lower risk of new STI infection compared to younger age groups, STI rates in older populations have, nonetheless, steadily increased. STI surveillance data from the UK, for example, show that rates of chlamydia in the 65+ age group increased from 1.6 per 100,000 to 3.0 per 100,000 from 2011–2015 (Public Health England, 2015). Over the same time period and age group, gonorrhoea infections increased from 0.9 to 1.8 per 100,000 (Public Health England, 2015).

Older adults may face some unique risks when it comes to STI transmission. Reduced production of ‘natural’ lubrication and thinning of the vaginal wall can place older women at a greater risk of STIs due to the increased likelihood of cuts and tears facilitating transmission (Minkin, 2010; Slinkard and Kazer, 2011; Spring, 2015). The routine omission of older adults from sexual health educational campaigns and policy works to construct safer sex and sexual health as a ‘young person’s’ issue of little relevance to older individuals (Bodley-Tickell et al., 2008).

What do we know about safer sex practices of older adults?

Research to date indicates that, while older individuals use a range of safer sexual practices, they typically do so in inconsistent and context-dependent ways (Bourne and Minichiello, 2009; Fileborn et al., 2017a; Foster et al., 2012; Reece et al., 2010). Condom use, for example, tends to occur at higher rates in new or casual relationships (Schick et al., 2010), and may be phased out or not used if a partner is perceived as ‘trustworthy’ (Fileborn et al., 2017a), while those who are single report higher rates of condom use than those in relationships (Bourne and Minichiello, 2009; Reece et al., 2010). This suggests that decisions about safer sex may be based on value judgments, rather than knowledge of STI status. The use of value judgments was further evidenced in another Australian study, which found that although women over age 40 were more likely to talk to a sexual partner about STIs than their younger counterparts, they were ‘less likely to refuse sex without a condom’ (Bateson et al., 2012, p.152). US- and UK-based research illustrates that older individuals have consistently low rates of condom use, and lower rates of condom use than younger age groups (Foster et

Sexuality in older age

al., 2012; Gott, 2005; Reece et al., 2010; Sanders et al., 2010; Schick et al., 2010).

Patterns of condom use are gendered. An Australian study of 2,438 individuals aged 50 or older presenting at a sexual health clinic found that men (54%) were much more likely than women (19%) to report condom use in the past three months (Bourne and Minichiello, 2009; see also Reece et al., 2010). Altschuler and Rhee (2015) argue that women's ability to negotiate condom use is closely tied to relationship power and self-esteem, 'with women who do not experience or command enough power in their relationships not insisting on condoms' (p. 301). Some women in Altschuler and Rhee's study were also met with violence or anger from male partners after requesting that they use a condom. Thus, older women's 'risky' sexual practices must be understood within a context of disparate gendered power relations, *in conjunction with* the systematic devaluing of older adults. In contrast, research from the UK (Gott, 2001, 2005) and the US (Foster et al., 2012) found that older men were more likely to engage in risky sexual practices than women.

Participants in Fileborn and colleagues' (2017a) study reported using a range of safer sex practices in addition to or instead of condoms. These included:

- Being in a monogamous relationship;
- Talking to their partner about their sexual history;
- Having an STI test, and;
- Engaging in lower-risk sexual practices (e.g., non-penetrative sex).

However, these strategies were not consistently used in all contexts where there was some likelihood of STI transmission. As with condom use, rates of STI testing in older cohorts also appear to be low (Schick et al., 2010).

Gott's (2001) UK-based research indicates that some older adults engage in risky sexual behaviour—in this case defined as inconsistent condom use despite having more than one sexual partner in the past five years—with 7% (n = 21) of participants (n = 319) falling into this category. Widowed heterosexual men who use erectile-enhancing medications are also more likely to engage in risk-taking sexual behaviour, as well as having greater opportunity to meet new sexual partners (Smith and Christakis, 2009). Delays in help-seeking behaviour and STI testing can result in older adults presenting with more severe symptoms, while ageist assumptions regarding older adults as 'asexual' can contribute towards delays in diagnosis or misdiagnosis (Minkin, 2010; Wilson, 2006). This is further compounded by the fact that some of the common symptoms of STIs and HIV overlap with common 'symptoms' of ageing (Nash et al., 2015).

Sexuality in older age

Together, this body of research suggests that older individuals who are ‘at risk’ of contracting an STI (i.e., those entering new relationships, dating casually, or with multiple sexual partners) may require support from healthcare professionals. As Minichiello and colleagues (2004, p. 125) note, ‘it is not age that decreases or increases risk [of STIs], but sexual practices’, suggesting that we must strive to be inclusive of sexual health needs across the life-course.

Knowledge of and attitudes about safer sex

Typically, older individuals did not receive comprehensive sexualities education at school. While the extent to which sex education was provided is contested, and historical work suggests that *some* sex education was generally provided (Carter, 2001; Cook, 2012), on the whole we cannot assume that older individuals have received extensive opportunities to learn about safer sex and sexual health (Fileborn et al., 2016b; Ross et al., 2013; Smith and Schmall, 1983). Even for those who did receive sexuality education when younger, this information may now be outdated or forgotten (Smith and Schmall, 1983).

Although a small number of sexuality education programmes targeted towards older adults have been developed (e.g., Garrity, 2010), contemporary sexualities education, safer sex campaigns, and sexual health policy are almost exclusively targeted towards younger people (Bodley-Tickell et al., 2008; Bourne and Minichiello, 2009; DeLamater, 2012; Gott, 2001, 2005; Kirkman et al., 2013; Kirkman et al., 2016). Conversely, ageing policy rarely considers the sexual health and wellbeing needs of older adults (DeLamater, 2012). This is further fuelled by the assumption that older individuals are ‘asexual’ or ‘past it’, and thus do not require information on sexual health (Altschuler and Katz, 2015; Kirkman et al., 2016; Ross et al., 2013). Older adults rely on sources including the Internet, media, and healthcare providers (Fileborn et al., 2016b; Slinkard and Kazer, 2011) to find information about sexual health. However, Australian research suggests that seeking such information is not common (Fileborn et al., 2016b).

There is evidence that older adults have some gaps in their knowledge on safer sex (Lyons et al., 2017; Ross et al., 2013; Smith and Schmall, 1983). For instance, participants in a qualitative Australian study tended to overemphasize the use of condoms as constituting ‘safer sex’, and were less likely to discuss strategies such as having an STI test and engaging in lower-risk sexual practices (Fileborn et al., 2017a). Older individuals may overestimate the level of protection provided by condoms, and have lower knowledge of how certain STIs, e.g. chlamydia, gonorrhoea, and genital warts, are transmitted (Lyons et al., 2017). Canadian research with 202 women aged 50 and older found that participants had ‘moderate levels of knowledge pertaining to general sexual health issues’, with slightly lower levels of knowledge on HIV/AIDS specific issues (Ross et al., 2013, p. 171; see also Foster et al., 2012). Knowledge about STIs and

Sexuality in older age

safer sex is gendered, with women typically having better knowledge than their male counterparts (Lyons et al., 2017).

Challenges or barriers to safer sex

The limited research on older adults' use of safer sex practices suggests that they can face a range of barriers to having safer sex. Recent Australian research (Fileborn et al., 2017b), for example, illustrated that commonly encountered barriers included:

Embarrassment: some older individuals were too embarrassed to discuss the need to use condoms or other types of safer sex.

Stigma: the need to use safer sex practices was associated with 'loose', 'promiscuous', or 'dirty' individuals. Stigma could make it difficult to discuss safer sex with a partner, for fear of offending them or implying that they must be 'promiscuous'. Gender also comes into play here, with women subject to negative responses and judgment more so than their male counterparts (as noted earlier). US research indicates that stigma is also shaped by race, with Lichtenstein (2008) reporting that African-American elders were more likely to perpetuate STI-related stigma than white participants—a phenomenon which is itself embedded in histories of racism and discrimination, and the social construction of black elders as 'morally upstanding'. Adherence to STI-stigma was also associated with 'desires to delay or avoid treatment for STIs' (Lichtenstein, 2008, p. 111).

Erectile difficulties: some older men were reluctant to use condoms, as doing so would result in them losing their erection.

Lacking the requisite skills and safer sex culture: many participants had grown up in the pre-AIDS era where comprehensive sex education not was provided, 'safe sex' tended to refer to pregnancy prevention (see also Bodley-Tickell et al., 2008; Fileborn et al., 2016a; Nash et al., 2015; Spring, 2015), and safer sex was not seen as relevant to long-term, monogamous relationships. As a result, some older adults may lack confidence and skills in using different safer sex practices (see also Foster et al., 2012), negotiating the use of safer sex practices (see also Bateson et al., 2012; Bourne and Minichiello, 2009; Smith et al., 2010), or may not incorporate safer sex as a routine part of their sexual lives (see also Spring, 2015).

Reduced pleasure: the perception that condoms reduced physical sensation was a disincentive to their use. Condom use could also be painful for older women who experience vaginal dryness.

Key points

- STI rates are increasing among older adults.
- Older adults can face a range of barriers to safer sex practices, and use them inconsistently.
- Some older adults have substantial gaps in their knowledge of STIs and safer sex practices.

Sexuality in older age

Sexual violence in later life

For the purposes of this chapter, we take a broad and inclusive approach to defining sexual violence. This is appropriate, given that we draw on research that stems from different legal jurisdictions, and studies that operationalize different definitions of sexual violence. We use the terms sexual violence and sexual assault interchangeably, and take these to refer to the same spectrum of behaviours. The World Health Organization (Krug et al., 2002, p. 149) defines sexual violence as:

Any sexual act, attempt to obtain a sexual act, unwanted sexual comments or advances, or acts to traffic, or otherwise directed, against a person's sexuality using coercion, by any person regardless of their relationship to the victim, in any setting.

Coercion is taken here to 'cover a whole spectrum of degrees of force' beyond physical violence to include 'psychological intimidation, blackmail or other threats ... [or when] the person aggressed is unable to give consent' (Krug et al., 2002, p. 149). Any older person can experience sexual violence. Likewise, it can occur in various relationship contexts, including same-sex relationships. Women can perpetrate this violence, albeit significantly less commonly than men. To date, the majority of research has focused on the experiences of older, heterosexual women.

Prevalence

International research indicates that sexual violence against older adults is relatively uncommon. For example, Bows and Westmarland's (2017) examination of police data in the UK revealed that those aged 60 and over constituted 0.6% of recorded rapes, and 1.4% of sexual assaults by penetration. Bows' (2017b) recent review of this issue found that estimates of sexual violence against older adults in the past 12 months ranged from 0.2%–8%, with these figures varying substantially across studies from different disciplinary and methodological approaches. While older men can be the victims of sexual violence, older women are disproportionately impacted. That is, as with sexual violence at other points in the life-course, sexual violence against older adults is a highly gendered occurrence (Bows, 2017a; Bows and Westmarland, 2017).

However, barriers to reporting and recording sexual offences complicate these findings. Older individuals, particularly those who reside in residential aged care facilities, are routinely excluded from surveys on sexual violence (Fileborn, 2016). Internationally, sources of large-scale data collection on sexual violence often have cut-off ages that exclude older cohorts (Bows, 2017a, 2017b; Bows and Westmarland, 2017; Fileborn, 2016). Different studies draw on diverse definitions of what constitutes sexual violence and, for that matter, 'older age' (Bows, 2017b; Fileborn, 2016). Much of the work done on this topic draws on different disciplinary perspectives, making it difficult to compare findings across this body of work (Bows, 2017a, 2017b; Fileborn, 2016).

Sexuality in older age

It is questionable to what extent older adults themselves understand and identify experiences of sexual violence. For example, older individuals may not recognize or label sexual violence when it occurs in the context of marriage or a long-term relationship (Fileborn, 2016; Mann et al., 2014; Vierthaler, 2008). It is important to recognize that older adults may downplay or minimize their experiences. Older adults with cognitive impairments may be particularly vulnerable to sexual assault, as they may have difficulty explicitly and verbally disclosing their experience (Fileborn, 2016; Mann et al., 2014; Speck et al., 2013).

Myths and stereotypes about sexual violence can also obscure older adults' experiences (Bows and Westmarland, 2017; Fileborn, 2016; Vierthaler, 2008). One such misperception is that sexual assault only happens to 'sexually desirable' or attractive young women, with older women falling outside of this category (Bows and Westmarland, 2017; Fileborn, 2016; Vierthaler, 2008). Indeed, the construction of older women as 'asexual' and undesirable renders them as supposedly unlikely targets for sexual violence (Bows and Westmarland, 2017; Fileborn, 2016). However, this assumption perpetuates the myth that sexual violence occurs because of men's 'uncontrollable' sexual desire, rather than as an act steeped in gender-based power and control (Bows and Westmarland, 2017; Fileborn, 2016). Bows and Westmarland (2017) illustrate how a range of myths and stereotypes has likewise developed about sexual violence against older adults. For instance, 'real' rape against an older person is typically depicted as involving a stranger, as taking place at night, and as occurring in the course of another criminal offence being committed, such as burglary. Further, they argue that older victims are constructed as being especially vulnerable *because of* their age and assumed physical frailty, regardless of whether this was actually a contributing factor. However, while it is undoubtedly problematic to construct older adults as vulnerable to sexual violence solely because of their physical frailty, we suggest it is equally unhelpful to ignore or downplay the material realities of older bodies and the ways in which these may shape older adults' experiences and the impacts of sexual violence. Indeed, some scholars have argued that the physical vulnerability of older adults may place them at increased risk of sexual violence, as some perpetrators may specifically target older adults *because of* this perceived or actual vulnerability (Vierthaler, 2008).

Together, the factors discussed here suggest that current prevalence estimates of sexual violence in later life likely underestimate the extent of this issue.

Sexual violence across the life-course

When considering the sexual assault of older adults, particularly older women, it is important to locate these experiences within a life-course perspective. While the research discussed earlier illustrates women's

Sexuality in older age

experiences in later life, women (and men) may have experienced sexual assault in childhood, adolescence, and across their adult years.

Globally, the World Health Organization estimates that one in three women and girls will experience some form of physical or sexual violence in their lifetime (WHO, 2013). Additionally, one in five girls and between 5–10% of boys are estimated to have experienced sexual violence in childhood (WHO, 2016). Women in particular may experience multiple forms of sexual violence across their life-course. Same-sex attracted and gender-diverse people experience sexual violence at similar, if not higher, rates to those of heterosexual, cisgender women (Fileborn, 2012). Again, there is very little research examining the impacts of these earlier experiences in later life. However, the work that has been done suggests that sexual assault in earlier life may resurface in later years in the following ways (see Clark and Fileborn, 2011):

- Disclosing experiences of sexual violence earlier in life for the first time
- Reliving or having ‘flashbacks’ to earlier experiences of sexual violence, especially those living with dementia or other cognitive impairments
- Aged care and other healthcare facilities can replicate the power dynamics of abuse (e.g., by removing individual control and autonomy), which may be triggering or re-traumatizing for victim-survivors

Aged care professionals should therefore be mindful of the fact that a substantial minority of older individuals will have experienced sexual violence at some point in their lives.

Offending contexts and offenders

Older adults experience sexual violence across a range of different locations and relationship contexts (Bows, 2017b; Fileborn, 2016; Mann et al., 2014). As is the case with sexual violence more generally, the vast majority of perpetrators against older adults are male (Bows, 2017b; Bows and Westmarland, 2017). In their analysis of UK police data, Bows and Westmarland (2017) found that perpetrators were typically younger than their victims. Perpetrators generally know their victims, and this is again consistent with sexual violence across the life-course (Bows and Westmarland, 2017). Perpetrators are most commonly partners or ex-partners, other family members, friends and acquaintances, carers (including informal and unpaid carers, and professional service providers), co-residents in residential care settings, and, less commonly, strangers (Bows, 2017; Bows and Westmarland, 2017; Mann et al., 2014). Sexual assault against older adults occurs across a range of different locations, most commonly in residential settings (such as the victim’s or the perpetrator’s home), or within residential and other care facilities (Bows, 2017b; Bows and Westmarland, 2017).

Sexuality in older age

Impacts of sexual violence

Sexual violence can have a range of physical, psychological, emotional, and social impacts on victim-survivors (Boyd, 2011). Some of these impacts are common to victim-survivors generally, while others are more specific to older victim-survivors. The impacts of sexual violence can occur in the immediate aftermath of an incident, and can also persist in the medium to long term (Boyd, 2011). The particular impacts experienced and their severity varies across individual victim-survivors, and are shaped by contextual factors surrounding the assault (Boyd, 2011; Ullman and Brecklin, 2003). For instance, older women who have experienced multiple forms of violence across their life may have more pronounced and longer-term impacts. However, some authors have argued that older women may experience more intense impacts (Bows, 2017a; Burgess and Morgenbesser, 2005).

Across the research, common identified impacts of sexual violence include (Bows, 2017a,b; Boyd, 2011; deVisser et al., 2007; Ullman and Brecklin, 2003):

- Psychological and emotional impacts:
 - Depression
 - Anxiety
 - Suicidal ideation and/or attempts, and self-harm
 - Fear
 - Memory problems, particularly relating to details of the incident(s), confusion
 - Post-traumatic stress disorder (PTSD)
 - Drug and alcohol abuse/misuse
 - Lower self-esteem
 - Difficulty sleeping, nightmares
 - Crying
 - Becoming withdrawn
 - Distress and changes in 'usual' behaviour patterns. This may be especially relevant for victims who experience cognitive impairments. Distressed behaviour may be particularly prevalent during personal care, such as assistance with showering and toileting, or exhibited towards men
- Physical impacts:
 - Genital injury—to which older women may be more prone (Poulos and Sheridan, 2008)
 - Incontinence
 - Loss of appetite

Sexuality in older age

- Physical injuries, such as bruising, cuts, broken or fractured bones. However, it is important to note that physical injuries only occur in a minority of sexual assaults
 - STIs and HIV
 - Increasingly impaired physical health and illness, including increased mortality (Ullman and Brecklin, 2003; Cook et al., 2013; Speck et al., 2013). This may be enhanced for women who have experienced multiple forms of abuse, or prolonged abuse, across their life
- Social impacts:
 - Withdrawing from friends and family
 - Decreased interest in or fear of engaging in consensual sexual activity, no longer enjoying consensual sex, finding sex painful (dyspareunia)
 - Avoiding social situations
 - Difficulty with trust and intimacy

Professionals working with older clients should be aware of these impacts, which may serve as indicators that someone has experienced sexual violence.

Identifying and responding to sexual assault

There is a dearth of awareness of the specific support needs of older adults who have been sexually assaulted, or regarding what constitutes 'best practice' in identifying and responding to older sexual assault victims (Bows, 2017a; Fileborn and Barrett, 2019; Mann et al., 2014). In this section, we address the small body of research on responding to older victim-survivors, and draw more broadly on research regarding the support needs of victim-survivors.

Recent research suggests that aged care service providers and other professionals can face barriers in recognizing when sexual violence has occurred, and in providing an appropriate response to the victim-survivor. Fileborn and Barrett's (2019) research with aged care service providers identified a range of barriers to implementing best-practice responses, including:

- Lack of institutional policy for how to respond
- Limited knowledge of what constitutes sexual assault (see also Vierthaler, 2008)
- Lack of training on how to respond appropriately
- Defensive responses from family members and/or alleged perpetrators
- Poor or non-existent relationships with support and counselling services. Recent UK-based research with sexual assault professionals

Sexuality in older age

found that they had minimal experience responding to older victim-survivors, suggesting that this group may not be accessing appropriate support (Bows, 2017a)

- The victim-survivor being unable to verbally communicate what has happened (e.g., due to cognitive impairment; see also Bows, 2017a). Some were also unable or unwilling to disclose, for example, due to embarrassment or shame (see also Bows, 2017a)
- The victim-survivor being in poor health, which may decline further post-assault (see also Bows, 2017a)

Bows' (2017a) work with sexual assault professionals likewise identified a range of challenges in providing support to older victim-survivors. These included physical challenges related to the victim-survivor's poor health or mental and physical impairments, similar to that discussed earlier. For Bows' participants, health-related challenges could also pose practical barriers in terms of performing forensic examinations, or for survivors being able to physically access and attend support services.

Evidence suggests that criminal justice professionals such as the police can also respond in problematic ways to older victim-survivors. Most victim-survivors never report their experience to the police, and this is also the case for older people (Connolly et al., 2012; Mann et al., 2014). The limited evidence available on older victim-survivors suggests that when they do report to the police, their cases are less likely to proceed to prosecution. Cognitive function may also play an important role, with research by Burgess and Phillips (2006) finding that sexual assault cases where the older victim had dementia were *less* likely to proceed to prosecution in comparison to older victims without dementia. This is concerning given that older individuals with cognitive impairments may be especially vulnerable to sexual assault (Payne, 2010). Payne (2010) found that cases involving cognitively impaired victims usually required another witness to the assault in order for the case to progress through the justice system, as victims with cognitive impairment may be unable to provide verbal evidence of what has happened (and, we would add, police are likely inadequately trained in communicating with older people with cognitive impairment). However, police and criminal justice system responses to the sexual assault of older individuals is another area that remains largely under-researched: we know little about the experiences of older victim-survivors who report to police, nor about the attitudes of police and criminal justice workers to older victim-survivors and the extent to which these may be shaped by ageist assumptions (Fileborn, 2016; Payne, 2010).

More general research on sexual assault disclosure has found that inappropriate responses to disclosures can also include (Ullman, 2010):

- Expressing disbelief or dismissing the victim's experience
- Blaming the victim for what happened

Sexuality in older age

- Excusing or downplaying the actions of the perpetrator
 - Reporting the experience to others without the victim's consent
- However, there is an important exception here for older adults with mental or cognitive impairments who may be unable to disclose by themselves. In some jurisdictions, healthcare professionals have a legal obligation to report sexual assault that has happened to individuals in their care, and readers should familiarize themselves with relevant legal requirements in their country
- Shifting the focus away from the victim-survivor, e.g., to the emotional response of the disclosure recipient. This is often termed an 'ego-centric' response

It is vital that those who receive a disclosure or become aware that sexual violence may have occurred respond appropriately. The response received can play a substantial role in victim wellbeing and recovery, and in their likelihood to seek further support (Ullman, 2010). The following factors tend to be associated with 'positive' and best-practice responses to sexual violence (Fileborn and Barrett, 2019; Ullman, 2010; Vierthaler, 2008):

- Believing the victim and taking their experience seriously
- Listening to the victim
- Offering tangible support and information, such as putting the victim-survivor in contact with a counselling service
- Avoiding intrusive questioning or 'detective' work. However, the use of gentle, open-ended questions giving the victim space to share their experience in their own words is often appropriate
- Affording the victim control over what happens next (again, with the exception of mandatory reporting requirements)
- Having clear policy and procedures in place in institutional or organizational settings
- Establishing trust and a sense of safety with the victim-survivor
- Being attuned to the victim-survivor's 'usual' behaviour, so that any changes are readily noticed. This may be particularly important for victim-survivors with cognitive or other impairments
- Collaboration and establishing professional relationships between aged care service providers and sexual assault support professionals
- Provision of education and training on sexual violence to aged care and other health professionals. Conversely, sexual violence support workers may benefit from training on elder abuse and other issues related to ageing

Key points

- Sexual violence against older adults appears to be relatively uncommon. However, barriers to reporting and disclosure mean that the true extent of violence is hidden.

- Sexual violence against older adults occurs across various relationship and offending contexts.
- Older individuals with physical and/or cognitive impairments may be particularly vulnerable to sexual violence.
- Sexual violence has short- to long-term impacts on older adults, including physical, psychological and social impacts.
- Aged care and healthcare providers face barriers to identifying and responding appropriately to sexual violence.
- Aged care and healthcare providers require training, and the implementation of organizational policy, to support best-practice responses to sexual violence.

Sexual consent and partner communication

In discussing sexual violence and older adults, it is important to consider the issue of sexual consent. Indeed, consent is often the key factor that distinguishes sexual violence from wanted, agreed sexual encounters. Effective sexual communication—or how we talk to our partners about our sexual wants, needs, and desires—is central in ensuring that sex is consensual, but also in maximizing the likelihood that partnered sex will be mutually pleasurable and fulfilling. Sexual communication has implications for sexual health, for example, being able to effectively discuss and negotiate condom use will in turn shape the likelihood of STI transmission. However, as with many other aspects of older adults' sexual relationships, sexual consent and communication remain highly under-researched. As a result, we know very little about how older adults understand the concept of sexual consent, or how they negotiate consent and pleasure within their sexual relationships.

Sexual consent can be conceptualized in a range of different ways, and has both legal and common-sense definitions. Legal definitions of what constitutes consent, and what needs to have taken place to show that consent was given, vary substantially across jurisdictions. Legal understandings of sexual consent are often not aligned with what sexualities scholars might consider 'best practice' in negotiating sexual consent: legally 'consensual' encounters are not always the same as 'ethical' ones (Gavey, 2005). We outline some criteria for considering whether a sexual encounter has been negotiated in, or consented to, in an 'ethical' manner later in this discussion.

Potential barriers to negotiating sexual consent

Older individuals can face a range of barriers to effectively and openly negotiating sexual consent and pleasure in their relationships. Some of these barriers are encountered across all age groups, while others relate more specifically to older cohorts.

Sexuality in older age

As we alluded to in the previous section, understandings of sexual consent have shifted historically and across different social and cultural contexts (Gavey, 2005). For example, a man's sexual access to his wife was once legally enshrined (and continues to be in many countries outside of the global north), meaning that sexual consent was implied and ongoing within a relationship, rather than something to be negotiated on a continual basis. Outdated notions of sexual consent presumed that the absence of a verbal 'no' was sufficient to indicate consent, rather than consent requiring active and willing participation (sometimes referred to as 'affirmative consent'). Heterosexual sexual scripts—that is, the rules or norms that tend to govern how our sexual encounters unfold—have often been based on the stereotype of men as active pursuers of sex, while women will initially resist and then acquiesce to sex but never actively initiate it themselves (Allen, 2004; Gavey, 2005). Such scripts tie into problematic misconceptions, such as that women say 'no' when they really mean 'yes', which can act as barriers to clear and effective sexual communication. For gay men, there is often the assumption that they are always 'up for' sex, making sexual refusal challenging.

Many of us are resistant to verbally discussing sexual consent and sexual pleasure with partners (Burkett and Hamilton, 2012). Often, this is based on the notion that sex and consent should not require verbal discussion. This is related to the pervasive cultural belief that discussion (for example, asking your partner to use a condom) disrupts the 'natural' flow of sex. Rather, we should 'just know' what our partners want, or believe that subtle bodily cues are sufficient in communicating consent and pleasure. While body language and other nonverbal cues are an important aspect of sexual communication, they are not always sufficient as a form of communication by themselves (Cowling and Reynolds, 2004).

Embarrassment and stigma also play a role. Many of us find it difficult to talk openly about sex and sexual pleasure, given that sex remains a largely taboo topic in many cultures. This embarrassment and stigma is likely heightened for women who grew up in a social context where they were often not supposed to enjoy or actively want sex: it is difficult to express our sexual desires if those desires are not supposed to exist, or are framed as aberrant if they do (Allen, 2003). Relatedly, this may cause challenges in communicating to a partner what we 'want' or enjoy sexually. While this challenge may be experienced by people of all ages and genders, it is likely to be particularly acute for older women (and 'sexual dissidents' such as same-sex attracted people) who may have been inculcated with the message that sex and sexual pleasure are 'wrong' and 'dirty' when growing up, and may have been discouraged from engaging in practices such as masturbation (Fileborn et al., 2015a, 2015b), which play a central role in exploring our own sexual desires and what 'works' for us in providing sexual pleasure. Men can face the pressure to have 'mastered' sexual skills, making any discussion of technique or what a sexual partner wants or enjoys an affront to their masculinity and a potential source of embarrassment.

Sexuality in older age

These gendered dynamics are also relevant when considering the potential consequences of sexual communication. Older women in Fileborn and colleagues' (2017a) qualitative research reported that they were reluctant to refuse sex without a condom out of concern that their partner would leave them for someone else who would have condom-less sex. It is certainly plausible that similar pressures would be experienced when it comes to refusing sexual activity, particularly when coupled with some of the sexual scripts discussed earlier that depict women as the passive recipients of sex. Australian research suggests that heterosexual male partners do not always respond 'well' to women's attempts to discuss their sexual pleasure and partnered practices. Some women in Fileborn and colleagues' (2015a) research, for example, reported that their male partner became angry and defensive when they tried to initiate conversation about their sexual technique, particularly if they adhered to the belief that 'real' sex required penetrative intercourse.

General principles of 'good' communication and negotiating consent

Much of the research on ethical sexual practices has focused on adolescents and young adults. Nonetheless, there are some valuable lessons from this work that will also apply to older adults. Rubin (1992, p. 110) argues that, in fostering ethical sexual practices, our focus should be placed on 'the way partners treat one another, the level of mutual consideration, the presence or absence of coercion, and the quantity and quality of pleasures they provide'. Carmody relatedly asserts that, 'all sexual encounters, regardless of the gender of the people involved, invite the possibility of ethical or unethical sexual behaviour' (2003, p. 201). Both Rubin's and Carmody's approaches to the ethical negotiation of sexual encounters focus on the extent to which the encounter is actively wanted, pleasurable, and enjoyed by both/all parties, rather than certain types of sexual practices and relationships being constructed as 'good' or 'bad' (e.g., anal sex, sex with multiple partners, same-sex relationships, particularly as compared to more 'normative' practices such as monogamous partnerships and penetrative, heterosexual sex). There is no one 'correct' way to communicate and negotiate sexual encounters under such a model. Rather, we must be attentive to the diverse range of ways our sexual partners may indicate their willingness to participate in a sexual encounter, as well as the pleasure they experience (or not).

There are many contextual factors to take into account in considering whether a sexual encounter has been negotiated in an ethical way. While we cannot cover these exhaustively in this chapter, based on the work of Carmody (2009), some key factors include:

- Gendered and other power differentials. For example, is it possible that one partner feels subtly pressured to engage in sex (perhaps they fear their partner will leave them if they refuse, as highlighted earlier)? Is one partner in a position of power over the other, such as an employer/employee? The existence of such power differentials does not mean that ethical, consensual sex *cannot* take place. However, they

Sexuality in older age

do require careful negotiation, particularly on the part of the person in a position of greater power

- Was sex and pleasure actively discussed? However, this should also take into account the diverse ways in which we communicate (e.g., body language, vocal tone, etc.)
- Was the use of condoms or other safer-sex practices discussed? Did all individuals involved feel able to openly raise issues about safer sex?
- Was there space for sex to be refused?
- Were all partners attentive to any signs that someone might be uncomfortable, disinterested in, not consenting to, or not enjoying a sexual encounter? Did they 'check in' with a partner if this was the case?
- Was the context of the sexual encounter taken into account? For example, what quantity of alcohol or other drugs had been consumed? Had anything else happened that might have impaired a partner's capacity to give free and full consent? Might someone feel afraid or unable to say no?
- Did each person involved in an encounter express concern for the physical and emotional safety and wellbeing of their partner, and themselves (that is, did they engage in self-care)?

Consent and dementia

When it comes to sexual consent and older adults, a key consideration is the capacity of those with dementia or other forms of age-related cognitive impairment to meaningfully consent to sex. This is a hotly contested issue, and one for which there are no straightforward answers or solutions. A delicate balancing act is required in ensuring that those living with dementia are protected from sexual harm and abuse (particularly given that people living with dementia may face a higher risk of sexual assault, as discussed earlier), while also ensuring that the sexual rights of the individual are upheld (Bauer et al., 2013; Fileborn 2016; Tarzia et al., 2012).

Living with dementia does not automatically mean that someone is incapable of giving sexual consent, although it may shape the *contexts* in which consent can be given. However, in practice it can be difficult to determine whether an individual is able to consent at any given time, particularly as the cognitive decline associated with dementia is not always linear, and individuals may have moments of lucidity (Archibald, 2002; Fileborn, 2016). Conversely, we must also remain cognizant of the sexual behaviours of older adults living with dementia, and the impact they may have on others. For instance, several qualitative studies (Mann et al., 2014; Fileborn and Barrett, 2019) have documented older women being 'badgered' for sex by male partners living with dementia, with the men unaware of the extent of their demands. In some instances, men with dementia continue to be prescribed erectile-enhancing medications,

Sexuality in older age

contributing towards their (unintentional) harassment of partners. Clinicians in a position to prescribe erectile-enhancing medication to older men with dementia or other cognitive impairments should discuss this with the man's partner if possible.

Key points

- Older adults can encounter barriers to negotiating sexual consent and talking about sex with a partner, including norms about how sex is 'done', gendered power differentials, and shame and stigma associated with sex.
- Ethical sexual encounters focus on the extent to which sex was wanted, free from coercion, and mutually pleasurable.
- Dementia can make it difficult to determine if someone has capacity to consent to sex. However, the sexual rights of an individual living with dementia should be promoted where possible, provided that the potential for abusive or coercive sexual encounters is minimized.

Sexual difficulties in later life

As indicated already, various sexual difficulties can be experienced by older adults. A recent literature review identified that for women the main age-related sexual difficulties were vaginal dryness and discomfort and a lack of interest in sex (Træen et al., 2017b). For men, the main difficulties were erectile dysfunction, low sexual desire, and inability to orgasm (Træen et al., 2017b). While not all older adults will experience a sexual difficulty, the frequency of problems related to sexual desire, orgasm, and sexual function increases with older age (Carpenter and DeLamater, 2012).

Research consistently reports that there is a connection between poor health and sexual difficulties (Træen et al., 2017b), and in particular medical comorbidities (Gewirtz-Meydan and Ayalon, 2016). This could be due to the disease/illness itself, psychological factors connected with it, or indeed the drugs that are used to treat or manage the condition. Many medications prescribed for health problems, including long-term conditions that are more likely to be diagnosed at midlife, have sexual side-effects. For example, some antihypertensive drugs are associated with delayed or absent orgasm in women, and ejaculation dysfunction (dry orgasm) in men (Dean, 2015).

Many of the drugs prescribed to manage mental ill health can induce or exacerbate sexual dysfunctions. For example, SSRIs to treat depression can cause erectile difficulties, lack of interest in sex, and inability to orgasm, and tricyclic antidepressants, which are also used to manage pain, can interfere with the ability to orgasm in both women and men (Wood and Runciman, 2015). Psychotropic drugs that can cause sexual

Sexuality in older age

dysfunction include paliperidone, haloperidol, and aripiprazole (De Hert et al., 2011). Dean (2015) cautions that the various ways of managing drug-related sexual difficulties, such as reducing the dose or substituting the drug, can be risky (e.g. relapse of the condition). Clearly, the treatment and prevention of drug-related sexual difficulties must be balanced against the effective treatment of the condition.

Sexual difficulties are common in patients with a psychiatric diagnosis and relate to various, potentially overlapping, factors, including the illness, physical illness, substance abuse, and medications (Balon, 2015). There is a connection between depression and decreased sexual desire, although we know that antidepressant medicines can also cause this and other sexual difficulties (Balon, 2015). Patients diagnosed with bipolar disorder can experience either 'hypersexuality' or low sexual desire (Balon, 2015). Increased sexual difficulties have been found in people with anxiety-related disorders (Balon, 2015). Research has shown that women and men with schizophrenia report high levels of sexual dysfunction when compared to the general population (Hallett and Rees, 2017). A common dysfunction reported in schizophrenia is decreased sexual desire, although some patients show signs of excessive masturbation (Balon, 2015).

Again, there are usually multiple contributory factors to sexual dysfunction in patients with mental ill health (Dean, 2015; Balon, 2015). As well as those indicated previously, social and interpersonal factors, e.g. relationship quality, sexual performance of the partner, body image, previous sexual trauma, can influence sexual desire, interest, and pleasure (Heiman, Long et al., 2011; Hinchliff, Gott and Ingleton, 2010). But it is important to note that sexual difficulties may not be a cause for concern. Indeed, clinicians should ask this question as many people report a sexual difficulty but do not experience it as a problem (Træen et al., 2017b). There is research evidence which highlights that women who have sex with women manage sexual difficulties better than women in sexual relationships with men (Winterich, 2003). Reasons include their wide repertoire of sexual activity, which is not focused predominantly on penetration, and equal gender relations that enable the negotiation of sexual acts. Taking a sexual history (see the next page: Guidance for health professionals to improve their sexual communication) helps professionals to ask the necessary questions, including about sexual orientation, identify potential factors that interfere with sexual function, and determine the way forward.

Key points

- There is an increased chance of experiencing a sexual difficulty at middle and later life.
- Sexual difficulties can be caused by biological, psychological, or social (interpersonal) factors.

- Medications used to treat health conditions and mental ill health can have serious sexual side effects.
- Not all sexual difficulties are a source of distress to the patient.

Sexual communication between health professionals and older patients

Despite the areas of need outlined throughout this chapter, there is consistent evidence that health professionals tend not to ask older adults about sexually related matters. The reasons vary, and we explore them here. But first it is interesting to note that research conducted in the area of healthcare and older adults' sexual health and sexual wellbeing indicates interesting differences in the perspectives of health professionals and older adults themselves. Quite simply, many older adults report that they want the health professional to ask them about sex, whereas health professionals think that patients should be the ones to raise the topic.

This finding holds particular relevance in the area of psychiatry, where psychiatrists have been found to underestimate the extent to which their patients experience a sexual difficulty. Indeed, Dossenbach and colleagues (2005) examined the prevalence of sexual difficulties in patients with schizophrenia (based on patient reports and psychiatrists' perceptions) and found that psychiatrists underestimated the sexual difficulties their patients could experience; a finding which was statistically significant (at $P < 0.0001$) and internationally relevant (across 27 countries).

Many studies report that older adults want their doctors to be proactive when it comes to sexual health (Bedell et al., 2002; Laumann et al., 2009; Lindau et al., 2007; Moreira et al., 2006; Sarkadi and Rosenqvist, 2001; Warner et al., 2008). But health professionals often think differently, and studies have identified that doctors are rarely proactive with their older patients. For example, they may not provide information about how a health condition can affect sexual function (Bedell et al., 2002; Sarkadi and Rosenqvist, 2001), provide details about STIs after patients have consulted a genito-urinary medicine clinic (Gott, 2001), or offer relevant tests, such as HIV, even when this is suggested by the patient (Lindau et al., 2007). When patients have sought help from their GP for sexual difficulties, there are reports of the GP not being helpful, including not offering treatments such as erection-enhancing medicines in the context of prostate cancer, or not answering patients' questions about sexual problems (Hinchliff et al., 2017; Rutte et al., 2016).

One recent study tested physician (the majority, 77.1%, were general practitioners) responses to a hypothetical male patient who was presenting with occasional erectile difficulties that had a clear

Sexuality in older age

psychosocial aetiology (Gewirtz-Meydan and Ayalon, 2016). Conducted in Israel, two identical vignettes were used, which differed only by the age of the patient: one was aged 28 years, the other aged 78 years. The results highlighted an age bias in terms of how the physicians diagnosed the men. For example, the younger man was more likely to be diagnosed with performance anxiety, and the older man erectile dysfunction. The older man's problem was more likely to be viewed as caused by health issues, hormone changes, and lowered sexual desire. He was more likely to be referred to urology, and advised pharmaceutical treatment such as testosterone replacement therapy and PDE5 inhibitors (e.g. sildenafil). The younger man was more often referred to a sexologist. The authors concluded that the young man received an overall more positive prognosis.

Bouman and Arcelus (2001) also identified differences in the ways in which psychiatrists responded to young and old male patients. They examined the attitudes of UK-based psychiatrists who specialized in either in general psychiatry or late-life psychiatry, and found that the psychiatrists were more likely to refer older patients with a sexual problem to community psychiatric nurses (CPNs), whereas younger (middle-age) patients were referred to sex therapy. Referring patients to CPNs was identified as inappropriate by the authors as CPNs do not receive training in sex therapy. Thus, the referred patients would not receive adequate treatment for their sexual problems. They also identified that both groups of psychiatrists were less likely to take a sexual history of older male patients than they were of younger patients, indicating that it was not appropriate to do so.

The reasons why health professionals do not always manage the sexual healthcare needs of older patients correctly are varied. Barriers that health professionals face include: stereotypes of older age, such as believing that older adults are not sexually active (Gott et al., 2004; Pascoal et al., 2017), or that it is a private topic that the older patient would not wish to discuss (Gott et al., 2004); the older person being seen as a parental figure (Wei and Mayouf, 2009); and the older-old, in that the older the patient, the less likely a physician would raise the issue of sex (Pascoal et al., 2017). Lack of time during consultations and inadequate knowledge of the issues that can affect the sex lives of older adults and their treatments have also been identified (see Hinchliff and Gott, 2011). Health professionals may be pessimistic about the effectiveness of treatments for sexual difficulties: an issue identified more widely in psychological and psychiatric services, and related to the societal assumption that older adults tend to hold negative attitudes (Knight et al., 2003).

In a review of the empirical literature, Hinchliff and Gott (2011) identified that many older adults who had a sexual problem did not seek help. One study in Korea found the 96% of women and 92% of men who reported a sexual problem had not sought professional help but had spoken with friends, family, or partners about it (Moreira et al., 2006). And a UK study

Sexuality in older age

identified that 40% of the sample of older women and men with sexual concerns had not sought professional help (Gott, 2001). Similarly, Rutte and colleagues (2016) found that 69% women and 68% men with type 2 diabetes who lived in the Netherlands experienced sexual difficulties, but not all were aware of the connection between diabetes and sexual difficulties. While few had looked for help for their sexual problem, men were more likely to have done so and this was from their GP. Believing they would be dismissed or receive an 'ageist response' were reasons given by older (heterosexual) Australian participants for not raising the issue of sex with their health professional (Fileborn et al., 2017b). Other barriers to seeking professional help include accessibility of the health setting, patient embarrassment, and preferring to seek help from family or friends (Hinchliff and Gott, 2011). We now look at what health professionals can do to facilitate communication in this area.

Key points

- Health professionals experience barriers to asking older patients about their sexual health and sexual wellbeing.
- Patients do not always disclose their sexual difficulty during consultations.
- Patients want their doctors to be proactive.

Guidance for health professionals to improve their sexual communication

Taking a sexual history is a useful way to collect information about a patient's sexual background and to assess their current levels of sexual activity, sexual function, and feelings about their sex lives. It offers an opportunity for two-way sharing of information, and acts as an indicator of where to go next. Althof, Rosen and colleagues (2013, p. 27) argue that taking a sexual history can 'strengthen the therapeutic alliance' because patients feel as though they are being understood and taken seriously. Further, a sexual history can provide baseline information that will be useful not only at the outset, but during future assessments as it can highlight issues that are causing sexual difficulties. This is important in the area of gerontology and psychiatry where multiple medications may be prescribed. Taking a sexual history at the initial visit and during routine consultations can allow the identification of problems caused by prescription drugs. Indeed, if a change in sexual function or response is noted within four weeks of introducing a new drug, then it is likely that the drug is to blame (Dean, 2015).

Researchers have found there is often reluctance among health professionals to take a sexual history, which is usually due to the perceived acceptability of the topic of sex at a social, institutional, or individual level (Virgolino et al., 2017). Other concerns include uncertainty about how to ask the questions, when to ask them, and where

Sexuality in older age

(Fitter, 2015). We therefore propose the 'Three Ps' approach to sexual communication with patients.

The 'Three Ps'

The 'Three Ps' approach provides practical advice on talking to patients about sex, including how to start the conversation, and ways to facilitate comfort for both the patient and clinician. The 'Three P's approach is based on a review of the literature,¹ and focuses on Privacy, Permission, and Practice.

Privacy—this entails two key aspects:

Ensure that the consultation takes place in a private setting to avoid being overheard or interrupted. Let the patient know that discussions are confidential (and that confidentiality will only be breached under certain circumstances in line with the policy of your service, usually when the patient or another person is at risk of serious harm).

Permission—which works in two ways:

It is imperative that the clinician lets the patient know that they can talk about sexual matters by giving the patient permission to raise it in the consultation. And that the clinician will be comfortable when it has been raised. Clear signs of discomfort (such as fidgeting with a pen, avoiding eye contact) can close down any conversation on this topic because of its sensitivity. To start the conversation, clinicians can request permission to ask about the patient's sex life. Generic questions are helpful here (discussed further on).

Practice—which includes ensuring patient comfort to help disclosure. There are various ways to do this:

Help the patient to feel more at ease by making the consultation less formal (e.g. not sitting directly behind a desk). Consider your own non-verbal behaviours: eye contact and active listening are important skills. Use diagrams, magazine articles, leaflets to help communicate about sexual matters. Develop a set of standard questions, or one opening question to help start the conversation.

Generic questions are useful to begin the conversation, and to ask for/give permission to talk about sex. There are many ways these questions can be phrased; we offer some suggestions here:

'People who I see in clinic sometimes have sexual problems. Have you noticed any difficulties?'

'Sexuality is an important part of life, so if it's okay with you I'd like to ask you some questions about sex as part of your health assessment.'

Sexuality in older age

'Just a few more questions, if that's okay. At this point I normally ask some questions about your sexual health.'

'As part of your assessment, I can take a sexual history. The questions may be sensitive, but they are important and can help me to provide the best care for you.'

'These medications are known to cause sexual difficulties for some people, is that something you have experienced?'

'Some patients lose interest in sex. Is this something that has affected you?'

'Women can experience sexual difficulties around the time of menopause. Have you been affected in this way?'

More direct questioning can follow. As mentioned, the preferred context to take a sexual history is during the patient's first full assessment, rather than when a difficulty has been highlighted. However, this may not be achievable in practice, so remember that taking a sexual history can be executed at any point in the patient's treatment pathway.

The format of a sexual history does not need to be prescriptive: it can be designed to fit the patient group and service provided. It can be tailored accordingly; however, Fitter (2015) suggests that the following areas should be included: the nature of the current sexual problem and the patient's understanding of it; past and current medications (including prescribed, non-prescribed, herbal, performance-enhancing); and past and present sexual relationships, including sexual orientation and gender identity. For specific items to include in these categories, see Fitter, 2015, p. 18.

Other considerations on sexual communication with patients include being aware that they may prefer to talk about sex with a doctor of the same sex and age group as themselves (Hinchliff and Gott, 2011; Omole et al., 2014). This might especially be the case when cultural or religious factors influence who a patient is able to talk about sex with. Taking a sexual history should always be carried out in a way that is culturally sensitive. Likewise, it is important not to assume that patients are heterosexual, particularly during initial consultations. The use of neutral terms such as 'sexual partner', rather than terms such as 'husband' or 'girlfriend', can help avoid this.

Given that the topic can be sensitive, clinicians should bear in mind that a longer appointment may need to be scheduled (Fitter, 2015). Also, that an appointment for the couple may be required. While potentially valuable in that the session provides a safe space to build trust and confidence in sharing information, risks include the patient feeling inhibited to share information in the presence of a partner (Fitter, 2015). Careful consideration of this issue is required. However, remember that referral to appropriate services may be the best course of action. Balon (2015)

Sexuality in older age

argues that sexual difficulties associated with psychiatric disorders are often complex and difficult to manage, and they may require specialist intervention.

Activities to develop staff skills

It is important that clinicians are aware of their own prejudice and should not make assumptions about a patient's sexuality, including whether or not the patient is sexually active, and the type(s) of sexual activity in which a patient engages (Balon, 2015; Taylor and Gosney, 2011). To improve our own awareness of sexuality and comfort in approaching the topic with patients, reflecting on our beliefs about sexuality and attitudes towards sex can be particularly useful. The following questions (adapted from Hallett and Rees, 2017) can guide the reflective activity:

1. Do you consider your patients' sexual health and wellbeing needs? If not, why not?
2. Do you find it difficult talking to patients about their sexual health and wellbeing? If so, why do you think that is?
3. Do you make assumptions about your patients' sexuality?
4. Do you feel comfortable with some people more than others? Why is this? It could relate to assumptions about people and stereotypes e.g. that people who are old, or with a disability, are not sexually active
5. Do you find yourself making judgments about the types of consensual sexual activity a patient has? For example, if they engage in non-traditional practices such as having more than one partner at the same time, group sex, or bondage, discipline, dominance/submission, sadism/masochism (BDSM). If so, why do you think that is?

Another useful activity to help develop communication skills in this area is to observe clinicians who work in psychosexual services (Fitter, 2015). Through training and clinical experience, they have acquired and tested techniques which put patients at ease when discussing sexual issues.

Conclusion

As noted earlier, it is recommended that sexuality is approached from a biopsychosocial model. Taking consideration of the biological, psychological, and social factors that can contribute to sexual difficulties can help us to fully understand and address them. The biopsychosocial model ensures that health professionals consider far more than the biomedical model allows, including the relational, interpersonal, and everyday contexts within which we live our lives. While approaches to treatment for sexual difficulties will vary depending on the specific problem(s) experienced, alongside the mental and/or physical health of the patient, there are some general, yet important, principles to consider. These include viewing the sexual difficulty in context of the patient's intimate relationship. Here, it is important to identify whether or not the

Sexuality in older age

sexual difficulty is a cause of distress, and whether distress is experienced by one or both partners. Relationships can be negatively affected by sexual difficulties, but relationships can also act as a significant source of support and buffer the negative impact of a sexual difficulty. To be a reflective practitioner we also need to be aware of the cultural determinants of the patient's sexuality, as ethnic background can influence what is considered to be a sexual difficulty and the approaches to treating it. Similarly, it is beneficial to identify beliefs that the patient may hold about sexual activity, and help them to negotiate around any unhelpful ideas and expectations.

To achieve the sexual rights of older people we must remember that in many countries older people are marginalized and subjected to damaging prejudice and discrimination simply based on their age. And when being old intersects with other social categories that are in the minority, such as sexual orientation, gender identity, and race, older people can be further marginalized. To add to the mix, individuals with a psychiatric diagnosis may have experienced a lifetime of prejudice and discrimination. It is thus imperative that clinicians are aware of the vulnerabilities that older patients can feel, that professional practice focuses on treating older patients with dignity and respect, and that services ensure that a sexual rights framework is in place.

Introduction

Ethics is about right and wrong, good or bad. Our decisions, if ethical, reflect our morality. It is reasonable to ask what the difference is between ethics and morals. The answer is that the words are mostly used interchangeably. But we can say this:

At root there is not much difference between the two words. 'Ethics' comes from Greek and 'morals' from Latin. Some people use the words slightly differently while others use them interchangeably. Many people associate 'morals' with deep-seated inclinations and intuitions. 'Ethics' are sometimes taken to be the rules and regulations of a group. [...] Ethics can be taken to imply the science of moral reasoning, while moral philosophy can be taken to imply the study of ethical debate and discourse. In

essence, both words are concerned with discriminating good from bad, right from wrong (Hughes and Common, 2015).

A simple way to consider matters would be to say that we have ethical standards as professionals that govern what it is to be a good doctor, nurse, or social worker, and so on, but we have deeper-seated moral obligations as human beings. This is simplistic, because it makes it sound as if somehow professional ethics is a less important topic. It is true that, just as we might sometimes break the law, so too we might ignore professional ethical standards. But there are two points: i) this would be exceptional; and ii) we would have to face the consequences. By and large, our professional ethical standards reflect our deeper-seated moral inclinations. If they did not, then on the grounds of conscience we might (exceptionally) consider breaking them. In any case, what we consider in this chapter are the underlying moral or ethical bases upon which we make our judgments and decisions.

The first point we are going to make is that all clinical decisions are, at one and the same time, ethical by nature. The same idea is conveyed by the idea of values-based practice (VBP), which I describe. We then go on to consider the major ethical theories and approaches. But at this point I raise a question about how we actually put ethics into practice. In the hurly-burly of clinical practice, it seems idealistic to think that we apply moral theories to the decisions and dilemmas we face in a calmly rational and logical manner. I suggest that the notion of patterns of practice might be a useful way to think about what we actually do. I explore this more fully in due course. In clinical practice, we face a huge array of ethical issues, especially in connection with dementia, but in other areas of old age psychiatry too. I highlight such issues, but I also demonstrate that the notion of patterns of practice is useful when we are thinking about these issues.

Clinical decisions are ethical decisions

The most everyday clinical decision, to discharge someone from follow-up, for instance, might be fraught with ethical dilemmas. Have I discharged him too soon? Am I just responding to managerial pressures not to keep people on my books too long? Have I discussed it with the patient in a suitable manner? Was he properly prepared? Are there enough support mechanisms in place? Should I have spoken with his daughter before discharging him? Does he really understand how to take his tablets? Will they be properly monitored by the general practitioner (GP)? Could he still be suicidal? These are all questions and worries about whether I did the right thing. The point to note is that they are also questions and worries about whether I have been a *good* doctor. To take another example, old age psychiatrists should know when and when not to prescribe an antipsychotic, and they should know the correct dosages to use. In all such cases—and this is the point—at one and the same time,

Ethics and old age psychiatry

as well as doing things in a ‘technically’ correct manner, being a good old age psychiatrist entails knowing and doing the right thing ethically.

If I have not properly prepared the person for discharge from follow-up, if I give the antipsychotic solely to settle the complaints from the care workers without thinking about alternative approaches, it is not just that I’ve performed poorly in a technical manner, it’s that I’ve failed to be a *good* clinician. Even if all I do is get the dose of a drug slightly wrong, there is still an ethical component to it. Whatever the excuses, which may be very reasonable (perhaps I’m overworked), I *ought* to get the dosages right. The ‘ought’ is a moral ought. It says that, potentially, I’ve failed in some sense as a good human being if I get this wrong. Getting the dose wrong is not a *good* thing to do. It may not mean that I’m a *bad* human being, but I still have not been as good as I *ought* to be, even if there are plausible excuses and even if the drug error is inconsequential.

I think there are several important points to be drawn from this. To be *good* doctors or nurses or occupational therapists or whatever, by definition we must be professionals who act ethically. Now in many cases, most in fact, the ethical dimensions of our practice will not be overt. I might prescribe paracetamol for a headache knowing instinctively that this is all that is going on and that nothing else needs to be considered. No ethicist is required: it is an easy clinical decision. But this does not mean that such a decision has no ethical connotations. All such decisions are made in the context of an ethical or moral field. After all, I could ignore a complaint about a headache. That I pay some attention to it is driven by my standing as a doctor, where the good thing to do, *qua* doctor, is to take account of the patient’s symptoms and signs. My decisions and judgments are in a sense determined by the background or context, which informs or shapes them, which makes them the clinical or professional judgments that they are (Hughes and Ramplin, 2012).

There will be times when the decisions are more overtly ethical, when I and the team struggle to decide what is right. Perhaps the decisions are so difficult that we need outside advice from a more experienced clinician, who will—just by dint of being more experienced clinically (according to the analysis I’m offering)—also be more experienced at making difficult ethical decisions, whether or not this is recognized. Or, occasionally perhaps, we shall need advice from a clinical ethics committee, where the combined expertise of several different types of professionals and of ethicists can come to bear on a difficult ethical dilemma.

Another point to be drawn from the statement that clinical decisions are ethical decisions concerns the status of the ‘technical’ aspects of the decisions that we make in old age psychiatry. They carry, inherently, ethical weight. That this patient now satisfies the criteria to be given electroconvulsive therapy (ECT) is not *merely* a technical decision. In itself it is (or is not) the ethically right thing to consider: in making this technical decision we are aiming at doing good. But the technical aspects

Ethics and old age psychiatry

of our decisions are not the whole deal. This is precisely because they are made in the context of an ethical field. Mostly the technical and the ethical will go together without our even noticing it. Even if we have made a completely correct technical decision, however, it does not follow that the decision is the right one. Perhaps ECT is indicated, but the patient wishes to wait a little longer and the dangers in waiting can be managed by careful nursing. But what if the dangers are too great? It is yet true that this technically correct decision still needs to be made (and then enacted) in the ethically correct manner. The rightness or wrongness of the decision is not decided purely on technical grounds. Who, for instance, has been involved in the decision? Has the patient been consulted and in what way? Should the decision involve the family? Hence, whether or not the clinical decision is a good one is decided not by the technical but by the ethical details of the case. Indeed, we might decide to do something that 'technically' does not seem best, but might nonetheless be the right thing ethically and we should do it for this very reason. Despite the evidence of psychosis, for example, we agree not to start treatment this week, even if technically we could use compulsory powers to do so, because we wish to establish a degree of trust and a therapeutic relationship with the patient by showing that we respect his views. The ethical trumps the technical because this *is* good clinical practice: clinical decisions are ethical decisions.

Ethics informed or shaped the practice of old age psychiatry when it was in its infancy and it will continue to do so, however technically advanced the field becomes. This is not to downplay the importance of technical know-how, because any professional ethic worth its salt should require that its practitioners are technically competent and up to date.

Yet, *how* we do things will often be of more importance than exactly *what* we do. In this vein, writing of virtue ethics as an approach (to which we shall return shortly), Hursthouse says:

Although I am, personally, sympathetic to doctors rather than otherwise, one does hear occasional hair-raising stories about the arrogance and callousness of some. What people often complain about is not whatever decision the doctors made, but the manner in which they delivered it or acted on it (1999, p. 48)

Values-based practice

Before turning to consider ethical theories and other approaches to ethical issues, it seems worthwhile to notice that the idea that all clinical decisions are at one and the same time ethical is mirrored in VBP, which is regarded as complementary to evidence-based practice (EBP). The evidence and facts are always going to be important, but we must not forget the values. Part of the benefit of VBP is that it reminds us that values are ubiquitous: they are never absent and must always be attended to if things are not to go wrong. Our values guide our actions, but so too

Ethics and old age psychiatry

does evidence: they go hand in hand. Both must be understood. Consider, for instance, someone with severe panic disorder. It might be tempting to suggest a mixture of psychotherapy and medication. But, of course, if the person's values were such that she hates medicines (say she believes in homeopathy) there would be little point in offering medication. A person, on the other hand, whose values were on the side of biomedical interventions, who could not see the point of waiting for talking therapies to work, would not be a candidate for psychotherapy. In both cases, the same evidence base might apply, but it is the values which make the difference in terms of what will work.

VBP describes a process of ten elements under four broad headings (see Table 51.1). It is 'a process that supports balanced decision-making within a framework of shared values where complex and conflicting values are in play' (Fulford et al., 2012, p. 24).

Table 51.1 The ten elements of the process of values-based practice (VBP).		
Clinical skills	1. Awareness of values	Being aware of the values that are in play is crucial to VBP, but it is a skill that must be acquired, especially when there are differences in values
	2. Reasoning about values	Having become aware of values, practitioners need to know how to reason about them, how to compare different moral stances, and understand them
	3. Knowledge of values	Awareness of relevant literature will support clinical decisions and allow negotiations around values
	4. Communication skills	Understanding diverse values and navigating between them will always require good communication skills
Professional relationships	5. Person-centred practice	The person, with his or her values, is always at the centre of the process

Ethics and old age psychiatry

	6. Multidisciplinary team work	But the input of an extended team is crucial, to include everyone concerned in a particular case since all views must be heard
EBP and VBP	7. The two-feet principle	Evidence is important, but so too are values: one cannot be used without the other
	8. The squeaky wheel principle	Values become most obvious when they are diverse and conflicting
	9. The science-driven principle	As science progresses the likelihood of values diversity increases, but both facts and values remain important
Partnership	10. Consensus and dissensus	If consensus can be reached, good; but when it cannot and there is dissensus it still remains important that all of the values, even the divergent ones, are acknowledged and remain potentially in play

Cambridge University Press, Cambridge; data from General Medical Council (2017). Confidentiality: patients' fitness to drive and reporting concerns to the DVLA or DVA. GMC, London.

As well as recognizing values and their importance, VBP also indicates a process that can allow a situation to move forwards when there are difficulties. Imagine someone with advanced dementia where a decision has to be made about whether or not to pursue a treatment, such as antibiotics for a chest infection. It may be that there are different opinions within the care team but also within the family. It is important to acknowledge that there are differences first of all and to understand where they come from. Perhaps one daughter is placing heavy emphasis on something she heard her mother (the person with dementia) once say. Perhaps some staff are recalling how well a previous patient did when

Ethics and old age psychiatry

they received intravenous (IV) antibiotics in hospital. Perhaps it is a son who has deeply held religious beliefs that motivate his desire for everything that can be done to be done for his mother. Good communication will allow the different values to be expressed and negotiated, so that it is clear what everyone is saying. Knowledge about some of the values, e.g. religious beliefs, might be helpful. Keeping the mother centre stage, along with her values, is important, but the values of others should not be ignored. It will be useful to have the input of all the members of the multidisciplinary team, so that different perspectives are represented. Although there are diverse values, it may be that a consensus can be reached once everyone's views have been aired. But it may be that, while acknowledging one person's unhappiness at the decision, e.g. not to instigate IV antibiotics in hospital, it is agreed that the situation will be reviewed daily and if things do not go as expected, then the decision can be changed.

Ethical theories

In this section I outline the main ways in which philosophers have understood ethics and ethical reasoning. Consequentialism, deontology, principlism, and virtue ethics are the theories that I outline here (see also Hughes and Baldwin, 2006). There are all sorts of other approaches to ethical thinking, summarized in Box 51.1, which are not all discussed, but the references provide further details.

Box 51.1 Theories and approaches to ethical issues

Absolutism

The view that certain actions are *always* wrong or *always* obligatory, whatever their consequences.

Care ethics

This can be seen as a development from feminist ethics, where care itself and the nature of care are regarded as the crucial components in deciding whether something is right or wrong.

Casuistry

Arguing case by case, in the light of basic moral instincts, but with regard to the important differences between cases.

Communicative ethics

The correct answer to an ethical dilemma requires a commitment to free and open communication on the part of individuals and institutions.

Ethics and old age psychiatry

Communitarianism

A tendency, over liberalism, to stress tradition, the community, and the social context of practices and of selves.

Consequentialism

The rightness or wrongness of an action depends on its consequences.

Deontological ethics

Certain actions must be done as a duty (*deon*) regardless (to *some* extent) of their consequences.

Emotive theory

Moral language is intended to convey and to elicit an emotional response; so, an ethical decision mostly reflects an emotional, rather than a rational, response.

Feminist ethics

Taking into account experiences and values more typical of women than of men, feminist ethics stresses the importance of interdependent relationships in which caring for others is implicit in a person's moral life.

Hermeneutic ethics

Actions should be judged by an interpretation that allows their meaning in a context to be understood.

Intuitionism

What is right can be directly seen (or intuited) by the mind or conscience.

Liberalism

The guiding light of western democratic traditions, which stresses the need to respect each citizen as free and equal; as such, associated with the notion of *egalitarianism*, which stresses the primacy of equality.

Narrative ethics

The rightness (or wrongness) of an action will become apparent in the context of a detailed story.

Natural Law ethics

A moral theory favoured by the Catholic religious tradition: reason can determine basic human goods, constitutive of human flourishing, which ought to guide action.

Perspectivism

The way to seek the right thing to do is to take account of the different perspectives on any given situation, which will make it more likely that answers to problems have greater validity. This approach to philosophical problems is associated with the name of Friedrich Nietzsche (1844–1900).

Prescriptivism

Moral terms are used primarily to guide action, to tell people what to do.

Principlism

Beneficence: doing good;

Nonmaleficence: avoiding harm;

Autonomy: allowing self-rule;

Justice: distributing goods fairly.

Prioritarianism and sufficientism

These are approaches used in connection with resource allocation. 'Prioritarianism is the view that we ought to give priority to benefiting those who are worse off. Sufficientism, on the other hand, is the view that we ought to give priority to benefiting those who are not sufficiently well off' (Brown, 2005).

Religious ethics

What is right or wrong depends upon religious traditions (e.g. *Halakah* in the Jewish tradition; *Sharia* in the Islamic tradition) or precepts.

Situation ethics

In ethical dilemmas in medicine, issues must be decided on the basis of the actual situation: different decisions reflect different situations.

Utilitarianism

A form of consequentialism that takes the maximization of pleasure (and the minimization of pain) as the measure of a good action.

Values-based practice

Involves acquiring practice skills that encourage practitioners to look carefully for the values (as well as the facts) at play in clinical practice and to seek ways to be as inclusive as possible in negotiating outcomes in the light of mutually recognized but sometimes diverse values.

Ethics and old age psychiatry

Virtue ethics

What counts in ethics is the habitual disposition of the person: an action is good if it reflects a virtuous character.

Notes: For further details and theories the reader should consult the sources of this table: Honderich (1995) and Ashcroft et al. (2007). Communicative ethics is discussed in Moody (1992). For hermeneutic ethics see Widdershoven and Berghmans (2006). For more details about values-based practice, see Fulford (2004). Amended from Table 36.1 in Hughes, 2002.

Adapted with permission from Hughes, J.C. Ethics and the psychiatry of old age. In: Jacoby, R. and Oppenheimer, C. (Eds) *Psychiatry in the elderly*, 3e. Oxford University Press, Oxford, UK. Copyright © 2002, OUP.

There are, however, two general points to be made. First, it is interesting that a number of the approaches in Box 51.1 are similar in that they stress context and relationships. Care ethics, communicative, hermeneutic, and narrative ethics, for instance, all place some emphasis on the concrete circumstances of real individuals who need to be understood in particular times and places. This is one of the things that make these approaches to ethical problems and thinking so appealing: they embrace the real-life messiness of moral decision-making. But this focus on the particularities tends to go against the idea that definitive statements can be made in advance of actual situations. There are deep issues lurking here, which cannot detain us for long, but which it seems important to acknowledge.

When doctors (and others) find themselves discussing ethical issues, one of the most commonly heard statements, at least in my experience, is that there are no right or wrong answers in ethics. I fully appreciate why people make this statement. One reason is precisely because the particular circumstances of each individual case will be what make the difference. Recall that it is the focus on the real particulars that makes these approaches appealing, in that they are not just theoretical and abstract, but engage with the clinical realities. These realities are as various as the cases from which they are drawn. In one, it might be the serum potassium that helps to decide the right thing to do; in another, it might be the fact that the patient's daughter lives abroad that determines the action that is taken. In most cases, it will be an amalgam of biological, psychological, social, legal, familial, cultural, and spiritual factors, and so on, that will lead to a particular course of action being chosen. In many cases, from the ethical perspective, it might be reasonable to do either A or B. For instance, it might be ethically reasonable, in the case of the person with a severe depression, either to wait a further week to see if the antidepressant is starting to work or to go ahead this week and give ECT. This is not, however, the same as saying there are, ethically, no right or wrong answers. It certainly would not be acceptable in the case I am

Ethics and old age psychiatry

imagining to do *C* or *D*, where these involve either stopping all treatments and discharging the patient or beating him twice a day with the leaves of the plant celandine. In other words, there *are* right and wrong answers.

Sometimes there is more than one right answer; and sometimes we cannot be sure what the right answer is. But the point of ethical debate is to move towards the good outcome, to try to do or to clarify the thing that is right; and if this were not the case, there would be no point in the debate in the first place. In saying this, I am taking a stance against a type of subjectivism in morals: I do not think that morality simply boils down to matters of taste. But, of course, not all philosophers have agreed with this (see Mackie, 1977). Nevertheless, I claim that there is some horizon, which can be argued for on rational grounds, against which our arguments and actions must be judged (Taylor, 1991). There are right or wrong answers in ethics, just as there are in clinical practice.

The second point I draw from Box 51.1 follows from the earlier discussion. For if there is such a variety of theories and approaches, how can we know which to use in any given circumstance? One approach might give us one answer and an alternative might give us some other answer. Is there a rational way to pick between them? Is the point that we should decide on which approach or theory is the best and then always stick to that one? Or can we pick and choose? In which case, is there a rational way to do this?

I think the answers to these questions are important. They may, in a sense, be disappointing answers. Doctors and other healthcare professionals are, by nature, practical people. We are typically faced with problems (e.g. of diagnosis or treatment) for which we wish to have solutions. One appeal of clinical ethics is that it can help us by offering solutions to the practical dilemmas we face. To some extent I think it is true that clinical ethics achieves this. If we are faced with a difficult treatment decision, then of course the right thing to do will be to discuss it with the patient. It is easy enough to give reasons why we should do this, for instance, to respect the person's autonomy. If the person is unconscious or incapable, we may still be able to find ethically justifiable ways to respect what would have been his or her autonomous wishes by looking for advance directives or by seeking the views of relatives.

The disappointing answer is that, notwithstanding the evident practicality of clinical ethics, perhaps it never was a realistic expectation that moral reasoning would provide practical solutions in any direct sort of way. To come to the point, the theories and approaches of Box 51.1 give us ways to think about difficulties, without necessarily giving us answers. In certain situations, it may be helpful to think in terms of narratives: this will help us to understand the lives of our patients with dementia, which will in turn make it more likely that we shall think in a manner that is appropriate if we are now having to make decisions about treatment at the end of life. If we think through a problem, keeping in mind the different perspectives of all concerned, as in perspectivism, we are more

Ethics and old age psychiatry

likely to make the right decision about the treatment for the recidivist drug abuser. Taking the communitarian approach may help us to reach better decisions about how to deal with problems associated with a particular nursing home, because we are more likely to take a broader view and consider the historical and social context for patients, relatives, and staff.

It is still, however, necessary to take a practical view of matters: these ethical approaches must help us to arrive at this or that solution. But there is something deeper, too, because moral theories also provide us with ways of understanding our moral inclinations, not just with answers to practical problems. In other words, when I decide that I should break confidence and report a patient whom I consider to be driving unsafely, it is not necessarily because I have been through a process of ethical reasoning. It may just be part of the clinical protocol. But having acted thus, or perhaps having decided that the psychotic patient needs to be detained under compulsion, I can use the various ethical theories to provide my actions and decisions with a rational basis. We can understand the ethical structure of the world through these theories in a similar way to how we understand the physical structure of the world through physics and chemistry. My knowledge of atoms and electrons does not affect the way in which I walk down the street. Even if they do not help me to argue, ethical theories give me an insight into the rational structure of thought and into the history of ideas so that my judgments stem from an informed background. This background may be of some practical help when I am faced with a dilemma, just as knowing about electrons may in some way be useful for the medical physicist. More than this, it could be argued that understanding the nature of ethical issues around the practice of medicine simply makes us receptive to the nuances of language, meaning, and emotion in our multi-layered encounters, which will in the end make us better practitioners. Whether or not this argument—about how moral reasoning may have practical implications but is also valuable in itself as a means of understanding the world—can be defended, it is not one that I shall pursue here. But I shall come back to the question of what it feels like to make ethical decisions and how it can feel almost automatic, as if there is no real ratiocination.

Consequentialism

Consequentialism is the idea that our actions are properly judged to be right or wrong on the basis of their consequences. The best-known form of consequentialism is utilitarianism. The classical Utilitarians, Jeremy Bentham (1748–1832) and his godson John Stuart Mill (1806–1873), regarded happiness or pleasure as the main outcomes to consider in terms of consequences; but, of course, there could be other consequences of actions, such as knowledge, success, and the nature of relationships, that could be used as ethical markers if we wished. Utilitarians might respond that these other factors are simply markers of different types of pleasure or happiness. Nevertheless, consequentialism and utilitarianism do not need to be regarded as the same thing and we might decide that

Ethics and old age psychiatry

the broader notion of consequentialism seems more useful in clinical ethics.

Perhaps a more significant distinction is that between act utilitarianism and rule utilitarianism. Act utilitarians consider particular actions and ask, in order to decide whether or not something is the right action, if it would maximize happiness or pleasure (and minimize pain). Rule utilitarians, on the other hand, look at whether or not acceptance of the rule, of which the act is an instantiation, would tend to maximize pleasure and so on. Thus, an act utilitarian might argue that we should say that people with mild dementia cannot drive because they might cause accidents. Although individuals with mild dementia will be upset and inconvenienced, happiness (or perhaps welfare) will be maximized by the avoidance of accidents. A rule utilitarian, alternatively, might be inclined to take a more sanguine view of people with mild dementia driving, on the grounds that to have a rule that they cannot drive would undermine broader conceptions of fairness in society and thereby reduce overall happiness (or welfare). The rule utilitarian can still accept that a particular person, Mrs Green, should be disqualified from driving if she fails some specific cognitive or practical test, which accurately predicts the likelihood of an accident, because to have a rule that involved ignoring accurate predictions of this nature would increase actual pain and decrease general pleasure in society.

So, even within utilitarianism, we can discover different approaches to similar ethical dilemmas. But the distinctions allow us to understand the ethical dimensions of our decisions more clearly. There are the consequences for Mrs Green and those with whom she might be involved—that is, both those she might help by retaining her ability to drive, and those she might harm by driving—and there are the broader consequences for society of making decisions in this one case that should then govern all.

Consequentialism is often compared to deontology, which concerns duties, to which I shortly turn. A typical example concerns lying. A consequentialist might argue that it is better to lie to a person with dementia because in this way you maximize happiness. So, it is all right to tell the person that his mother has said he can stay in the day-care unit, if this helps him to settle, even though his mother has been dead for some years. A deontologist might, alternatively, take the view that there is a duty to be truthful with people even if they have dementia, and so it should be explained carefully to the person that his mother has died and he needs to stay in the unit to be looked after properly; or, at least, that the lie should be avoided, e.g. by the subject being changed. In passing, it might be noted that in this case the deontological view might also be the view that the rule utilitarian would take; for to accept it as a rule that it was right to lie to people with dementia could conceivably be deeply undermining of social welfare. Again, we are presented with different ways of thinking about moral issues by considering different moral views.

Ethics and old age psychiatry

In the following sections, however, I discuss the possibility that each of the four main types of ethical theory would end up saying the same thing. Practically, therefore, there would be no difference between them in terms of outcome. But conceptually they are different, and by considering the same case with the same outcome we can see how the different theories allow us a different perspective on the world.

Case study 1 The Case of Miss Burns

Background

Miss Burns has always lived alone. She worked as a secretary in a local government office. She was known to be someone who could be relied upon to keep matters confidential. In retirement, she has enjoyed listening to classical music, but she has not tended to socialize. Her GP has received reports from neighbours, who state that Miss Burns is behaving in a gradually increasing paranoid manner, seeming to spy on them through her curtains and always avoiding social contact. When the GP visits, Miss Burns is reluctant to let her into the house, but when she does, the GP finds the house to be dangerously cluttered. It is very unhygienic, with evidence of infestations, and there is an obvious fire risk. The GP writes a referral to the old age psychiatry team. They find that, although Miss Burns is unwilling to be tested in a formal manner, a degree of cognitive impairment is evident. In addition, Miss Burns demonstrates some paranoid delusions. She will not accept any help, and all concerned decide that it would be reasonable to assess her further as an inpatient using compulsory powers to detain her. But they are aware that this will be very distressing for Miss Burns. Are they doing the right thing?

Comment

In discussing this case, we have to presume that the GP and the old age psychiatry team have thoroughly assessed the risks and genuinely explored options other than compulsory admission. The consequentialist would, I think, find little difficulty in giving an opinion on the case. Of course there may be some bad consequences following an admission: being removed from her house will be traumatic for Miss Burns; she may suffer side effects of any psychotropic medication she is given; she may decompensate once she is out of her own environment so that it becomes harder for her to return to independent living. But there are bad consequences to her staying in her home: she may become ill because things are so unhygienic; the infestations will shortly affect her neighbours; her paranoid behaviour is attracting the attention of the local youths who seem inclined to victimize her; she may inadvertently cause a fire. And the good consequences of assessment and treatment are also more than probable: she will be kept safe; her health will be

Ethics and old age psychiatry

maintained; she might settle into a new environment where she can be cared for and where she might be happy; or she might return to live at home more comfortably with appropriate support. In addition, her neighbours will not be put at risk by her behaviour. Similarly, a rule utilitarian would have little difficulty in concluding that a rule which stated that people who were putting themselves or others at risk and were not willing to accept help should, to maximize happiness, be subject to compulsory treatment. In the view I have presented, therefore, a consequentialist appraisal of the case of Miss Burns would support the use of compulsory powers, at least to assess her.

Deontology

The deontologist is someone who believes that there are things one *must* do (the Greek verb *dei* translates as 'ought', describing a 'necessity' or a 'must'; *deon*, then, means 'duty' and *logos* translates as 'reason'). In other words, ethics is to do with duties and 'deontology' suggests reasoning based on a sense of duty. If utilitarianism is associated with the names of Bentham and Mill, deontology is often associated with that of Immanuel Kant (1724–1804). He argued that the rightness or wrongness of an action cannot depend on its consequences. More important, in his view, is the motive or the will of the person performing the action. A person might do something for good motives and yet it might have bad consequences or, contrariwise, the person may be willing something bad, but nevertheless the consequences of the action are good. Someone who is well motivated will respect the moral law, according to Kant, which will involve acting from a sense of duty, that is, on the basis of what must, of necessity, be done.

If we were to look more closely at the philosophy of Kant, we might be struck by a similarity between his notion of a categorical imperative, which provides the underpinning motivational grounds for our actions when they are right, and rule utilitarianism. One way in which Kant formulates the categorical imperative is to say that we should only live by maxims that could be made into general laws. Ignoring the intricacies of Kantianism, however, it is easy to see how the deontologist might well also agree that Miss Burns should be compulsorily detained for further assessment and perhaps treatment. We would not wish there to be a universal rule that people who were failing to look after themselves and were thereby becoming ill and threatening the health of others should be left to their own devices. We might well argue that a civilized society ought to be caring for those who are ill and unable adequately to care for themselves. We might also, more simply, state that we have a duty to care for people like Miss Burns. The argument is not based on the good or bad consequences of what we might have to do; it is more directly that the moral law tells us where our duties lie. The Golden Rule, 'Do as you

Ethics and old age psychiatry

would be done by', which is found in almost all religions, is another way of expressing Kant's notion of the categorical imperative. It is then reasonable (i.e. rational) to say, if we were ill in the way that Miss Burns appears to be, we would want people to help us, even if we could not appreciate the need for such help. The key thing, however, is that the action is motivated by good will informed by universalizable reasons. The goodness or badness of the action does not depend on its consequences.

Principlism

The so-called four principles of medical ethics (see Box 51.1) have been set out over a number of years by Tom Beauchamp and James Childress in their book *Principles of Biomedical Ethics*, which is now in its seventh edition (Beauchamp and Childress, 2013). The book is about much else besides, but the four principles have become a way of summarizing in a useful manner much thought in the field of bioethics (Gillon, 1986). As Gillon (1994) said about the four principles approach: 'It offers a common, basic moral analytical framework and a common, basic moral language'.

We can, thus, use the four principles—autonomy, beneficence, nonmaleficence, and justice—to discuss the case of Miss Burns. Respecting autonomy is the thing that makes us put off intervening too soon. We know that, under normal circumstances, Miss Burns has the right to determine her own future, to make choices about how she lives, and to decide for herself when she wishes to seek help. The difficulty is that there must be limits to autonomy, even though it is often regarded as the primary principle. Normally, to guard against paternalism (i.e. doctors, or anyone else, thinking they know what's best for someone), stress is put on the idea that the individual is best placed to decide for him- or herself what should happen. But this principle cannot ride roughshod with no concern for the rights of others. The etymology of 'autonomy' suggests the notion of self-rule. For any individual, the area over which I can exert my rule will be limited, not only by others who also wish to rule their domains (so that our areas of dominion come up against those of others), but also by biological, psychological, social, or alternative circumstances, which mean that I cannot exercise self-rule apart from in a circumscribed fashion. Under the current arrangements (i.e. with no help or support and given the nature of the threats she poses to others), Miss Burns cannot continue to live independently without at least some investigation, if not some treatment.

The principle of beneficence comes into play under the current circumstances. All those concerned wish to do Miss Burns some good. The principle of beneficence suggests that we must aim to help her. At the same time, we must do this without causing her any harm, or at least we must limit the harm that we do insofar as this is possible. This is in keeping with the principle of nonmaleficence.

Ethics and old age psychiatry

Finally, there is the principle of justice, which entails that we should deal with people fairly. In the case of Miss Burns, this principle might be used to support the use of compulsory powers. Such powers ought always to be used in a fair and equal manner. In addition, justice demands that people should have rights of appeal against decisions to remove their liberty by compulsion. The principle of justice is also used in connection with resource allocation. A case might be made that not to detain Miss Burns would lead to increasing costs in attempts to maintain her in as good a state as possible in the community. But such *costs*, particularly in the face of her refusal to comply with the measures that would have to be established, might be prohibitive; and in addition, when weighed in the balance, the *benefits* of ameliorating matters by admitting her for further assessment seem more than likely to outweigh trying (probably unsuccessfully) to look after her at home.

Virtue ethics

The four principles give us an easy-to-recall 'moral language' (Gillon, 1994). In a sense, virtue ethics changes the language altogether. In so doing it also extends it. If, very roughly speaking, consequentialism looks at outputs ('do it because it leads to X') and both deontology and principlism look at process ('do it because it is in accordance with Y'), then virtue ethics tells us to look at the input ('do it because it comes from Z'). The virtues are inner dispositions, such as honesty and compassion. Virtue ethics says that you should do what the virtuous person would do. (For the best detailed philosophical account of virtue ethics, see Hursthouse, 1999.) We might object that the judgment that someone is virtuous seems highly subjective (what if I said that I thought Hitler was a man of virtue?!). Virtue theory, however, has an inbuilt defence against this objection, because a virtue can be defined in terms of human flourishing. If we had to characterize what it is to be a good human being—what it is to flourish humanly, that which is admirable in the human character—we would quickly find ourselves using the virtue words. In this sense, virtue ethics extends moral language far beyond the four principles.

Objectivity comes from the background agreement that the good person is the one who demonstrates compassion, integrity, honesty, and so forth. Even when we know their shortcomings, there are people in the world whose virtue is readily recognized: Mother Teresa (1910–1997) was one and Nelson Mandela (1918–2013) another. But we do not have to look to the world stage to find examples of virtuous people. There will be people around us, friends or colleagues to whom we turn for advice precisely because we recognize their virtues. We go to them, and not to some others, because we know them to be honest, to have integrity, and to be people of practical wisdom. We go to them because of these virtues.

One criticism of virtue ethics has been that, while providing a good description of human character, it does not actually direct action: it does

Ethics and old age psychiatry

not tell us what to do. Again, however, virtue ethicists have a direct response this:

Not only does each virtue generate a prescription—do what is honest, charitable, generous—but each vice a prohibition—do not do what is dishonest, uncharitable, mean (Hursthouse, 1999, p. 36)

Virtue ethics has had a renaissance in recent years, including in connection with medical practice (Pellegrino and Thomasma, 1993). It is usually taken to derive from Aristotle (384–322 BCE). From Aristotle, for instance, comes the notion of ‘human flourishing’, which is a frequent translation of his term *eudaimonia* (ευδαιμονία). A useful brief account of virtue ethics is provided by Oakley (2007). But there are reasons to think that we—as professionals—should pay this ethical theory more attention.

The concept of a virtuous character has been portrayed as central to professionalism [...] Traits such as trustworthiness, fidelity, honesty, and integrity have been identified with professional status (Radden and Sadler, 2010, p. 69).

To return to the case of Miss Burns, the virtuous professional, because of his or her compassion, practical wisdom, honesty, fidelity, and courage, will take the necessary steps to make certain that Miss Burns is well looked after and cared for appropriately. This will involve, up to some point, supporting her in the community; but when the time comes, the right thing to do will be to use compulsory powers to detain her for assessment and for treatment as required. To fail to take this step would be a failure in terms of compassion, practical wisdom, honesty, and the like. The professional would not be a good professional, would not flourish as a doctor or social worker, for instance, if he or she were unwilling to demonstrate the courage and the compassion occasionally required to take away a person’s liberty.

Elsewhere, I have argued that the virtues might also be used to support occasionally going against even authoritative guidelines—I was thinking of the guidelines established in England and Wales by the National Institute for Health and Clinical Excellence (NICE) governing the use of antimentia drugs (NICE, 2006)—on the grounds that not to do so would be to ignore the virtues that underpin social justice and human community (Hughes, 2012). More broadly, Radden and Sadler (2010) have argued that virtue ethics provides the most appropriate approach to moral thinking in connection with psychiatric practice. In order to show the richness of this approach, I have listed in Box 51.2 (and explained where this seemed necessary) the virtues (or the virtue-type words) highlighted by Radden and Sadler as relevant to psychiatry. To these I have added the virtues described by Pellegrino and Thomasma (1993).

Box 51.2 Examples of virtues for psychiatrists

Authenticity, sincerity, and wholeheartedness

These suggest the idea of being true to oneself.

Emotional intelligence

Empathy and compassion

Fortitude, patience, and perseverance

Gender-sensitive virtues

By this is meant the virtues of respectfulness of the patient's autonomy, tolerance, humility, self-knowledge, imagination, trustworthiness, scrupulosity, self-control, and gender sensitivity and awareness.

Genuine warmth

Hopefulness

Humble propriety

This suggests not just a pretence, but a genuine awareness of and sensitivity to the effects of one's words, behaviour, and deportment.

Integrity

Justice

This is not simply an attention to fairness with respect to resource allocation; as a virtue, it suggests a fundamental ability to make good judgements.

Moral integrity and leadership

Practical wisdom

This virtue is also seen as fundamental, for it allows deliberation about the ends or goals of practice and treatment, and the discernment to pursue the right path towards those ends or goals. It is sometimes called prudence or, to use the Greek word, phronesis (φρόνησις).

Realism

This term suggests that thoughts, beliefs, and responses are kept in line with the facts, to give a balanced appraisal and steady perspective.

Respect for personhood

Ethics and old age psychiatry

Self-effacement

In other words, a type of humility.

Self-knowledge

Self-unity

It is seen as useful for the therapeutic relationship if the practitioner has a unified and insightful sense of self.

Temperance

Usually this implies keeping check of one's appetites, but more broadly it can also be regarded as a form of self-mastery, which enables the practitioner to live an intelligent life, i.e. one in keeping with broader notions of human flourishing.

Trustworthiness or trust

Also conveyed by words such as 'fidelity', which suggests the idea of 'being true', and reliability.

Unselfing

This term refers 'to the personally effaced yet acutely attentive and affectively attuned attitude toward the patient, the relationship, and its boundaries, adopted by the ethical and effective practitioner' (Radden and Sadler, 2010, p. 132). This is not intended to be simply detachment, which involves an emotional distancing, since the doctor needs to be aware of his or her emotions and to use them appropriately.

Source data from: Pellegrino, E.D. and Thomasma, D.C. (1993). The virtues in medical practice. Oxford University Press, Oxford and New York; Radden, J. and Sadler, J.Z. (2010). The virtuous psychiatrist: character ethics in psychiatric practice. Oxford University Press, Oxford and New York.

The listed virtues do not follow the exact ordering of Radden and Sadler, Pellegrino and Thomasma, and the descriptions are not necessarily those that would be given by them. But Box 51.2 is enough to suggest that virtue ethics significantly broadens the view of what might be relevant in our ethical deliberations.

Summary

Let us make the assumption that we would all agree that Miss Burns requires compulsory hospital admission for assessment and perhaps for treatment. Albeit there might yet be some disagreement in real life if we actually brought together ethicists from these different theoretical

perspectives, we can see that the four ethical theories we have outlined each provide useful views. Of course, it makes sense to be aware of the *consequences* of our actions; these might well alter what we think it is right to do. But, at the same time, there is a *duty to care* for Miss Burns, whatever the outcome; and this duty to care is supported by the principle of *beneficence* and guided by the principle of *nonmaleficence*. We must respect her *autonomy*—the *rule utilitarian* would agree with this—but *justice* dictates that we have to think of the others involved, for example her neighbours, who might wish to argue on *act utilitarian* grounds that assessment and treatment are now required to maximize the welfare of all concerned. All of this, however, is motivated in the first place by those dispositions of character, the *virtues*, that come together to support broader conceptions about what it is to flourish in the world as human beings. Our concern about the outcome for Miss Burns, if it is ethical, is fuelled by our *compassion*; meanwhile, our discernment concerning the best outcome reflects *practical wisdom*, which we have acquired through training and experience; and our judgments about how to achieve the outcome are guided by an underlying sense of *justice*. Combining these ethical theories, therefore, gives us a rich and layered appreciation of the nature of the world of morals and values in which we live. Ethical theories give us perspectives on the world as surely as theories in physics and chemistry do. They also help us to live in and act on the world. But how we use our theories is not always as clear-cut as those theories sometimes suggest. The old utilitarian view that we could simply apply a felicific calculus (i.e. a machine-like calculation of happiness) to arrive at the maximum amount of happiness in order to guide our actions is about as primitive as the view that the earth is flat. How we put theory into practice in the real world is the subject of the next section.

Patterns of practice

In this section I suggest that the notion of patterns of practice¹ might provide a useful way to think about ethical decision-making. An immediate point to note is that, if this is so, patterns of practice might be useful not only in the clinical field, but wherever ethical decisions have to be made: in political life or in the financial world, for example. It is also only honest to acknowledge that this aim should, in large measure, be fairly easily achieved. Our ethical decision-making, whether in clinical, financial, or political settings, will sit within some pattern of practice or other. At least, most ethical decisions will be describable in terms of a pattern of practice. Only highly idiosyncratic or aberrant decisions are likely not to conform to some pattern or other; and, even then, their idiosyncratic or aberrant nature is likely to reflect the precise fact that they stand outside normal patterns of practice. So, of course patterns of practice—as a notion—can provide a way to think about ethical decision-making! My aim, however, is easily achieved only *in large measure*. The more interesting point is *the extent to which* the notion of pattern of practice is *useful*. My suggestion is that it is useful at the level of practice

Ethics and old age psychiatry

and at a profound philosophical level. Indeed, it is a notion that brings these levels together.

What are patterns of practice?

Patterns of practice are quotidian and pervasive. At a superficial level, we can hardly escape the extent to which our lives are patterned. Our routine behaviours, eating and sleeping say, tend to conform to patterns and we suffer when the behaviours are too radically disturbed. Social behaviour is also deeply reliant upon patterns of practice: safe driving, for instance. Even good manners are a matter of accepting certain patterns of practice and it is disconcerting when such codes of practice are ignored. Cultural patterns of practice can be observed in sporting arenas around the world, or in concert halls, with subtle and not so subtle differences depending on the precise type of sport or brand of music.

At a deeper level, perhaps, in the case of religions we speak of patterns of prayer or worship. There is an obvious philosophical debate to be had concerning whether such patterns merely reflect different sociocultural traditions, or whether the practices themselves are in some deeper sense constitutive of religious belief. To be of a particular religion is to engage in (and with) its patterns of worship. To fail to attend Mass on Sundays is to be a lapsed Catholic. Like other religions, Islam dictates certain practices: 'Recite from the Koran as many verses as you are able ... Attend to your prayers, render the alms levy ... Implore God to forgive you ...' (Dawood, 1956, p. 410). To disregard the precepts of any religion wilfully and persistently would be incompatible with the practice of the religion.

Something very similar can be said about clinical practice. Medical practice is full of patterned responses. We learn to take and report a history in a standard way. Particular routines for the examination of a patient are pursued. Particular symptoms and signs trigger certain investigations. One set of complaints triggers immediate admission to hospital; different complaints might prompt a referral to social services. Although there may be regional variations and occasional innovations in precise practice, if the pattern of practice is woefully wrong the doctor risks losing his or her licence to practise. Clinical patterns of practice also pervade how we communicate with patients and carers, how we think of them (e.g. as cases or as people), and ultimately how we treat them.

So far in this section I have: (a) shown the extent to which our personal and social lives are patterned; (b) gestured at the possibility that patterns of practice might not just reflect our beliefs, but might play a constitutive role in them; and (c) indicated how clinical practice is also patterned in a pervasive and ubiquitous fashion. Before moving on to consider the extent to which the notion of patterns of practice might be useful, I pause to consider two particular ways in which the idea of practice proves profound: first, in the context of the philosophy of thought and language; secondly, in connection with virtue ethics. In both cases I draw on the

Ethics and old age psychiatry

work of philosophers that helps to underpin my suggestion about the extent of the usefulness of patterns of practice in medical ethics.

Patterned language

To say that language is patterned might be to make a purely linguistic point about the structure of language. The philosopher Ludwig Wittgenstein (1889–1951) claimed that ‘To understand a language means to be master of a technique’ (Wittgenstein 1953, §199). This might be taken simply at this linguistic level. But Wittgenstein’s interest was in philosophical issues to do with meaning. In this regard, in his famous discussion of rule-following, he pointed to the normative nature of our descriptions of mental states. In other words, when I say that I understand something it entails that certain things are or will be the case. Saying something is normative is to establish criteria of correctness. It means that certain things are constrained to be the case. The mental state seems to exert its normative constraints over things that are not yet in existence; for if the content of the mental state is to have meaning, certain things in the world must be or will be true. Mental states with content—that is, my true beliefs, thoughts, wishes, and so on—just like rules (which govern the future), are similar in that they exhibit this normativity.

A wish seems already to know what will or would satisfy it; a proposition, a thought, what makes it true—even when that thing is not there at all! Whence this *determining* of what is not yet there? This despotic demand? (Wittgenstein, 1953, §437).

The conclusion of Wittgenstein’s famous rule-following discussion ‘is that understanding cannot be further explained other than as an ability to enact a practice ...’ (Thornton 1998, p. 35). According to Wittgenstein:

... there is a way of grasping a rule which is *not* an *interpretation*, but which is exhibited in what we call ‘obeying the rule’ and ‘going against it’ in actual cases [...] And hence ‘obeying a rule’ is a practice (Wittgenstein, 1953, §§201-2).

In the course of presenting his interpretation of Wittgenstein, Thornton puts it thus:

When one comes to understand the meaning of a word, one acquires an ability to use it correctly which cannot be further explained. One simply masters a practice or technique [...] Understanding a meaning is a piece of ‘know-how’, a practical ability. One way of putting this is to say that meanings and rules are individuated by practices and that understanding a meaning or a rule is thus individuated by the practice over which one has mastery (Thornton, 1998, p. 90).

When Wittgenstein himself is talking about how he might justify following a rule in the way that he does, he says:

Ethics and old age psychiatry

If I have exhausted the justifications I have reached bedrock, and my spade is turned. Then I am inclined to say: 'This is simply what I do' (Wittgenstein, 1953, §217).

In this adumbrated account, we see that certain types of mental state (understanding, remembering, meaning, and the like), represented by linguistic practices, are rule-governed. Their rule-governed nature manifests an essential normativity (things seemingly couldn't be otherwise than they are), but what this boils down to is a matter of practice. There are, of course, alternative interpretations of normativity (cf. Thornton 1998), but on the one being considered here the normativity of mental states amounts, somewhat shockingly, to a mere practice: 'This is simply what I do'.

Those aspects of our life that seem so essential to our make up as human beings—our ability to think, understand, believe, hope, remember—turn out on this interpretation to be practices, things that we do in a particular way simply because we are thus! These patterns of practice reflect our standing as agents of this type in the world. This is simply how we act in the world. The important point is that we act normatively. As Luntley says:

... our thinking lies in the pattern of our actions, where actions are causal encounters with the world. The normativity of thought is the normativity of the pattern/structure of our causal encounters ... We say that the patterns of our causal encounters with the world are irreducibly normative ... Some of the patterns that physical things, like us, get into are normative patterns (Luntley, 1999, p. 345).

The argument I have been wishing to imply, therefore, is this: language and thought are essentially normative; normativity is a matter of practice; thus, at heart our lives as embodied agents are situated in a realm of practices (Hughes, 2011). Hence, the notion of patterns of practice makes a profound link with our standing as human beings of this sort (with minds and language) in the world. These patterns of practice involve (constitutively) normative constraints, the despotic demand that we live thus and so, because this is how we are. In other words, there is an essential link between our actions, what we do, and how we have to be as human beings in the world. Elsewhere Luntley has said: 'The moral world has its being in, it rests upon, what we do and how we act. It is in our actions and the way we treat one another that values come into being and are preserved in being' (Luntley, 1995, p. 218).

With this thought, I turn to a connection between patterns of practice and the virtues.

Patterns and virtues

The emphasis on action and practices might, at first blush, seem to sit uncomfortably with virtue ethics, where the emphasis is more on the agent than the action. While it is true that virtue ethics stresses what the

Ethics and old age psychiatry

person *becomes* by acting this way or that (rather than, say, the consequences of actions), it is also true that virtue ethics is concerned with actions themselves inasmuch as these are specified by the virtues. To the prescriptions and prohibitions of the virtues and vices, virtue ethics adds a corrective by focusing attention on how the action is performed. The right action, done badly, might be as harmful as the wrong decision.

Hursthouse (1999) argues that, even if virtue ethics can generate action guides (i.e. 'do this' or 'don't do that'), there are reasons to pull back and consider *the agent* in our judgments of moral action. For one thing, she argues, this allows room for regret, even if the right action has been performed. With explicit reference to medical practice (in the continuation of a quote we've seen earlier) she contends:

... if someone dies, or suffers, or undergoes frightful humiliation as a result of [a doctor's] decision, even supposing it is unquestionably correct, surely regret is called for. A dose of virtue ethics might make them concentrate more on how they should respond, rather than resting content with the thought that they have made the right decision (Hursthouse, 1999, p. 48).

Hence, the notion of patterns of practice links to virtue ethics not simply because of the way action can comprise a practice, but also because *how* we act—with regret, compassion, integrity, and so on—is conveyed by the notion: our patterns of practice include not only actions, but also demeanours and dispositions.

There is another subtle way in which a link can be made between virtue ethics and patterns of practice. To those who are not predisposed to virtue ethics as a normative theory this may seem contentious, and I suggest the link tentatively. While discussing religious practices I suggested that such practices are in some sense not just reflective of religious beliefs but constitutive of them. Similarly, it might be argued that moral practices do not just reflect ethical beliefs, but play a role in constituting them. There is something heretical in this because the normal presumption in medical ethics is that we use normative ethical theories to judge our actions, whereas I am suggesting that—in some albeit sketchy way—the normative simply emerges from the action. We might say that the normative is immanent.

Virtue ethics, it seems to me, squares with this view because it suggests the importance of what I *become* by what I do. It is as if we do not need the normative theory first, but rather the actions show us the possibilities for human beings. In an analogous manner, MacIntyre (1985), in his seminal study *After Virtue*, gave an account of the virtues that proceeded through three stages. The second and third stages considered the narrative unity of a whole life and the importance of an ongoing social tradition. But his account begins with practices. Other moral philosophers

Ethics and old age psychiatry

start with passions or desires or some conception of duty or goodness. But in such cases MacIntyre suggests,

the discussion is all too apt to be governed from then on by some version of the means-ends distinction according to which all human activities are either conducted as means to already given or decided ends or are simply worthwhile in themselves or perhaps both (MacIntyre, 1985, p. 273).

MacIntyre continues:

What this framework omits from view are those ongoing modes of human activity within which ends have to be discovered and rediscovered, and means devised to pursue them; and it thereby obscures the importance of the ways in which those modes of activity generate new ends and new conceptions of ends (MacIntyre, 1985, p. 273).

Once again, of importance here is what we become by what we do and the possibility that practices have the potential to enlarge our view of human flourishing. A key feature of the virtues is that they require a prior account of certain aspects of social and moral life in terms of which they can be defined and explained (MacIntyre, 1985, p. 186). The concept of a virtue requires a background against which it is made intelligible. The notion of a practice, which forms the first stage of the background, is defined by MacIntyre in a technical way:

By a 'practice' I am going to mean any coherent and complex form of socially established cooperative human activity through which goods internal to that form of activity are realised in the course of trying to achieve those standards of excellence which are appropriate to, and partially definitive of, that form of activity, with the result that human powers to achieve excellence, and human conceptions of the ends and goods involved, are systematically extended (MacIntyre 1985, p. 187).

The idea here is that, in order to pursue certain human goods, which help to constitute human flourishing, we have to engage in practices, where a practice itself aims at what is excellent for human beings. Football, chess, architecture, history, and medicine would all be examples of practices in this sense. Furthermore, according to this definition, such practices are patterned in a way that allows the possibility that they will reveal to us new and perhaps unexpected ways to flourish as human beings. From this virtue ethics perspective, the immanence of normativity is seen in the way that, within patterns of practice, conceptions of human goods are discovered and rediscovered through the actions of agents and by what they thereby become. Once a framework or pattern of practice is adopted there is a normative constraint on how things should go. The success or otherwise of a particular person engaged in a specific practice is not something that is open to subjective fiat. There is a normative constraint

Ethics and old age psychiatry

on what counts as excellence in a particular pattern of practice; but this constraint is internal to the practice; the normativity is quintessential despite ultimately depending on what people 'simply do'.

Thus, the notion of patterns of practice can be employed to do some difficult philosophical work in connection with thought and language as well as in the sphere of morals. I now come back to clinical practice, and to old age psychiatry in particular. The ethical question will always concern why one pattern of practice is better or worse than another. How do we justify community treatment over against in-patient admission? I do not intend to deal with this particular issue in detail, but merely to indicate the form of the argument. In order to do this, I require an overview of how patterns of practice are justified.

Justifying patterns of practice

The clinical problem is this: there may be different patterns of practice with respect to particular decisions. One community mental health team (CMHT) might try very hard to keep people in the community in their own homes for as long as possible. While this sounds laudable—it is what patients tend to say they would want and, therefore, it respects their autonomy—it does impose a good deal of stress on some family carers and there is always the risk that something will go wrong. The risk of self-harm is harder to manage in the community. Contrariwise, another CMHT tends to admit people very readily to an in-patient assessment ward. There are obvious concerns about this tendency in terms of cost, stigma, institutionalization, lack of respect for autonomy, the possibility of worsening behaviour learned from other in-patients, and dependence, not to mention the loss of liberty, especially if compulsion is required under mental health legislation. But, on the other hand, the admission might instantly de-escalate a tense situation for all concerned in the community and reduce the risk of violence towards self or others.

So, there are two patterns of practice. While I have said that the *clinical* problem is deciding between them, it is also an *ethical* problem: which pattern of practice is, from both the clinical and the ethical points of view, to be preferred? How do we justify one over the other? In passing it is worth noting that one way in which the notion of patterns of practice might be useful is *precisely because it brings together the clinical and the ethical*; and, in addition, it brings in the legal, the psychological, the social, the spiritual and any number of other potential aspects of a practice. Recall that MacIntyre (1985) defined a practice (in part) as a 'complex form of socially established co-operative human activity'. Whereas it is all too easy for there to be a discontinuity between clinical practice and ethical theory, or at best the latter is imposed on the former, the notion of patterns of practice inherently involves the complexity of clinical practice, whereby biological, psychological, and social considerations do not exhaust the possible levels of human involvement,

Ethics and old age psychiatry

which are likely also to involve ethical, spiritual, legal dimensions, and so on.

The other word used by MacIntyre (1985) in his definition of practice was 'coherent'. I argue that the coherence of a pattern of practice is the way in which it must be justified. This is to recommend a coherentist account of justification, which is often pitted against a foundationalist account. But recall that Wittgenstein spoke of 'bedrock', suggesting foundations, and then promptly appealed to a practice: 'this is simply what I do'. It might be that we do not need to enter further into this dispute: perhaps patterns of practice can be foundational, too, but they also require a mixture of internal and external coherence. Whether there is some 'ultimate' pattern of practice on which others rest and against which, therefore, judgments can be made when other patterns of practice clash, needs further consideration (Hughes 1995). But it is worth noting what Wittgenstein says in response to a question he puts to himself about judging the rightness of an action (where he is talking about obeying an order). He asks us to imagine ourselves as explorers in an unknown country with a strange language. He asks how in that country you would be able to judge whether orders were being given, understood, obeyed, and so on. Then he states:

The common behaviour of mankind is the system of reference by means of which we interpret an unknown language (Wittgenstein, 1953, §206).

This brings to my mind a picture of patterns of practice around particular words or phrases, with broadening patterns of practice as we expand to language and, finally, 'the common behaviour of mankind' when we start to think of language itself. And why should this picture not have some sort of application in the moral field? There may be local justifications for calling a particular practice virtuous, but in the end, we need something common: shared beliefs about what constitutes human flourishing.

Leaving the broader debate in favour of coherentism aside, I suggested earlier that there is a need for internal and external coherence. The first CMHT would be indulging in an internally incoherent pattern of practice if they strove to keep people in the community unless they lived in houses with yellow doors. The pattern of practice would be incoherent because it lacks consistency. If there were a good reason to discriminate against people in houses with yellow doors—if it signified a strange sect with a propensity to violence, for instance—then this consideration would need to be built into the complexity of the pattern of practice, which would thereby retain its coherence. Or, there could be different patterns of practice for people with yellow and non-yellow doors. More seriously, there might be different patterns of practice because of resources, depending on whether the crisis occurs on a weekday or over a weekend. This in turn raises the question about external coherence. Is the pattern

Ethics and old age psychiatry

of practice of the first CMHT better than that of the second? And is the weekend or weekday pattern of practice to be preferred?

Well, before moving away from these particular patterns of practice it might still be worthwhile to consider their internal coherence. MacIntyre (1985) spoke of 'co-operative human activity through which goods internal to that form of activity are realized'. The first CMHT needs to ask itself what the internal goods are at which its pattern of practice aims. The aim might be delineated by the virtue of respectfulness, in which case the CMHT would need to assure itself that variations in its pattern of practice (e.g. in response to weekends or yellow doors) still conveyed appropriate respect towards the person. If we imagine that they have to admit that they simply cannot strive towards respect at weekends, then to this extent they lack internal coherence. This internal incoherence will need to be weighed up against the putative coherence of the second CMHT, who always aim at both benevolence and fidelity: doing good and staying true to their patients. Of course, it can be questioned whether you always do good to people by pursuing a pattern of practice that inevitably leads to in-patient admission. But this is again to stress internal coherence. Here I have been gesturing at the possibility of external comparisons of internal coherence.

True external coherence comes when we ask how this particular pattern of practice squares with our other patterns of practice, or with the patterns of others. We must judge coherence within a broadening field, finally against something akin to 'the common behaviour of mankind'. For instance, a pattern of practice that encouraged compulsory admission would have to be squared with those other practices that valued liberty and autonomy. A pattern of practice that compelled psychiatric admission and treatment on those with political views at variance with the state would have to cohere with those patterns of practice that foster democratic rights and justice, or show them to be incoherent. By implication there is a connection—made by the interconnecting and overlapping of our patterns of practice—between an inclination to admit someone to a ward against their wishes and the pattern of practice embodied in our politically democratic institutions. Obviously, there is no easy way to compel a regime (or a person) to check its own patterns of practice against others, but this refusal to openness itself represents a pattern of practice that would be repudiated by other human practices. The iterative process of checking our patterns of practice for internal and external coherence might itself be regarded as a manifestation of human flourishing.

For the sake of external coherence, the inclination to use compulsory treatment should be modulated by our libertarian values. The weighing up of these different values can occur as an overt comparison between patterns of practice. More likely the process of balancing and assessing occurs naturally within the broad patterns of practice that constitute our clinical and ethical lives. When values are shared between patterns of practice, there is no incoherence; but when values diverge, we have to

Ethics and old age psychiatry

look elsewhere in order to figure how our patterns of practice might cohere. Thus, the business of assessing coherence between patterns of practice aligns with VBP: both reflect how in real life we must deal with diversity.

Clinical practice inevitably involves negotiating between values and navigating between patterns of practice. The aim is to find a way through and, according to the line I have been pushing, the form of the argument will always involve looking at patterns of practice for internal coherence and checking that any particular practice coheres with our broader patterns of behaviour and demeanour. In short, we justify particular cases by reference to our broader forms of life. And, inasmuch as these broader patterns of practice constitutively express the aims and aspirations of human beings generally, inasmuch as they manifest an essential normativity, they can be regarded as embodying something given for human beings like us.

What has to be accepted, the given, is—so one could say—*forms of life* (Wittgenstein, 1953, p. 226).

Summary

I have suggested that the notion of patterns of practice provides a useful way to think about ethical decision-making. I have suggested that this notion is useful both as a way to justify particular practices and as a way to uncover the connections between moral decisions and deeper philosophical concerns about the constitutive nature of normativity in our lives. Not only, therefore, might patterns of practice be clinically useful as a way of situating our ethical decisions and judging them for coherence, but also, through reflecting on patterns of practice, our ordinary clinico-ethical decisions are located in the broader patterns of human life.

The scope of ethical issues

A wide range of ethical issues can occur in the practice of old age psychiatry. In the world of dementia, we have the benefit of a systematic review to highlight the ethical issues that seem to be specific to dementia (Strech et al., 2013). In this section I discuss some of the issues that emerge from the review using vignettes, which are fictitious but are (mainly) based on real cases. I do not, however, limit the discussions to dementia, but I draw on the notion of patterns of practice to see if this is helpful. The point to note about patterns of practice is that they are automatic: this is simply what we do. This does not mean that there is no rational basis to what we do, but the basis is inherent in the practice in terms of its internal and external coherence.

Case study 2 Early diagnosis

Background

Mr Able's wife was worried that her husband might have Alzheimer's disease. He is 52 years old and is self-employed. He is aware that it takes him longer to remember names and even that he has some difficulties recalling words, but he's not otherwise worried. However, both of his parents developed symptoms of dementia when they were in their 70s. His father died from a heart attack, but his mother lived on into advanced dementia and ended her days in a care home in a very dependent state. This worries Mr Able, so he finally agrees to visit his GP. He is given some tests. Aware that he made one or two errors, he is nevertheless a little surprised when he is referred to the local memory clinic. There he undergoes further assessments, including a brain scan. At the end of the process he's told that he has mild cognitive impairment (MCI) and that he should come back the following year.

Comment

According to many people, Mr. Able has done the right thing: he has sought diagnosis early. Furthermore, the system has worked effectively and he has been given the diagnosis of MCI. He will be followed up and can be given treatment and advice when the time is right. He can already be given advice about a healthy lifestyle and perhaps about making advance directives, and so on. The practice described here has a certain internal coherence. Early detection and management is the way to go!

It is, however, worth noticing that the diagnosis of MCI—in line with the principles of VBP—is not value-free (see Hughes and Williamson, 2019, pp. 123–6). It is not automatically true that a diagnosis of MCI will be helpful—indeed it may be harmful—partly because of the uncertainty. The label of MCI can be distressing (Corner and Bond, 2006). It needs to be recognized, too, the extent to which it is a social construct (Moreira, et al., 2008). With respect to MCI we can see values diversity. To some extent, at least, it may represent a good example of the medicalization of normal ageing. But, there again, some people regard ageing as a disease that needs be treated (Nuffield Council on Bioethics, 2018).

The system that views the management of Mr. Able as appropriate, therefore, could be regarded as—from at least some points of view—prone to a lack of external coherence if put into practice without careful consideration. There needs to be a good deal of practical wisdom shown. Compassion requires that the individual's values should be taken seriously and considered carefully. Emotional intelligence, genuine warmth, hopefulness, humble propriety, and a host of other virtues (see Box 51.2) need to be in evidence if things

are to be handled well for Mr. Able. How we impart an early diagnosis or a diagnosis of MCI will be crucially important. We may do these things automatically—and we may do them well or badly—this will be our pattern of practice. But whether that practice is good or bad, right or wrong, will depend on the external coherence of the values and dispositions (the virtues) that underpin our routine practice. There is at least a danger that we might get things wrong, whatever the scientific justification.

Case study 3 Biomarkers and early diagnosis

Background

Winning a large research grant is always exciting. Professor Klemperer's team has been working on the biological basis of Alzheimer's disease (AD) for some years. Now it's possible to look at normal middle-aged adults with and without a family history of dementia to screen for a variety of biomarkers that might indicate a risk of AD. The biomarkers are accessed via blood samples, cerebrospinal fluid, and neuroimaging. The neuroimaging includes a PET scan looking for amyloid. By chance, Professor Klemperer's nephew put himself forward as a control subject. However, when the results came back the nephew was positive for all of the biomarkers. Most alarmingly, his brain seemed to have significant amyloid deposition. The data was anonymised once the research team had it to hand and the protocol specifically said that participants would not have their results fed back to them. Professor Klemperer was bound by these rules, but felt terrible knowing that his sister's son had AD pathology even though he did not yet have dementia.

Comment

Professor Klemperer is abiding by the protocol submitted to the Research Ethics Committee. His actions are internally coherent. Incidental findings on imaging is a topic that has been given considerable thought (Royal College of Radiologists, 2011). Participants in studies are standardly told about incidental findings that are clinically significant and best practice would ensure appropriate support. In Professor Klemperer's study, however, the positive findings of Alzheimer's pathology in his nephew was not expected (in the absence of the family history), but was covered by the protocol. Because there would be no effective treatment, despite amyloid pathology, there seemed no good reason to worry participants with uncertain information about an uncertain future. Studies have looked at the effects of telling people that they are positive for biomarkers, but the issue deserves further ethical deliberation (Hughes et al., 2017). As in the case of Mr. Able (i.e. in connection with early diagnosis), therefore, undertaking studies of

prodromal dementia requires careful thought. The ways in which we do this (i.e. our patterns of practice) can usefully be subjected to analysis in terms of external coherence: to what extent does the practice cohere with the virtues that should inform and underpin actions? Does the practice of either telling or not telling someone of their biomarker status allow appropriate fidelity and respect for the person and demonstrate moral integrity and leadership (see Box 51.2)?

Case study 4 Families, autonomy, and confidentiality

Background

Mrs Sharma has been noticeably confused since her husband died, but she refuses to acknowledge that there is a problem. She says she is just getting used to life without him. But she seems to be putting herself at risk, sometimes wandering over to the park in the evenings, as she used to do with Mr Sharma. She is also ringing her family multiple times every evening, but still resists their offers of help. Her daughter, Nitya, takes her mother to the GP, but Mrs Sharma will not allow her to accompany her into the consulting room. Nitya rings the GP when she gets home, but the GP will not discuss Mrs Sharma with Nitya without her mother's permission, which the GP does not have.

Comment

This is a real bone of contention for carers of people with dementia. In the early stages they can, in effect, be told to get on with looking after their relative in the absence of any information about what is going on, all in the name of patient confidentiality. This would seem to be a practice with strong internal coherence. It coheres with the general practice of keeping confidential information confidential, which holds sway in all other branches of medical practice (in the absence of a threat to public safety and the like).

On closer scrutiny, however, cases like Mrs Sharma's may not be fairly compared with cases of, say, cancer or a multitude of other illnesses. When a person with cancer says she doesn't want her relatives told the diagnosis, this confidence is maintained. But this is because the person with cancer is deemed to have the capacity to make this decision. Even if the clinician feels that it would be beneficial to tell the family, she must not unless she has explicit permission. In the case of someone like Mrs Sharma, if it is true she does not recall that she is ringing her family all the time, it can be argued that she does not have the capacity to make a decision about her family's involvement with what is happening (Nuffield Council on Bioethics, 2009: para. 12). A decision would then have to be

Ethics and old age psychiatry

made in her best interests concerning whether or not to inform Nitya about Mrs Sharma's diagnosis and management. Internal coherence, therefore, requires that presumptions should not be made. This also has the benefit of supporting the family and other carers of the person. A pattern of practice that involved simply refusing to speak with any relative would be wrong. It would fail on grounds of internal coherence, but would also fail in terms of external coherence partly because of its lack of compassion for those who support the person living with dementia.

Case study 5 Advance care plans

Background

Mr. Moloznik always said that if he had severe dementia, he would not wish to be kept alive. Now he has advanced dementia, but he's been surprisingly happy for a long time. He seems to enjoy life. Indeed, he seems happier to be with people now than he ever did when he was younger, before his dementia. Many years ago, he and his wife made Enduring Powers of Attorney (EPAs) in favour of their daughter, Betty. Mr. Moloznik has now developed a chest infection. Before the family can stop it, he is admitted to the nearest hospital and the doctor wishes to give him IV antibiotics. Betty says that she does not wish for this to happen, but it is pointed out to her that an EPA only covers decisions relating to finance and property. The newer Lasting Powers of Attorney can cover welfare issues, including health decisions. But as things stand it is a medical decision as to whether Mr. Moloznik receives antibiotics.

Comment

Once again, the process of VBP would seem to be helpful. It would place Mr. Moloznik centre stage, but would ensure that all of the relevant facts and values were heard. Not to listen to Betty's views seems strange (if not shocking), especially given that she is the donee of the EPA and so was obviously someone that Mr. Moloznik trusted. In any case, given that he lacks the relevant capacity, a best-interests judgment should be made (in keeping with the MCA which covers England and Wales) and should involve 'anyone engaged in caring for the person or interested in his welfare' (MCA, s4(7b) and see Chapter 52). In addition, particular attention should be paid to Mr. Moloznik's past wishes and feelings, because we know that he said he'd not wish to be kept alive. This does not inevitably mean that he should now just be left to die! But it might be that, weighing everything up, including the fact that he's seemed to have a reasonable quality of life recently, it might have been decided to

Ethics and old age psychiatry

keep him in the care home and to try to give him oral antibiotics if possible, avoiding the hospital admission for IV treatment.

To demonstrate internal coherence, the doctor in this case would have had to say that he or she never listened to the views of close family members, or at least not if it was potentially a question of life or death and the family were on the side of 'allowing nature to take its course'. Although this somewhat extreme position would show internal coherence, it would fail on the grounds of a lack of external coherence, because it would not show compassion, nor fidelity to the patient's wishes, nor practical wisdom (that oral might be preferable to IV medication on this occasion, with room for the decision about treatment to be reviewed). In any case, most doctors would not take the extreme position and, I would suggest, this is precisely because it would not cohere either (internally) with their other practices or (externally) with the demands of the virtues that shape a good life.

Case study 6 Resource allocation

Background

Mr De Paul has had a diagnosis of schizophrenia for about 40 years. The community psychiatric nurse (CPN) has been visiting every two weeks to give him a depot injection of medication, which seems over the years to have kept his symptoms at bay. He is 73 years old and lives on his own. The CPN's manager is now questioning why other arrangements cannot be made to save the expense of the frequent visits. Possibly the injection could be given by one of the health visitors from the GP's surgery, who visits in any case to monitor his diabetes. Or perhaps he doesn't still require the injection given that there are now safer medications which can be taken by mouth.

Comment

The CPN is concerned about the therapeutic relationship that he has built up with Mr. De Paul. It would be reasonable to point to the risks of relapse and readmission to hospital, which would themselves involve considerable costs. It could further be pointed out that some of the 'safer' newer antipsychotics must be used with caution in people with diabetes. So, there are a number of arguments in favour of the status quo, but a number of arguments against it. These could be regarded as empirical details that could, in principle, be sorted out. This would be an example where the utilitarian approach might seem to fit, albeit there are imponderables, such as the likelihood of a relapse in this particular case.

Of course, if there were a sense that this saving was being imposed on against grounds, then there would be greater reasons to resist.

Ethics and old age psychiatry

This would be because of a lack of justice. It would, in part, then, show a lack of coherence with other practices, where people of a younger age were treated differently for no apparent reason other than their age. But the issue of justice is also a matter of external coherence, where social justice requires that practices are implemented with fairness, compassion, and integrity across society at large.

The issue here might be one of a lack of regard for the person. Ethical theories such as consequentialism can be criticized for their lack of attention to the individual. Virtue ethics, on the other hand, makes a virtue of partiality! There is a demand that we see ourselves as interconnected in ways that mean the person in front of you should appropriately command your attention and respect. Criticizing theories such as utilitarianism, Michael Stocker put it this way:

What is lacking in these theories is simply ... the person. For, love, friendship, affection, fellow feeling, and community all require that the other person be an essential part of what is valued. ... The defect of these theories in regard to love ... is not that they do not value love (which, often they do not) but that they do not value the beloved (Stocker, 1997: pp. 71–2).

The inclination of the CPN to continue to see Mr. De Paul—this pattern of practice—may well be motivated by the more or less conscious concern—love even—felt for him as a person. The need for this sort of external coherence is not a bad motivating force. At the very least, if the demand for efficiency wins out, handing on the care of Mr. De Paul is likely to be pursued in a better fashion if ‘love, friendship, affection, fellow feeling, and community’ hold more sway than might otherwise be the case.

Case study 7 Driving

Background

Bir Kaza has a diagnosis of bipolar affective disorder made in his late middle age. He has not tolerated lithium and refuses to take any other form of mood-stabilizing drug. He mostly seems to be a little high, although this could be put down to eccentricity. When he is obviously high it is sometimes possible to persuade him to take an antipsychotic drug for a couple of days. He is on an antidepressant at a low dose permanently. He relies on his car to get him to the shops and to the GP's surgery. Today he is high in his mood. He visits his GP, Dr Siradan, who tries to persuade Mr Kaza to take medication, but he refuses. When Mr Kaza goes into the car park, he reverses into Dr Siradan's car. The GP is watching from the window

Ethics and old age psychiatry

with horror. He immediately calls the Driver and Vehicle Licensing Agency (DVLA) and tells them he doesn't think Bir Kaza should be driving.

Comment

Issues around breaking confidentiality in connection with driving are well covered by General Medical Council guidance (2017). Dr Siradan has not complied with the guidance in that, apparently, he has not spoken to Mr Kaza about his driving and yet he is now speaking with the DVLA without warning him. But we are lacking details that might mitigate the GP's actions. For instance, it may be that the driving was very clearly reckless, as opposed to just a little careless. It might also be that the GP feels Mr. Kaza is so significantly manic as to be lacking in capacity to make decisions for himself about contacting the DVLA, and so forth (but in which case, perhaps he should have arranged a Mental Health Act assessment).

Dr Siradan's pattern of practice could be criticized because he might not have behaved in this way with another patient who did not have mental illness. In other words, perhaps the diagnosis of a mental illness has overshadowed judgments about the patient. A small prang in the car park might have been dealt with in an alternative way in a younger patient without a mental illness. So, the practice lacks internal coherence. And it shows, perhaps, a lack of the compassion, justice, temperance, and fidelity (see Box 51.2) that would allow the practice to have external coherence.

Case study 8 Sexuality and intimacy

Background

Mr Jones has marked dementia and lives in a care home. When the carers go into his room in the mornings to help him get ready, he is frequently found masturbating. He does not stop when he sees them. He laughs when they express alarm or consternation, which makes them think he is doing this deliberately. He has also asked staff to do it for him. Now he has been found masturbating in the lounge and one of the female residents has complained to her family who have seen the manager and asked that Mr Jones should be removed from the home, saying it's disgusting.

Comment

You sometimes hear it said that death is the last taboo; but it seems plausible to argue that sexuality in older people with dementia might be. The casuist line that we have been gesturing at in connection with the internal coherence of patterns of practice is applicable. Casuistry is about looking at things case by case, about immersing

Ethics and old age psychiatry

yourself in the details of the case, and about comparing difficult cases with paradigm cases, as well as about applying relevant moral theories (Louw and Hughes, 2005). Looking for internal coherence amounts to casuistry. A question in connection with Mr. Jones's case, therefore, is how would it be dealt with if he did not have dementia? Or, what if the behaviour that was giving offence was not sexual? These questions are not asked to excuse him, but to shed light on the coherence of our responses to him. Attention must be paid to the feelings and sensibilities of other residents as well as to those of the staff. But a natural thing would be to speak with Mr. Jones about the behaviour. This may not have been tried. Punishing him would not seem to be appropriate because, after all, he does have rights in relation to his private life and the home should be affording him both privacy and dignity. It may be that there are practical steps to be taken: leaving him to sleep for longer, giving him periods of time to be alone in his room at certain times of the day, engaging him with more meaningful activities at other times of the day, and so on. Staff need to treat this as they would any other type of behaviour that is challenging if their practice is to be coherent.

But there is a broader issue to do with our needs for intimacy and relationships (Hughes et al., 2014). Sexual behaviour in people with dementia must not always be dealt with solely as if it is a matter of capacity and safeguarding. External coherence might involve broader notions relevant to intimacy, such as friendship, compassion, charity, fulfilment, understanding, and so on.

Case study 9 Assistive technology and robots

Background

Ms Futuro received the diagnosis of dementia in 2032. She has been kept fairly stable by the mixture of medications that she has been receiving, but she does have mild to moderate cognitive impairment. This, together with her mobility problems, which her doctor said she had to accept at the age of 108, has started to make it difficult for her to continue to live independently. Luckily, her son has been able to buy a robot for her that will remind her of some day-to-day routines and can prompt her with certain tasks. It will also bring things to her, dispense her tablets, and monitor her movements so as to alert a controller if she runs into problems. Ms Futuro likes the robot, but she wishes she could see more of her son.

Comment

It may be that robots and assistive technology will turn out to be the way to care for the increasing numbers of older people in the world. We shall have to see! But we also need to be asking the right

questions as the technology develops. To what extent do these developments square with (show internal coherence with) our other practices of care where the emphasis has been on person-centredness? To what extent does an emphasis on technological care square with (show external coherence with) our notions of the good life, of a life that can be lived well and exhibit, insofar as possible, human flourishing? The move, in thinking about assistive technology, has been away from concerns about privacy to concerns about loneliness (Hughes, 2014).

Case study 10 Truth-Telling

Background

Verity always wanted to work with older people. Now she is a care assistant in a care home. There is a particular older woman called Mabel, who is visited every day by her devoted husband, Otto. Verity has formed a bit of a bond with them both. She then hears from the family that Otto has been taken ill and is in hospital. Mabel is told this and, although she has been vague about who Otto is recently, she becomes noticeably upset by the news. She does not seem to be able to remember the news, but she does ask where the man is, which is how she refers to Otto. Two days later, Verity hears from the family that Otto has died. But the family say that Mabel must not be told, because it would upset her unnecessarily and she would not remember anyway. They say she should just be told that he's visiting tomorrow.

Comment

Verity may well feel a sense of tension. Her general style is to be honest with everyone. It will be difficult for her to tell a blatant lie, but she would generally wish not to upset the family, especially not at this difficult time; and she's been told that she must do as they wish. Verity's pattern of practice, to maintain a sense of coherence, has to negotiate her inclination to tell the truth with her inclination not to upset anyone. This shows how internal coherence and external coherence coalesce at times. Verity's other practices tend to be truthful; the external demand, as part of human flourishing, for honesty also influences her practice.

Luckily, we can think of a spectrum from full truth to outright lies. Perhaps the full truth will sometimes not be possible, even if it should always be the aim of professionals. But there are techniques such as distraction and changing the subject which avert the need to lie and avoid upsetting someone (Williamson and Kirtley, 2016). Nevertheless, it is also not unlikely that Mabel will accept the truth much more readily than the family believe, that she will be more

Ethics and old age psychiatry

unsettled without the truth, and for these reasons, they should be gently encouraged to try to tell her the truth at a suitable moment. Not to do so may be to undermine her standing as a person and not demonstrate the sort of respect she deserves as a matter of charity and fidelity.

Case Study 11 Antipsychotics and behaviour that is challenging

Background

Since his admission, Jock has been pacing around the assessment unit for people with advanced dementia clearly looking for a way out. When staff try to distract him, he becomes aggressive. This has only been verbal aggression, but last night he was again trying a door when another male patient walked past and Jock suddenly hit him. The team are now considering whether or not Jock should be prescribed an antipsychotic.

Comment

The management of behaviour that is challenging in dementia is covered in Chapter 19. The counsel of perfection is to use nonpharmacological means first, before drugs, unless the situation is dangerous. The point I wish to draw out here is that we (as prescribers) have a strong inclination to use medication because we know that it will work quickly, whereas other methods will take some time to work, if they will at all. But we need to recognize that this inclination may not cohere with inclinations elsewhere in our practice. It might well be that for a mild depression we would always recommend psychological approaches first. Even if this is not the case, we still pay lip service to the importance of evidence-based medicine. The evidence tells us that prescribing antipsychotic drugs for people with behaviour that challenges is not the most appropriate treatment here (even if it might be under other circumstances). So, there is the potential for a lack of coherence in our practices. In addition, the requirement that we should put into effect person-centred care should also encourage a broad view, based on a broad view of the person (Hughes and Beatty, 2013). External coherence, therefore, involves fidelity to the person, as well as charity, integrity, perseverance, and so forth (see Box 51.2).

Case Study 12 Covert medication

Ethics and old age psychiatry

Background

It is decided to give Jock an antipsychotic. The difficulty is that he refuses to take it. It's suggested that they might give it to him covertly, by crushing it into copious jam in his sandwich, which he loves. Some staff are uneasy about doing this, but they've been told that it is legal when done in his best interests.

Comment

There are guidelines and established principles for giving covert medication. Treloar and colleagues (2001) felt covert medication was acceptable under exceptional circumstances. This seems right, but (of course) a judgment is then required about what is exceptional. If it is likely that a person's health will decline unnecessarily without covert medication, then this would seem like the exceptional circumstances required to justify its use. The internal coherence will be with practices that are beneficent and nonmaleficent. But there can hardly be coherence with the principle of respect for autonomy. External coherence, therefore, must support the practice despite the loss of autonomy. Virtues such as trustworthiness, realism, practical wisdom, compassion, and so on (see Box 51.2) will be relevant.

Case Study 13 Forced care

Background

Margaret screams every time she is taken for a bath. She fights the staff. They feel that they cannot force her to wash. So, they adopt a policy of offering her a bath every other day, but they don't push the issue in case she gets aggressive. However, Margaret has double incontinence and needs to be changed several times a day. It is always a struggle and she always resists. They are not able to clean her properly, but they feel this is all they can do given that she is not able to consent to such treatment and they are concerned it would look like assault if they insisted she bathed. The difficulty is that she is becoming smelly. Other residents do not wish to be near her. They are calling her names. Her poor hygiene is also putting her skin integrity at risk.

Comment

The issue here is that the care Margaret requires increasingly must be given, but she strongly resists. So, the care must be given forcibly. The staff are not keen to do this because they feel it is against legal and ethical guidance. In other words, they are aware of

Ethics and old age psychiatry

a tension in terms of their normal patterns of practice. Normally they seek consent or cajole, but they do not force.

The reorientation required is to see that their inclination to care actually does cohere with the practice of providing 'forced' or necessary care; and can also be legal (Jackman et al., 2014). The key thing is that they should provide such care in accordance with best practice: only using force when it is absolutely necessary, documenting their reasoning behind the use of force, still showing respect to Margaret and protecting her dignity, using enough staff so that it can be done effectively, safely, and swiftly. Under these conditions, 'forced' care can also cohere with the appropriate virtues (compassion, charity, patience, and the like) that underpin all good-quality care.

Case Study 14 Withholding and withdrawing

Background

Mr Bolus, who is in the terminal stages of his dementia, has started choking almost every time he is fed. His son, who lives in America, has suggested by email that his father should be given a percutaneous endoscopic gastrostomy (PEG) tube through which he can be fed. The staff looking after him are not in favour of this and nor is his daughter. She, however, still wishes for him to be fed. At the same time, it is being questioned whether he still needs to receive all of the medication that he previously took. First, he cannot swallow the tablets. Secondly, it is not obvious that they are of benefit to him. Some staff feel it would be better if he were to die.

Comment

First, we need to pay attention to the relevant evidence and, such as it is, this suggests that PEG feeding is not worthwhile (Sampson et al., 2009); secondly, we need to keep in mind the tenets of VBP and acknowledge the diverse values that are in play around the feeding of Mr Bolus. The same impulses that make us not want to use a PEG tube, because it will not do him good and may do him harm, also make us want to stop his unnecessary medication. This shows internal coherence in our patterns of practice. But we still wish to feed him and judgements about the risks and benefits make us believe that oral feeding is still worthwhile, partly because of the human contact it brings. Despite the increasingly difficult circumstances for Mr Bolus, there is a pattern of practice—to do with feeding him appropriately despite the risk of choking—which coheres (externally) with virtues such as empathy, justice, moral integrity, practical wisdom, respect for personhood, and self-effacement. Meanwhile, as in many end-of-life situations, the

Ethics and old age psychiatry

doctrine of ordinary and extraordinary means applies: we must do the ordinary things, but are not morally obliged to do the extraordinary, where 'extraordinary' is defined as actions which are unlikely to work and are likely to be burdensome.

The feeling that it would be better if Mr. Bolus were to die is perfectly understandable. The doctrine of ordinary and extraordinary means allows us not to pursue every means possible to keep someone alive. However, this feeling has for many people turned into support for euthanasia or for physician-assisted suicide. Deliberately aiming at the death of patients does not, in my view, cohere with the patterns of practice that should characterize good medical care. The argument in favour of killing patients is that it can show respect for autonomy, but there is no reason to consider autonomy an overriding principle. Fuller discussion can be found elsewhere (Hughes, 2010; Hughes, 2013). And doctors should note the Statement of the World Medical Association (accessed 4 February 2018):

Physician-assisted suicide, like euthanasia, is unethical and must be condemned by the medical profession. Where the assistance of the physician is intentionally and deliberately directed at enabling an individual to end his or her own life, the physician acts unethically. However, the right to decline medical treatment is a basic right of the patient and the physician does not act unethically even if respecting such a wish results in the death of the patient. [<https://www.wma.net/policies-post/wma-statement-on-physician-assisted-suicide/>]

Conclusion

This chapter has explored a number of different moral theories and approaches and highlighted VBP. It has also introduced the notion of patterns of practice and shown its relevance to everyday practice in old age psychiatry. This is despite the variety of ethical issues that arise. In conclusion, I repeat a quote from the philosopher Michael Luntley, which in some sense sums up the attitude I've been, however shakily, seeking to sketch: 'The moral world has its being in, it rests upon, what we do and how we act. It is in our actions and the way we treat one another that values come into being and are preserved in being' (Luntley, 1995, p. 218).

Mental capacity and decision-making

Chapter: Mental capacity and decision-making

Author(s): Charlotte Emmett and Julian C Hughes

DOI: 10.1093/med/9780198807292.003.0052

Introduction

In 1998, American psychiatrists Thomas Grisso and Paul S Applebaum made the following observation in their text: *Assessing Competence to Consent to Treatment: A Guide to Physicians and Other Officials*:

Competence is a pivotal concept in decision-making about medical treatment. Competent patients' decisions about accepting or rejecting proposed treatment are respected. Incompetent patients' choices, on the other hand, are put to one side, and alternative mechanisms for deciding about their care are sought. Thus, the enjoyment of one of the most fundamental rights of a free society—the right to determine what shall be done with one's body—turns on the possession of those characteristics that we view as constituting decision-making competence (Grisso, T. and Applebaum, P. (1998) *Assessing competence to consent to treatment: A guide for*

Mental capacity and decision-making

physicians and other health professionals. Oxford University Press, p. 1).

What Professors Grisso and Applebaum are describing here is the idea that mental capacity, or competence as they term it, acts as a gateway to personal autonomy in medical decision-making (Donnelly, 2010; Beauchamp, 2013). In most western legal systems, competent adults are free to make significant health, welfare and financial decisions—even unwise decisions—which are, by and large, respected in law. By contrast, those who lack decision-making capacity can have their express wishes overridden by others, acting in their perceived ‘best interests’. Mental capacity exists, therefore, as a boundary or threshold concept in law, distinguishing those who have the right to make autonomous decisions and to carry out legally significant acts from those who do not (Richardson, 2010).

Specialists in old age psychiatry are frequently called upon to assess capacity in relation to medical treatment decisions, determining living arrangements, and a range of other contractual and financial matters relevant in older people’s lives. Issues of capacity and impaired decision-making are particularly prevalent in old age services; this is largely because older people are more likely to have chronic physical and mental health problems that may directly compromise their decision-making ability (Moye et al., 2013). The success of modern medicines and life-sustaining interventions, particularly in the tertiary health sector, has meant that older people’s lives can now be prolonged for many years, even after their cognitive abilities have become impaired, or totally obliterated, by underlying disease or trauma (Buchanan and Brock, 1990). The effects of stroke, infection, coma, the side-effects of medicines, learning disability, dementias, psychosis, and other forms of mental disorder and mental illness, can all have the potential to impact upon an older person’s cognitive functions and consequent capacity in later life.

When significant health, welfare, and financial decisions are proposed, it is usual for health, social care, and legal professionals to be tasked with determining who sits above or below this capacity threshold. Accordingly, these professional gatekeepers wield great power. If an older person is judged to lack capacity, this can have profound and often enduring impact on that person’s freedoms. If, for example, we were to find that Mrs Jones lacks the required capacity to remain living at home and should move into a nursing home, we would be taking away her legal agency, in the sense that her right to choose where she lives and her ability to act on that choice may no longer have legitimacy or legal consequence. We would also be removing, or at the very least diminishing, her sense of personhood, and her social standing as a rational, competent human being. So, it follows that the way we determine capacity and make best-interests decisions must be carefully considered, because if our judgements are not legally and ethically defensible, we can arbitrarily

Mental capacity and decision-making

deny people their rights of self-determination and liberty, which are fundamental human rights.

In this chapter, we focus on the concept of mental capacity, how it is assessed, and its relevance to old age psychiatry. We consider the legal consequences of incapacity, both for the older person concerned and others, before moving to look at some broader principles governing the use of restraint, deprivation of liberty, and support for decision-making. Finally, we turn our attention to how international human rights legislation, and the international disability rights movement generally, increasingly shape the legal approach to capacity and decision-making in the UK.

Although our discussion in this chapter focuses primarily on the *Mental Capacity Act 2005* (MCA), which is the legal framework governing decision-making for those who lack capacity in England and Wales, we have also referred to the *Adults with Incapacity (Scotland) Act 2000* (AISA), which provides an equivalent, albeit very different legal framework in Scotland. We also make reference to the newly enacted *Mental Capacity Act (Northern Ireland) 2016* (MCANI) which takes a radical break from the traditional approach to mental health treatment adopted in mainland UK by ‘fusing’ mental health and mental capacity laws. Once the Act comes into full force in Northern Ireland, mental health treatment in all cases will be based on consent or a lack of decision-making capacity. In this way, the legislation seeks to minimize the stigma associated with compulsory treatment for mental disorder and places the person concerned at the centre of decision-making. The Law Commission has urged the UK and Welsh Governments to consider introducing a similar capacity-based approach in England and Wales in any future reform of mental health law (Law Commission, 2017b, (13.18)).

What is mental capacity?

At its simplest, mental capacity suggests the ability to make a decision, or to perform a task (Culver and Bernard, 1982). This characterization of capacity as an *ability* suggests something practical: that capacity involves practical knowledge, or knowhow (Hughes, 2014). We can see this approach reflected in the ‘functional’ test of incapacity under the MCA in England and Wales: it is the *inability* to understand, retain, and weigh relevant information, or communicate a decision, that indicates a lack of decision-making ability. When any one of these inability is caused by an impairment of, or disorder in the functioning of the mind or brain, then the test of incapacity is satisfied. To this end, the statutory test appears relatively straightforward. However, there are inherent problems when it is applied in the real world of clinical practice.

First, capacity is not an objective scientific term that can be measured with forensic precision. Identifying whether a person lacks the required level of understanding to be deemed incapable of making a specific

Mental capacity and decision-making

decision at a particular time requires rigorous medical and lay assessment and can rarely be stated in absolute or conclusive terms (Gostin, 1986; *Re T (Adult: Refusal of Medical Treatment)*, 1992). Lord Carnworth's rather lyrical view of incapacity from the 1857 case of *Boyse v Rossborough* serves to illustrate this point:

Between ... an extreme case (of mental illness) and that of a man of perfectly sound and vigorous understanding, there is every shade of intellect, every degree of mental capacity. There is no possibility of mistaking midnight for noon; but at what precise moment twilight becomes darkness is hard to determine. [para. 45]

Secondly, capacity can be unpredictable. A person's capacity to understand and retain relevant information may be intermittent, or fluctuate over time according to the effect of his or her illness or disorder (Law Commission, 2017a). Take Mrs Murray, who has vascular dementia; there might be certain times of the day when she thinks more clearly than others. Her capacity may fluctuate from hour to hour and from decision to decision. Equally, her decision-making abilities will depend on the nature of the decision to be made. She may be capable of making simple decisions about what to buy from the shops, but lack the capacity to deal with more complex financial transactions, like selling her property, or making her will. Her abilities will therefore vary according to the objective demands of the task in question (Buchanan and Brock, 1990).

To this end, the MCA favours a time- and decision-specific approach to capacity: capacity is assessed not in a general sense, but in relation to a particular decision to be made at a particular point in time (*Code*, para. 4.4; *A Local Authority v TZ* (2014) at paras. 24–25). The important consideration is whether, at the time a decision is required, or an act needs to be carried out, Mrs Murray has capacity to make that particular choice. To describe her as simply 'lacking capacity' in a general sense, in relation to all matters, would be meaningless in law (39 Essex Street, 2017).

So, by adopting a time- and decision-specific approach to capacity, we recognize that, although people may lack capacity in some aspects of their lives and need support, they are still able to act independently in others. It also becomes apparent that a capacity assessment will be difficult to do well if an assessor has no previous knowledge of a person's particular characteristics and routines, and how their physical and mental problems affect their decision-making capacity (Buchanan and Brock, 1990).

This leads to the related point that capacity is a 'value-laden' concept (Greener et al., 2012). While it might be tempting to view capacity as a test of a person's cognitive ability to weigh up factors, rationally, and to reach a logical conclusion about a singularly correct course of action, to do so would be to take a restricted view of capacity. Decision-making is heavily influenced by values, beliefs, and other relational and emotional

Mental capacity and decision-making

factors that shape the way we weigh up information and make personal choices in life (Gibson, 2017). An interesting report published by the Joseph Rowntree Foundation (2012) on improving decision-making in the care of older people suggests that the decisions older people make are heavily influenced by relational and contextual factors and do not always reflect assumed notions of 'conscious rationality'. Hence, the way we judge another person's capacity should not ignore the 'situated perspective' of the individual being assessed (Hughes, 2014), but pay attention to any cultural, ethnic, or religious life choices which may influence their way of thinking, behaviour, and communication.

This also suggests that those assessing capacity must be alive to their own biases and prejudices and think broadly when making judgements about the abilities of others to make decisions. It is all too easy for unjustified assumptions to be made about an older person's abilities based on a person's diagnosis or age, or because of a desire to keep the person safe. Paternalistic practices can often result in older people being judged to lack capacity simply because they make decisions that are perceived to be risky, or contrary to an assessor's own value system (Wong et al., 1999; Emmett et al., 2013). This would adopt an 'outcome-based approach' to capacity assessment, which the Law Commission of England and Wales has rejected as it 'penalises individuality and demands conformity at the expense of personal autonomy' (Law Commission, 1995, (3.4)).

All the same, outcome-based approaches to capacity assessment appear a lot in practice (House of Lords, 2014). In many ways, this is understandable. If an older person, who might have a degree of physical or mental vulnerability, makes it plain that he or she wishes to choose a course of action that has the potential to lead him or her to harm, those who care might determine that the person concerned lacks the requisite capacity. Yet it is an approach which militates against accepting unwise decisions and respecting autonomous choices and for this reason should be avoided. After all, the purpose of the MCA's jurisdiction is to enable those who lack capacity to enjoy life to its fullest with the potential available to them; and to lead life to its fullest is, inevitably, to incur some risks (Hedley, 2014).

So, if we consider Mrs Murray again: she wants to remain living at home, she struggles with her continence, is unkempt, and her fridge contains out-of-date food. She says that she understands the risks of living at home, but would rather die on her own kitchen floor than in a care home.¹ In this situation, the temptation is to conclude that Mrs Murray lacks decision-making capacity, as her wish to stay at home in squalor might be at odds with our view of how she should live her life. Yet, by doing so we are making judgements about how she should live her life based on our own values; and by denying Mrs Murray her mental capacity to make her own choices about her living arrangements we are denying her the exercise of her human rights. So, this is not a step we should take

Mental capacity and decision-making

lightly—and not without a conducting a careful enquiry into her capacity to make this decision.

Which brings us to the question of how capacity should be assessed.

Guiding principles of the MCA

The MCA begins at section 1 with a set of five guiding principles, or benchmarks, which must be applied to all acts and decisions taken under the Act. Principles 1 to 3 are particularly relevant to capacity assessment. The MCA's guiding principles are reproduced in Box 52.1.

Box 52.1 The principles of the Mental Capacity Act 2005 (Section 1)

The following principles apply for the purposes of this Act:

- 1** A person must be **assumed to have capacity** unless it is established that he lacks capacity.
- 2** A person is not to be treated as unable to make a decision unless **all practicable steps to help** him to do so have been taken without success.
- 3** A person is not to be treated as unable to make a decision merely because he makes an **unwise decision**.
- 4** An act done, or decision made, under this Act for or on behalf of a person who lacks capacity must be done, or made, in his **best interests**.
- 5** Before the act is done, or the decision is made, regard must be had to whether the purpose for which it is needed can be as effectively achieved in a way that is **less restrictive of the person's rights and freedom of action**.

Mental Capacity Act, 2005. © Crown copyright

The presumption of capacity

The starting point in any capacity assessment, and the first guiding principle of the MCA, is the presumption of capacity: 'A person must be assumed to have capacity unless it is established that he lacks capacity.' Just because someone has a diagnosis of a mental disorder or impairment, does not mean, of itself, that they are unable to make a decision and lack capacity.

Case Study 1

Mental capacity and decision-making

John Thompson is a 45-year-old man with Down syndrome. There is a question as to whether he might now be developing dementia: there has been some deterioration in his ability to attend to his daily needs. He has been living for some years in a supported home with three other men with intellectual disabilities. The home now has to be sold and the charity which runs the home is looking for alternative accommodation for the four residents.

A first step we must assume that John has the capacity to decide his own living arrangements unless it is proven otherwise. In this way, we are much less likely to take away his right to make autonomous decisions. John may well have some strong preferences about the area he wishes to live in and about with whom he wishes to live. If he has the capacity, he should be allowed to make his own decision and we would not want to take away that right without a careful enquiry into his decision-making capacity. To assume that he lacks capacity without further enquiry would deprive him of his legal right to make a decision about where he lives as well as show him considerable disrespect: not only in general terms as a person, but also specifically in terms of his autonomy.

Equally, nothing should be presumed merely on the basis of John's diagnosis of Down syndrome, whether or not he also has dementia. This would assume a 'status' or 'category' approach to capacity based on John's membership of a particular diagnostic group. This is explicitly precluded by s2(3) MCA, which states capacity cannot be established 'merely by reference to a person's age or appearance, or a condition of his, or an aspect of his behaviour, which might lead others to make unjustified assumptions about his capacity'. Such an approach has also been rejected by the Law Commission as oversimplifying the question of whether a person has decisional capacity and undermining the respect for individual rights (Law Commission, 1995 (2.43)).

The onus is on the person who considers that it may be necessary to take a decision or step on John's behalf (the 'decision maker') to displace the presumption of capacity, on the balance of probabilities. It is not for John to show that he has capacity, but for the decision maker to show that, on balance (more likely than not), John lacks the capacity to decide his living arrangements. Also, care should be taken to reflect the correct standard and burden of proof in any record of the assessment made. In *Heart of England NHS Foundation Trust v JB* (2014), a case in which a patient with paranoid schizophrenia refused the amputation of a gangrenous foot—in terms of facts reminiscent of the well-known case of *Re C (Adult: Refusal of Treatment)* (1994)—Mr Justice Jackson stated in his judgment:

At all events, it is for the Trust to displace the presumption that JB has capacity on a balance of probabilities. It is important that the right question is asked. When assessing JB in October, Dr O approached matters on the basis that JB was 'unable to *clearly* show

Mental capacity and decision-making

that she had considered the option' of amputation. Similarly, in January, Dr B remarked that 'one needs to *be certain* of her capacity' while in February, Dr O recorded that JB 'is unable to *fully* understand, retain and weigh information ... '. These formulations do not sit easily with the burden and standard of proof contained in the Act (emphasis added). [para. 27]

Turning again to John Thompson, and recalling that capacity is always task- and time- specific, we should question whether John has the capacity to make the particular decision that is required at the moment. If he does not, two questions follow. First, might he regain the required decision-making capacity? If it is reasonable to wait, then the decision should be postponed (s4(3) MCA). Obviously, if the decision genuinely cannot be put off, then it will have to be made for him; in which case we must act in his best interests. But before we get to that, the second question, which follows if John is struggling to demonstrate the level of capacity to make the particular decision required, concerns whether he might be helped to gain or regain the required capacity. This is the second principle of the MCA.

The supported decision-making principle

The MCA specifies at s1(3) that 'a person is not to be treated as unable to make a decision unless all practicable steps to help him to do so have been taken without success'. This is sometimes referred to as 'the supported decision-making principle' of the MCA and is arguably one of the most important principles of the Act, yet one that is often ignored in practice (House of Lords, 2014). Its purpose is to maximize capacity by enabling a person to make an autonomous decision wherever possible.

Given the importance of the principle, the new MCANI 2016 sets out concrete examples of what may amount to supported decision-making explicitly on the face of the Act at section 5, under the heading 'Supporting person to make—decision'. Under the MCA, ways of enhancing a person's capacity are to be found in the MCA *Code of Practice* at Chapter 3 (Department of Constitutional Affairs, 2007). These include making sure that the person has all the relevant information he needs to make the decision, including any options that might be available. Relevant information needs to be presented in a way that is easy for the person to understand, using pictures, photographs, videos, tapes, or sign language where appropriate. Relatives, friends, or advocates should assist with the assessment, if they are better able to help the person understand. Similarly, thought should be given to whether the timing and venue for the assessment are appropriate (Poole et al., 2014). Assessments should take place when the person is most likely to be functioning well—perhaps in the morning, or a period when an older person is known to be more lucid. Consequently, capacity assessments must not be conducted at random times on busy wards with frequent interruptions from other staff and distractions and noise.

Mental capacity and decision-making

It is also worth reflecting on the meaning of 'practicable'. We are told that what are practicable steps to maximize capacity 'may vary depending on the decision to be made and the timescale for making the decision and the individual circumstances of the person' (*Code* para. 3.1). We might be tempted to regard some things as not 'practicable', because there is not enough time, because people are too busy, because it will cost too much money, and so on. These might be reasonable excuses and they might mean that a certain course of action is not 'practicable'. But the wording of the MCA is uncompromising: a person cannot be regarded 'as unable to make a decision *unless* all practicable steps' have been 'taken without success' (with the emphasis added). The clear implication is that all practicable steps must be attempted. 'Practicable' does not mean 'convenient'; it rather suggests that if it can be done, however inconveniently, it should be. That being said, 'practicable' does not mean 'possible', so it is accepted that what is practical will vary and compromises may have to be made. Much depends on the urgency and nature of the decision to be made and the circumstances or condition of the person concerned. Significant, one-off decisions (such as deciding upon a change of residence, or whether to undergo a serious medical procedure) may warrant greater efforts to maximize a person's capacity compared to day-to-day decisions about care and welfare. However, the same general processes should apply to each decision (see *Code*, para. 3.3).

Case Study 2

Mr Chan has severe Parkinson's disease and dementia. He is now unable to communicate, but requires a decision about his future care. The clinical team take the time required to involve the speech and language therapists to see if it might be possible to facilitate some form of communication. The speech and language therapists spend several sessions with Mr Chan trying to find ways to help. His Parkinson's medication is reviewed. He is seen by the old age psychiatry liaison team in case some feature of his mental state (depression or confusion) might be amenable to treatment but impeding his communication.

These are 'all practicable steps', which accordingly have to be taken, not just to comply with the law, but also because to do less than this would be to undermine Mr Chan's standing as a human being with rights, who is worthy of respect.

So, too, with John Thompson. The charity running the home in which he lived arranged for a team of specialists to see him over several weeks and months to try to understand his wishes about his future place of residence and care. They used pictures, and stories, held conversations

Mental capacity and decision-making

with John as well as the other residents and staff, took John to look at several different areas and possible places to live, and reflected with him and with his family. Again, all practicable steps were taken to allow him to participate in the decision.

What prompts a capacity assessment and who should assess capacity?

If we believe that a person may have lost (some components of) capacity we have to be careful about how we determine whether this is true. We should, after all, presume capacity (see Box 52.1). Where there is a suggestion that capacity may be impaired, then there are grounds for making an assessment, without which the person may be vulnerable. By and large this will not create problems, if handled sensitively and appropriately.

There is often no one thing that prompts the need for a capacity assessment, although there are factors which, when considered together, may suggest diminished decision-making capacity. These signs should not be taken alone as proof of incapacity, but may indicate a need for further evaluation and assessment. So, any abrupt changes in mood or personality, confusion in time or space, difficulties completing familiar tasks, or where a person makes a series of unwise transactions or decisions which puts himself or others at risk, may be markers of declining capacity. Often family members and carers may be the first to notice these changes and may express concerns. When these indicators are coupled with the presence of an impairment or disturbance that affects the abilities of a person to decide, this may prompt a more detailed enquiry into their mental capacity.

It is widely acknowledged that capacity is more likely to be questioned in practice when a person disagrees with a proposed course of action (Shah et al., 2009; House of Lords, 2014). There is also evidence to suggest that people who do not question professional opinion might avoid an assessment of capacity altogether, even when there is cause to doubt the presumption of capacity (Okai et al., 2007; House of Lords, 2014). However, as previously mentioned, anyone who carries out an act or treats relying on an invalid 'incapacitated consent', or with no consent at all, would be acting unlawfully (*Re F (Mental Patient: Sterilisation)* (1990)).

Most often the professional who is directly concerned with the individual at any one time, and who proposes to carry out an act, or make the particular decision, will assess capacity as 'decision maker'. This person must have a reasonable belief that the person concerned lacks the requisite capacity before they can act lawfully in the incapacitated person's best interests. Occasionally, where there is a question over a person's capacity, where it is borderline or fluctuating, or where a decision is particularly serious or likely to be challenged at a later date, then assistance from a specialist psychiatrist or other medical

Mental capacity and decision-making

professional might be sought (*Code*, para. 3.37). For example, a solicitor who needs to be satisfied that an older person has the requisite capacity to make a will, or create a Lasting Power of Attorney, may request the assistance of an old age psychiatrist when forming this opinion. In this situation, the consultant psychiatrist, as assessor, will be acting purely in an advisory role, with the decision maker (the solicitor) remaining the person who is ultimately responsible for the capacity decision.

Given that so many decisions need to be made in respect of an older person at any one time, it is likely that different decision makers will assess a person's capacity to make different decisions at different times throughout the day. Although a person's capacity needs to be assessed every time that person is required to make a decision, the formalities surrounding the assessment, and who should be the assessor, depend on the seriousness of the decision to be made, or the acts to be carried out. Professionals qualified in a particular field are normally expected to undertake a fuller assessment of capacity than family members or other carers who have no formal qualifications, reflecting their higher degree of knowledge and experience (Donnelly, 2009). For example, nurses and lay carers may make countless capacity assessments every day when caring for older people. These are made almost intuitively, without any formalities and it would be highly impractical to document these types of assessments against the requirements of the MCA on each occasion. Nevertheless, lay carers, like professionals, will still need to justify their objective reasons as to why they believe an individual lacks capacity if required to do so by a court.

The capacity test under the MCA

The Mental Capacity Act 2005 defines incapacity in the following way, at section 2(1):

... a person lacks capacity in relation to a matter if at the material time he is unable to make a decision for himself in relation to the matter because of an impairment of, or a disturbance in the functioning of the mind or brain (section 2(1)).

There are two distinct elements to this definition.

The first focuses on the person's inability to make the decision at the material time. This is known as the 'functional test' and centres on a person's decision-making abilities.

The MCA then sets out what it means to be 'unable to make a decision'; namely, the person is unable:

- 'To understand the information relevant to the decision
- To retain that information
- To use **or** weigh up that information as part of the process of making the decision, **or**

Mental capacity and decision-making

-
- To communicate his decision (whether by talking, using sign language or any other means).’ (section 3(1))

The second element is that a person’s inability to make a decision must be ‘caused by an impairment of, or a disturbance in the functioning of the mind or brain’. This is commonly known as the ‘diagnostic test’. This impairment may be temporary or permanent and would encompass those who lack capacity following a physical injury to the head or body that results in confusion, or unconsciousness; those suffering from a confusion brought on by alcohol and drug misuse, severe pain, shock or fatigue; as well as the more obvious categories of psychiatric illness, dementia, or the long-term effects of brain damage.

It is important to stress that, according to the definition of incapacity under the MCA, the inability to make the decision must be *due to, or because of*, an impairment or disturbance in the functioning of mind or brain. The courts have referred to this as the ‘causative nexus’ that must exist between the inability to make a decision and the impairment of mind or brain. In *PC and NC v City of York Council* (2013) the suggestion by experts that PC’s inability to make the decision to cohabit was ‘referable’ to or ‘significantly relates’ to her mental disorder fell short of finding that the inability was ‘because of’ her disability as required by MCA s 2(1).

Of course, the tendency in practice is to approach capacity assessments by focusing first on the diagnostic threshold before moving onto the functional test—after all, this is what the *Code* advises us to do! However, the Court of Appeal in *PC and NC v City of York Council* suggested that this approach (focusing on the diagnostic test first) might mean that the ‘causative nexus’ of the test is ignored. According to McFarlane LJ,² we should instead ask whether the person concerned is unable to make a decision by applying the section 3 functional test first, before moving to ask whether this is because of the underlying mental or brain impairment. Whether this advice is widely taken up in practice remains to be seen, although it probably matters very little as long as the person’s diagnosis does not lead to an assumption of incapacity, or the causative nexus is not overlooked.

Information: How much and what needs to be understood?

When providing information, careful thought must be given to the nature of the decision to be made and the relevant legal test that might apply. In the UK, there is a variety of common law tests of capacity, which include tests for testamentary capacity, capacity to make a gift, to marry, or to litigate, and so on. These tests are not replaced by the MCA. Some, as in the case of testamentary capacity, hold sway in other jurisdictions too. These specific tests are well described in the excellent guide published by The British Medical Association and the Law Society, now in its fourth edition (British Medical Association and Law Society, 2016). In Scotland, similar BMA guidance can be found online (British Medical Association, 2009). So, if capacity is being assessed in relation to the making of a will,

Mental capacity and decision-making

for example, the assessor should be aware of the extent of the person's property and the identity of those who may have claims on the estate, such as a spouse or family members (for further details on testamentary capacity, see Chapter 58). In terms of medical treatment, relevant information would include specific information about what is involved in the proposed course of treatment, why the treatment is necessary, any options or alternatives to the treatment, and the reasonably foreseeable consequences of consenting to or refusing treatment, or indeed failing to decide—i.e. the risks and benefits (MCA *Code of Practice*, Chapter 3).

The required level of understanding must not be set too high; the person concerned need not understand every detail of what is being explained, just the salient factors. What is clear is that the person concerned must be given something to weigh and assess, such as detailed options; it is not appropriate to start an assessment with a 'blank canvas' (*CC v KK and STCC* (2012)).

Given that 'the more information that the participant must understand, and the more complex the nature of that information, the more impact it will have on an individual's capacity to understand' (Gunn et al., 1999, p. 278) the type of information and the way in which it is presented is of the utmost importance. In cases of borderline capacity, this may well tip the balance in favour of a finding of capacity. In *Heart of England v JB*, Peter Jackson J summarized the approach to be taken:

[w]hat is required here is a broad, general understanding of the kind that is expected from the population at large. JB is not required to understand every last piece of information about her situation and her options: even her doctors would not make that claim. It must also be remembered that common strategies for dealing with unpalatable dilemmas—for example indecision, avoidance or vacillation—are not to be confused with incapacity. We should not ask more of people whose capacity is questioned than of those whose capacity is undoubted. [para. 26]

Clear communication is necessary even when certain outcomes make for uncomfortable conversations; the use of euphemism should be avoided (Emmett et al., 2013). This underscores the supported decision-making principle of s1(3) discussed earlier.

Retaining information

Capacity is assessed at the 'material time', that is at the time the decision needs to be made and the assessment carried out. The fact that an older person with memory deficits can only retain the information for a limited period does not prevent the person having capacity as long as information is retained for as long as is needed to make the decision (s3(3)). If an older person suffers from dementia, it is irrelevant that the information is lost and forgotten after this relevant period has passed. Aids to assist a person to recall information might need to be considered, such as

Mental capacity and decision-making

pictures or photographs, in line with the supported decision-making principle of the Act.

Using and weighing relevant information

One of the trickiest aspects of the MCA capacity test is judging a person's inability to 'use and weigh' relevant information as part of the process of making the decision. The ability to use and weigh information is often affected by psychiatric disorders, psychoses, delusions, and affective states (Hotopf, 2013).

The courts have interpreted the using and weighing requirement as testing whether a person can 'engage in the decision-making process itself and . . . be able to see the various parts of the argument and to relate the one to another.' (*PCT v P, AH and the Local Authority* (2009), para. 35). In the United States, the capacities for *reasoning and deliberation* have been said to require:

... capacities to draw inferences about the consequences of making a certain choice and to compare alternative outcomes based on how they further one's good or promote one's ends. Some capacity to employ at least very rudimentary probabilistic reasoning about uncertain outcomes will commonly be necessary, as well as the capacity to give due consideration to potential future outcomes in a present decision. Reasoning and deliberation obviously make use of both capacities mentioned earlier: understanding the information and applying the decision-maker's values (Buchanan and Brock, 1990, p. 25).

As before, it is important to remember that not all the details of a proposed act or decision need to be weighed and used, just the salient details. Also, because a person makes a perceived unwise decision this does not necessarily mean that she is unable to use and weigh relevant information.

Case Study 3

Miss Jackson is an intelligent, unmarried, retired solicitor, who lives alone. She has a history of bipolar affective disorder. She seems to be a little high in her mood. She continues to take her medication and she manages her day-to-day affairs without any obvious difficulties. Her nephew, also a lawyer, is concerned that she is giving excessively large sums of money to the local charity for homeless people. He thinks she may not have the capacity to make such decisions because her reasoning has been affected by her mania. He wants to approach the Court of Protection to argue that she lacks the capacity to run her financial affairs. She disputes this

Mental capacity and decision-making

vigorously and points out that she has always given money to local charities.

If we believe Miss Jackson is simply being unwise, we cannot on that ground alone say that she lacks capacity. She must be allowed to make unwise decisions. But if we believe that her decision to spend her money this way is made because she is unable to weigh and use information owing to her disorder, then we should decide she lacks capacity and take steps to make sure that decisions are made in her best interests, which may or may not include giving money to this particular charity. In this case, the amounts of money given to the charity may assist the determination of capacity. Are the sums broadly the same as given previously, or are they significantly inflated above what she would usually consider giving?

But, more importantly, what is the rationale for her donations? Does she understand the sums involved, how much money she has at her disposal, and the consequences of her actions? In other words, is she able to weigh the advantages and disadvantages of her actions?

Of course, the difference between being unwise and being unable, due to mental disorder, to weigh up matters appropriately in order to make a decision, which would constitute a lack of capacity, is sometimes going to be a fine distinction to draw. There is also a certain amount of flexibility in this provision. Some of the more controversial findings of incapacity made by the courts in the past have been as a result of applying this rather amorphous standard (Bartlett, 2005, para. 2.24). Some commentators have questioned whether it makes sense to argue that a wholly unwise decision could yet be capacitous (Culver and Gert, 2004). But this is to suggest that an outcomes-based assessment of capacity (as mentioned earlier), rather than a functional one, should be preferred. This is a point of view that might seem to have some initial validity, except that it impedes the person's ability (and right) to make autonomous decisions. It tends to position the individual's choices as vulnerable to outside interference. If the world thinks that Miss Jackson is being unwise, on this view, she can be declared to lack capacity, even if she can give adequate reasons for her choices. This runs counter to the position adopted by the MCA, which allows that we can be eccentric without thereby lacking capacity.

Communicating the decision

Some people with physical disorders of the brain following head injury or stroke, for example, might be unable to communicate a decision, and so may be unable to satisfy this part of the functional test. A small minority of people may also have what is termed 'locked-in syndrome', so while being able to understand, retain, and weigh information, they may not have the ability to communicate a choice. Remembering that all practicable steps should be taken to assist a person to demonstrate

Mental capacity and decision-making

capacity, it is particularly important to consider (and record) any tools, specialists, or carers who could be brought in to aid communication. Any residual ability to communicate, such as blinking an eye to indicate 'yes' and 'no', would be enough to exclude a person from this category (Explanatory Memorandum to the MCA, para. 27).

Unwise decisions

As we touched on earlier, unwise decisions do not alone lead to a finding of incapacity. This is made explicit at s1(4) of the MCA: 'A person is not to be treated as unable to make a decision merely because he makes an unwise decision.'

As we know, human beings are not wholly rational and are prone to make unwise decisions. However, separating unwise decisions from incapacitated ones and allowing people to make choices that might be considered manifestly unwise can be particularly challenging for professionals who have been 'trained to a protective instinct' (Hedley, 2014). Research suggests that assessors will often struggle to reconcile the need to respect an older person's autonomy with their perceived duty to keep that person safe (Emmett et al., 2013; Williams et al., 2012; Series, 2015). As a result, it is not altogether surprising that people who make what are perceived to be foolish decisions are more likely to be found to lack capacity than those who agree with the decision maker—especially when the decision impacts on the person's health and welfare in some serious way (House of Lords, 2014). Nonetheless, the courts have repeatedly cautioned against what judges have termed the 'protective imperative' in case law. Turning again to *Heart of England v JB* (2014), Peter Jackson J noted:

The temptation to base a judgement of a person's capacity upon whether they seem to have made a good or bad decision, and in particular upon whether they have accepted or rejected medical advice, is absolutely to be avoided. That would be to put the cart before the horse or, expressed another way, to allow the tail of welfare to wag the dog of capacity. Any tendency in this direction risks infringing the rights of that group of persons who, though vulnerable, are capable of making their own decisions. Many who suffer from mental illness are well able to make decisions about their medical treatment, and it is important not to make unjustified assumptions to the contrary. [para 7]

Case Study 4

Mr Siddique was admitted to an acute medical ward with a delirium caused by a urinary tract infection. When he recovered it was found that he still had cognitive impairment and his niece, his closest relative, confirmed that he had been forgetful for over a year. He

Mental capacity and decision-making

said that he wished to return to his home, but he was disoriented on the ward, and an occupational therapy assessment at his home showed that it was squalid and that he had sequencing problems when asked to make a pot of tea. The multidisciplinary team felt that he would be much better off in long-term care.

In order to take things forward, there must be an assessment of Mr Siddique's capacity to make a decision about his place of residence. An outcomes-based approach might be inclined to the judgement that his wish to go home, despite the problems, is itself a sign that he lacks the capacity to make this decision given the potential risks. This would, however, be problematic because it suggests that our ability to make a decision depends on us making the right decision. The question that is then begged is: who decides what is right? The reason this approach is regarded as wrong is because it rules out from the beginning the possibility that the person concerned should be the one who determines what is right.

If Mr Siddique says that he wishes to go into a care home, it may well be said that he makes this decision with capacity (because he is clearly able to weigh up the retained information, which he understands, and he is able to communicate his decision). Conversely, if Mr Siddique says he wishes to go home, the judgement may well be that he lacks capacity (because he is not weighing up the relevant information in the right way). However benign, the outcomes-based approach is inevitably paternalistic: in laying great store by the need to do good and avoid harm it completely ignores the importance of respecting the person's autonomy. This is a strong temptation to caring professionals who wish to do the best for their patients or clients. It is an interesting phenomenon and takes us back to the point that evaluative judgements and emotions play a role in the assessment of capacity (Greener et al., 2012).

As a practical point, the assessment of residence capacity, which is at issue in the case of Mr Siddique, can seem tricky because the information the person is required to understand, retain, and weigh is not set down and might be debated. But we have suggested that the following would constitute the relevant information:

1. The person should know **why** a change of residence is being proposed: what have the problems been that have caused a concern (e.g. they should know why they had to come into hospital or what has caused a worry in the community).
2. The person should know **what** is being proposed (e.g. they should know that it is being suggested they should move into a care home).
3. The person should be informed if there are **other options** (e.g. that they could go home but extra help is recommended because of the risks identified).

Mental capacity and decision-making

4. The person should understand the **likely consequences** of making any particular decision, including a decision not to follow the advice being given, as well as the consequences of making no decision at all' (Hughes et al., 2015).

The sliding scale of capacity

One problem that emerges in thinking about capacity concerns whether the threshold of capacity varies depending on the decision that has to be made. In other words, does the more serious the possible consequences of the decision or the more complex the issue which is the subject of that decision mean that a higher threshold of capacity is required? This is sometimes called the concept of 'proportionality' and has received a good deal of judicial support over the years. Typically, the way capacity is assessed in proportional terms will depend on the complexity and gravity of any proposed decision or act. In *Re T* the Court of Appeal determined that although someone might have reduced capacity,

What matters is that the doctors should consider whether at that time he had a capacity which was commensurate with the gravity of the decision which he purported to make. The more serious the decision, the greater the capacity required. If the patient had the requisite capacity, they are bound by his decision. If not, they are free to treat him in what they believe to be his best interests. [para. 28]

Hence, we can think of a sliding scale, where decisions that are riskier require greater demands in relation to the information than decisions that are less risky (Gunn et al., 1999). However, the notion of a varying threshold for capacity is itself controversial (Buchanan, 2004) and on a practical level creates dilemmas for assessors who must decide where a particular capacity threshold lies. Set too high, a person's freedom to make an autonomous decision will not be respected in law; set too low and we run the risk of according respect to a decision that may not represent a person's true autonomous choice if masked by an underlying mental disorder, thereby exposing the vulnerable person to harm and/or exploitation (Richardson, 2013; Law Commission, 2017b).

An alternative approach is to argue that there is simply a threshold of understanding for all decisions (Jonas, 2007; Law Commission, 1995). The upshot of both approaches might be the same if more risky procedures are also more complicated to understand, which will not always be the case! Reflection suggests, however, that there are probably limits to both approaches. Otherwise we might, for instance, have to say that only a very few people would be able to give valid consent to undergo very complicated procedures (neurosurgery say) because only a few would have the requisite capacity based on either the level of risk or the complexity of the information.

Mental capacity and decision-making

The consequences of incapacity

Where a person lacks the mental capacity to make a particular decision, the decision-maker is faced with a dilemma: in the absence of consent or some other legal justification, any touching of an incapacitated adult may amount to a civil trespass to the person, a criminal assault, or may breach that person's human rights; conversely, failing to carry out a necessary act to protect a vulnerable person's health or wellbeing may expose a decision maker to liability in negligence for breaching the professional's perceived duty of care towards the incapacitated person (*Re F (Mental Patient: Sterilisation)* (1990) per Lord Bridge). In the past, the common law has afforded decision-makers with a defence against legal liability for non-consensual treatment and care through the common law 'doctrine of necessity', provided the proposed act is necessary and in the incapacitated person's *best interests*. This common law defence of necessity is now codified in the MCA at section 5.

The defence against liability under Section 5 MCA

Section 5 MCA allows certain decisions or acts in connection with the care and treatment of incapacitated people to be carried out without consent and without a decision maker incurring criminal or civil liability, if they have a reasonable belief that what is proposed is in the incapacitated person's best interests.

So, before any act is carried out, a decision maker must take reasonable steps to assess capacity under sections 2 and 3 MCA and in accordance with the guiding principles of the Act and *Code* before moving to consider a best-interests decision. What are 'reasonable steps' will depend on the individual circumstances and the urgency of the decision to be made. If a person lacks capacity, but is likely to recover capacity in the future, then if possible, any decision must be postponed until capacity is regained. Equally, we must be satisfied that the person concerned has not made a valid and applicable advance decision refusing the treatment being proposed. If this is the case, the advance decision refusing treatment must be complied with and section 5 would not provide us with protection from liability, even if we thought that treating a person would be in an incapacitated person's 'best interests'.

Section 5 talks about 'a person who does an act in connection with the care and treatment of another' and this wording would also include third parties who are instructed by that person to carry out certain acts. The *Code* suggests that more than one person may be acting in accordance with section 5 at any one time. So donees acting under Lasting Powers of Attorney, Court of Protection Deputies, family members, paid and voluntary carers, and healthcare and social care professionals, may all be involved in the care of the person and may need to make decisions and carry out acts in connection with the person's care and treatment.

Mental capacity and decision-making

The effect of section 5 is that it places those who make decisions or carry out acts in the reasonable belief that the person concerned lacks capacity, and that what is being proposed is in that person's best interests, in the same position as those who rely on the express consent of adults with capacity as legal authority to act.

Finally, it is important to note that some decisions are excluded from the remit of the Act and the general defence afforded by section 5. These decisions can never be made by a decision maker in an incapacitated person's best interests and can only be taken if the person concerned has capacity and consents to the decision in question. Excluded decisions include consenting on an incapacitated person's behalf to:

- marriage or to a civil partnership
- divorce or dissolution of a civil partnership
- have sexual relationships
- adoption
- voting in an election, and
- fertility treatment.

Section 4—the Best Interest Checklist

An important guiding principle of the MCA (as well as of the Mental Capacity Act in Northern Ireland) is that any act done or decision made for or on behalf of a person who lacks capacity must be done or made in that person's 'best interests'. The only exception is in respect of a valid and applicable advance decision refusing treatment, which must be followed whether or not the refusal is in the best interests of the incapacitated person concerned.

In Scotland, the Scottish Law Commission rejected the notion of best interests standard during the passage of the *Adults with Incapacity (Scotland) Act 2000*, primarily on the grounds that it believed the concept was too vague and did not give due weight to the views of the adult concerned, particularly to their wishes and feelings. Also, given the best interests concept developed in child law it was felt wrong to extend child law concepts to adults with mental disorder (Scottish Law Commission, 1995). Accordingly, the general principles refer instead to the notion of 'benefit':

There shall be no intervention in the affairs of an adult unless the person responsible for authorising or effecting the intervention is satisfied that the intervention will benefit the adult and that such benefit cannot reasonably be achieved without the intervention.
(Part 1, Section 1(2))

Mental capacity and decision-making

Whether it is 'best interests' or 'benefit', the question arises as to what these terms mean. Our focus here is on the best-interests principle under the MCA.

Determining what is in the incapacitated person's best interests

The *Code* suggests that the term 'best interests' cannot be defined on the grounds that individual cases will always require individual judgements as to what will be best for a particular individual. This can neither be stipulated ahead of time nor in general terms. Instead a checklist of factors is set out at section 4 MCA, to guide decision makers when determining what is best for the person concerned in each specific case. The steps in the list must always be considered (Explanatory notes to MCA, para 28), even if it is simply to acknowledge that a factor may not be relevant and can be disregarded. The section expressly instructs decision makers to consider all relevant circumstances as may be required, so the list is not exhaustive. A summary of the best-interests checklist is set out in Box 52.2.

Box 52.2 Summary of the best-interests checklist at section 4 MCA

Generally

- i Avoid discrimination:** don't decide what is best merely on the basis of a person's age, appearance, condition or behaviour for example.
- ii Consider all relevant circumstances.**

In Particular take the following Steps:

- iii Assess whether the person might regain capacity in near future:** if so, wait until the person can make a capacitous decision.
- iv Encourage participation:** the person concerned must be permitted and encouraged to participate as fully as possible in any act or decision.
- v Avoid being motivated in any way by a desire to bring about the person's death:** when best interests and life sustaining treatment are concerned.

Consider as far as Practicable:

- vi The person's wishes, feelings, beliefs & values:** in particular, any written statements
- vii Take into account views of those caring for him:** or anyone interested in his welfare, if appropriate to do so.

Mental capacity and decision-making

Each of the points in the checklist in Box 52.2 can be expanded. Here, however, we shall simply highlight particular issues. Some of the points in the checklist are drawn more or less directly from the guiding principles of the Act set out in Box 52.1. For instance, it is part of acting in the person's best interests that he or she should be encouraged to participate as fully as possible in decision-making, which chimes with the supported decision-making principle of s1(3). Similarly, we are enjoined to delay making a best-interests determination if there is the possibility that the person might regain capacity, which echoes the least restrictive intervention principle of s1(6) and the broader enabling spirit of the MCA.

Perhaps a point in the checklist that should be highlighted is the one that states that section 4 is not an exhaustive list and 'all relevant circumstances' must be identified. Arguably, this captures more than any other individual point the thinking behind the concept of 'best interests' being put forward, namely that it must be as broad as the circumstances require. Nothing which might be relevant should be overlooked. Everything should be considered, because almost anything might give an important clue as to what would be best, under these particular circumstances, for this individual person.

In doing so, we might need to consider a wide range of social, ethical, medical, moral, emotional and welfare issues (*Re MM (An Adult)* (2007) at para. 99). Also, we might be required to balance a number of conflicting factors, weighing 'the sum of the certain and possible gains against the sum of the certain and possible losses' in a balance sheet (see Thorpe LJ in *Re A (Male Sterilisation)* (2001) at page 60). Some factors may then need to be ascribed more or less weight, depending on their overall significance in the decision at hand, although the section itself establishes no priority between them. This can lead to practical difficulties associated with s.4 in relation to weighing up the importance of each factor in the checklist, which is a subjective exercise. So, what one carer will think is of great importance (factors which the courts have described as being of 'magnetic importance')³ when determining someone's best interest, another person may not; this in turn leads to different outcomes depending on the professional involved or issues arising between those involved.

An important subjective element must be present in any best-interests determination made. We will return to these criteria in more detail later, but suffice to say that a decision maker should consider, as far as is reasonably ascertainable, the incapacitated person's wishes, feelings, beliefs, and values—both his or her past competent views if known (in particular any written statements), as well as his or her past and current wishes and feelings.

Mental capacity and decision-making

In addition, reasonable and genuine attempts must be made to consult with those who know the person well. The purpose of this consultation is to find out more information about the incapacitated person, in particular their past and present wishes, feelings, beliefs, and values to help inform the best-interests decision. The consultation process is not to enquire of the consultee what decision should be made. In the Scottish Act, although not using the notion of 'best interests' this is summarized thus:

In determining if an intervention is to be made and, if so, what intervention is to be made, account shall be taken of—

- (a) the present and past wishes and feelings of the adult so far as they can be ascertained by any means of communication, whether human or by mechanical aid (whether of an interpretative nature or otherwise) appropriate to the adult;
- (b) the views of the nearest relative and the primary carer of the adult, in so far as it is reasonable and practicable to do so;
- (c) the views of—
 - (i) any guardian, continuing attorney or welfare attorney of the adult who has powers relating to the proposed intervention; and
 - (ii) any person whom the sheriff has directed to be consulted, in so far as it is reasonable and practicable to do so; and
- (d) the views of any other person appearing to the person responsible for authorizing or effecting the intervention to have an interest in the welfare of the adult or in the proposed intervention, where these views have been made known to the person responsible, in so far as it is reasonable and practicable to do so. (Section 1(4))

The details of individual laws are not something that we can dwell on. We can, however, point to principles. What we see in this statement (as well as in the MCA and the MCANI), is that it is both true that the person in question must remain centre-stage and that the person has to be considered in his or her context: of family, culture, social relationships, history, moral and spiritual beliefs, law, and so on. Our agency, we might say, is situated; which partly means that it involves others (Hughes 2011, pp. 51–3). Hence, we must be interested in what the person thinks now, but also in what he or she might have thought in the past. Similarly, if someone else might be able to tell us what the person once thought, which might be a clue as to what they would now think, we should speak with them.

As with the assessment of capacity, best interests and the availability of treatment must not be determined merely on the basis of a person's appearance, age or behaviour—all relevant factors must be considered. Also, we must not be led by existing prejudices and unjustified assumptions based purely on a person's appearance or diagnosis. This is sometimes called 'the principle of equal consideration'.

Mental capacity and decision-making

In terms of principles, there are two things to consider: substituted judgements and proxy decision-making. *Substituted judgements* are where someone else is asked to say what they think the person him or herself would have wished or decided under present circumstances, based on past things that he or she might have said or done. A *proxy decision*, alternatively, is where someone is simply asked to express an opinion as to what is best or what should be done. Of course, if asked to act as a proxy, someone may well make a substituted judgement. They may well base their views on things that the person concerned once said or did. But, in a stricter sense, a proxy decision is where the person does not ask ‘What would Dad have wanted under these circumstances?’, but ‘What do I think is best for Dad?’

The worry about proxy decisions is that someone may make a decision for Dad which reflects their own needs—e.g. not to be without a father—but does not express what would be the true wishes of Dad, who said on many occasions that he would not wish to be kept going ‘beyond my sell-by date’. Alternatively, to use a less benign example, we might wish Dad dead because the costs of providing care are eating into our inheritance. For this reason, the MCA’s *Code*, based on the deliberations set out in the earlier review by the Law Commission (Law Commission, 1995), suggests a strong element of substituted judgement: the family member or friend is mainly asked ‘What would she have wanted or said?’ But the fact is that sometimes we simply do not know what the person would have wanted: the particular issue never cropped up in the person’s life and no one can remember any comments directly relevant to it. Luckily, perhaps with this possibility in mind, the *Code* leaves what might be called some wiggle room!

The *Code* suggests, in paragraph 5.53, two aspects that the decision-maker should consider:

- ‘what the people consulted think is in the person’s best interests in this matter, and
- if they can give information on the person’s wishes and feelings, beliefs and values’.

This is significant because it suggests the MCA is concerned both about proxy decisions and about substituted judgements. Whoever is responsible for the decision has to ask about what someone ‘thinks is in the person’s best interests’. This sounds distinct from asking what they think the person him or herself would have thought. In other words, the views of the person concerned who lacks capacity are vitally important, but the views of others are important, too.

The interesting point to note is the suggestion that, even if everyone else agrees on one course of action, if the decision maker feels this is not in the best interests of the person concerned, she must act in accordance with her own judgement of what is best. This tells us that doing what is best for someone must remain a complex personal, social, and moral

Mental capacity and decision-making

judgement, which is not to be decided by a simple majority vote (Ruck-Keene and Auckland, 2015).

To return to the notion of how we are, inherently, situated in a context of relationships, it makes sense that others can say what would be best simply based on their own judgements. It would seem quite likely, after all (although not necessarily in all cases), that a daughter's sense of what might be best for her father is likely to be close, or as close as we can reasonably presume, to what her father's views might have been. A proxy decision, therefore, in the absence of evidence that might provide a substituted judgement, might actually be a 'proxy substituted judgement'. The direction of this discussion suggests how complicated are the notions of best interests or personal benefit.

In the end, when a person cannot make a decision, someone must decide and judge what is best. These judgements are by no means easy to specify fully. In an interesting clause in the MCA's *Code*, which discusses the possibility of disagreement and the need then to meet with all concerned in order to review the best-interests checklist, it states:

It may be possible to reach an agreement at a meeting to air everyone's concerns. But an agreement in itself might not be in the person's best interests. Ultimate responsibility for working out best interests lies with the decision-maker (*Code* 5.64).

The complexities, we are suggesting, are inevitable because the notions of what might be best or of benefit to a particular person are contingent upon the individual and the circumstances at the time.

Past and present wishes, views, and feelings

The extent to which such past wishes/feelings will influence the outcome of any best-interests determination has been deliberated at some length by the courts. In *Re M* (2009) Mr Justice Munby noted that the weight to be attached to P's [the incapacitated person's] wishes will always be case- and fact-specific:

In some cases, in some situations, they may carry much, even, on occasions, preponderant, weight. In other cases, in other situations, and even where the circumstances may have some superficial similarity, they may carry very little weight. One cannot, as it were, attribute any particular *a priori* weight or importance to P's wishes and feelings; it all depends, it must depend, upon the individual circumstances of the particular case. And even if one is dealing with a particular individual, the weight to be attached to their wishes and feelings must depend upon the particular context; in relation to one topic P's wishes and feelings may carry great weight whilst at the same time carrying much less weight in relation to another topic. Just as the test of incapacity under the 2005 Act is, as under the common law, 'issue specific', so in a similar way the

Mental capacity and decision-making

weight to be attached to P's wishes and feelings will likewise be issue specific. [para. 35]

In each case, when considering the particular weight to attach to a person's wishes and feelings, the following are important considerations:

- a.** the degree of P's incapacity, for the nearer to the borderline the more weight must in principle be attached to P's wishes and feelings;
- b.** the strength and consistency of the views being expressed by P;
- c.** the possible impact on P of knowledge that her wishes and feelings are not being given effect to;
- d.** the extent to which P's wishes and feelings are, or are not, rational, sensible, responsible, and pragmatically capable of sensible implementation in the particular circumstances; and
- e.** crucially, the extent to which P's wishes and feelings, if given effect to, can properly be accommodated within the court's overall assessment of what is in her best interests (para. 35(iii)).

So best-interests decisions may not always reflect what an incapacitated person wants, but those wishes and feelings will be a significant factor, sometimes *the* most significant factor, in any best-interests determination. Lady Hale confirmed this in the Supreme Court case of *Aintree University Hospital NHS Foundation Trust v James* (2013):

Insofar as it is possible to ascertain the patient's wishes and feelings, his beliefs and values or the things which were important to him, it is those which should be taken into account because they are a component in making the choice which is right for him as an individual human being. [para. 45]

It follows that where a patient's past, present, or future views are ascertainable they represent powerfully important factors in any best-interests decision and very good reasons should exist before deciding to impose treatment on a protesting, albeit incompetent, person (Gostin, 1986). It is also worth noting that the Law Commission, in its report and Draft Mental Capacity (Amendment) Bill, proposed that s.4 should be amended to give 'particular weight' to a person's ascertained wishes and feelings. In doing so, the wishes and feelings of a person would have been given a 'higher status' than all the other factors in s.4 when best-interests decisions were made. The Commission concludes: 'as a general rule, the stronger and clearer the ascertainable wishes and feelings, the greater the weight that should be given to them—due to the greater infringement on the person's autonomy under Article 8(1) of the ECHR if they are not followed.' (Law Commission, 2017b, para. 14.17). However when the Government published its Mental Capacity (Amendment) Bill 2018, which passed into law in May 2019 as the Mental Capacity (Amendment) Act 2019, those recommendations did not find their way into the new legislation.

Mental capacity and decision-making

Concluding this section, we can say that section 4 of the MCA is all about achieving a decision that is best for the person concerned. Compliance with the Act also provides important protection for decision makers who carry out interventions in the 'reasonable belief' that they are acting in the best interests of the patient. The protection is gained by following the steps set out in the best-interests checklist. Of course, what is necessary to evidence this belief will vary depending on the urgency and gravity of the situation. Nevertheless, if a challenge is subsequently made in the courts and there is a later judicial finding that the act is not in the person's best interests, protection will be given so long as the decision maker had a 'reasonable belief' that it was, and has objectively evidenced that he has followed the statutory steps. This highlights again the importance of detailed record keeping, as thorough and well-documented notes will evidence that the decision maker has acted lawfully if faced with any future legal challenge.

Limitations on Section 5 Acts: Restraint and deprivation of liberty

Occasionally, older people with declining cognition may behave in ways that pose risks to themselves or to others, so that restraint or force is required to administer treatment and care in their best interests. One of the most common reasons for older people with dementia to move into care is to manage risk when their behaviour might endanger them or be threatening to others (Jackman, 2014).

If we do an act that is intended to restrain the incapacitated older person, the protection under section 5 will only apply if the person doing the restraining reasonably believes it is necessary to prevent harm to the incapacitated person in their care, and the restraint is proportionate to the likelihood and seriousness of harm (i.e. the benefits of the treatment outweigh the harm caused by the restraint) (s6(2) and (3) MCA). Section 6 must be read in the light of the overriding principles (Box 52.1).

Principle 1(6) is relevant:

Before an act is done, or decision made, regard must be had to whether the purpose for which it is needed can be effectively achieved in a way that is less restrictive of the person's rights and freedom of action.

Accordingly, restraint must be in a person's best interests and other less restrictive options such as persuasion and discussion should have been explored first, before any restraint is used. This principle brings us back to the fundamental point of capacity legislation: one of its main aims is to protect the rights of people with impaired decision-making abilities. The aim is to promote their rights to participate in decisions made about them; and if others make decisions about them they should nevertheless be respected as individuals. A basic ingredient of this respect is that they should be allowed the freedom to do what they can with as much liberty as possible under the circumstances that apply to them.

Mental capacity and decision-making

The effect of these limitations is that the s.5 defence can only be relied on when restraint amounts to a *restriction* of liberty and only if the necessary conditions of s.6 are met (which should be documented) and it is in P's best interests.

If the circumstances surrounding the administration of treatment and care move beyond mere restraint to a *deprivation of liberty* (such as confining a person and repeatedly needing to restrain a person to administer treatment or care, or medicating an individual for prolonged periods in a person's best interests as part of a treatment plan), then it is not permitted by s.5, and alternative legal authority must be sought either from the Deprivation of Liberty Safeguards of the MCA, (which are shortly to be replaced by the new Liberty Protection Safeguards via the Mental Capacity (Amendment) Act 2019), via the Court of Protection, or using the Mental Health Act 1983 where appropriate.

Article 5 of the European Convention on Human Rights protects a person's right to liberty and security against arbitrary interference by the state (including state actors—such as NHS and local authority employees, police, judges, and so on). A person's right to liberty can only be interfered with lawfully in certain defined situations, one of those being where a person is 'of unsound mind', but only then when such interference is 'in accordance with a procedure prescribed by law' and when the detention can be reviewed quickly so that it can end when it is no longer justified.

Identifying when a deprivation of liberty (DoL) arises is, therefore, important, because depriving someone of his or her liberty without lawful authority, and without proper procedural safeguards, would potentially breach Article 5—which is what happened to the UK Government in the case of *HL v UK* (2005). Prior to this, a large number of disabled people in the UK, many of whom were older people with dementia, were being confined in long-stay hospitals and nursing homes without the capacity to consent to their living arrangements and without any proper procedural safeguards against arbitrary detention. The Deprivation of Liberty Safeguards (DoLS) under the MCA were subsequently introduced to address this gap.

Of course, this still left the thorny issue of what a deprivation of liberty looks like. The Supreme Court ruling in *P v Cheshire West and others* (2014) offers the most authoritative domestic guidance on what may amount to a DoL in health and social care settings.

The Court stated that we should look first at the concrete situation of the person concerned, looking at 'the type, duration, effects and manner of implementation of the measures in question' (*Guzzardi v Italy* (1980) (at para. 92)). Moreover, the difference between restriction and deprivation is 'one of degree and intensity, and not one of nature or substance' (para. 93).

Mental capacity and decision-making

Where the person lacks the capacity to consent to their care and treatment arrangements, the 'acid test' would then fall to two central elements: whether the incapacitated person concerned

1. is under 'continuous supervision and control' and
2. is 'not free to leave'

Case Study 5

Mrs L is 93 and has severe Alzheimer's dementia. She lives alone in the upper floor flat of a 2-storey building. There is a fence and two gates enclosing the garden to prevent her from wandering. She has access to her garden via a door which is locked with a yale lock and which Mrs L can operate to access the garden when she wishes. Door sensors switch themselves on in the evening and off in the morning and would be activated if Mrs L were to leave the property at night. An alarm call would automatically be made to one of her daughters nearby and, if not available, would re-route to the emergency services. This would enable Mrs L to be guided safely back home, but has not been triggered since they were installed. She is provided with a package of care by the Local Authority, which consists of three visits a day by specialist dementia carers.

These facts are taken from *W City Council v Mrs L* (2015), a reported decision of some interest as it is a rare example of where a person is considered not 'free to leave', but is otherwise not 'under continuous supervision and control'. On the facts, although Mrs L would have been returned home had she attempted to leave, and there were measures in place to ensure this happened, she was, nevertheless, found to have 'ample time to spend as she wished in her own home, and the carer's visits were the minimum necessary for her safety and wellbeing, being largely concerned to ensure that she is eating, taking liquids and coping generally in other respects'. Accordingly, she was not under continuous supervision and control in her own home, and despite being not free to leave her house she was found not to be deprived of her liberty.

The case also raises the important point that a DoL can potentially arise in the privacy of a person's own home. For Article 5 to be engaged, any DoL must be 'imputable to the state', meaning it is one for which the state can be said to be responsible. This can arise, and usually does arise, when a public authority is directly responsible for the care and treatment of the incapacitated person in a state-run nursing home or hospital for example. Nonetheless, it is easy to imagine that a person could be deprived of her liberty in a private nursing home, or hospital—or indeed her own home (or other private living arrangement)—which is exactly what was being argued by the local authority in Mrs L's case. In such

Mental capacity and decision-making

situations, the state may still have a positive obligation to provide effective protection of an individual, where it:

knows or ought to know that a vulnerable ... adult is subject to restrictions on their liberty by a private individual that arguably give rise to a deprivation of liberty (*Re A and Re C* (2010) at para. 95).

This would then lead to a duty on the part of the state authority to investigate the DoL and 'a positive obligation, both under Article 5 alone and taken together with Article 14, to take reasonable and proportionate measures to bring that state of affairs to an end, involving the court if necessary' (para. 95). Although these issues were not argued fully in Mrs L's case, the case illustrates the potential positive obligations the state can have to protect vulnerable people from deprivations of liberty, even where it has only a partial or indirect involvement in that person's care arrangements (Law Society, 2015 at para. 2.50).

Life and death issues

The observant reader will have noticed that we did not deal with the item in the best interests checklist (Box 52.2), which states that those providing care should avoid being motivated in any way by a desire to bring about the person's death. This seems worthy of consideration separately because many difficult decisions will need to be made in connection with dying patients.

Rightly or wrongly, when the MCA was being passed into law there was a concern that it would allow euthanasia or physician-assisted suicide 'by the back door'. In UK law there is a distinction made between, on the one hand, unlawfully cutting off life deliberately by administering, say, a lethal injection of drugs which ends life prematurely and, on the other hand, withdrawing treatment in a dying patient's best interests so nature can take its course. Given the concerns expressed at the time of the MCA around the risk of euthanasia however, a number of clauses were inserted that aim to close down such a possibility (e.g. sections 26(5a) or 62).

In any case, medical care and treatment should, on the whole, be aimed at maintaining life (*Airedale NHS Trust v Bland* (1993)). But the issues need to be measured carefully.

In 2013 the Supreme Court case of *Aintree v James*, Mr James had acquired an infection in hospital in May 2012, which led to him being admitted to the critical care unit where his condition rapidly deteriorated and he suffered multiple organ failure. Some four months later, the hospital applied to the Court of Protection for a number of declarations, including that it would be in Mr James's best interests not to receive certain treatments, including CPR, in the event of further deterioration. The family, conscious that, in spite of his condition, Mr James appeared still to enjoy his life, contested the application. They were successful at the first hearing in the Court of Protection. By the time the case came on

Mental capacity and decision-making

appeal to the Court of Appeal, Mr James's condition had significantly deteriorated to the point that he was largely comatose and ventilator-dependent. The Court of Appeal allowed the Trust's appeal and granted the declarations sought. On 31 December 2012, Mr James suffered a cardiac arrest and died, although his widow was allowed to appeal his case to the Supreme Court. Lady Hale (with whom the other Justices agreed) delivered the lead judgment. In doing so she clarified a number of established principles relevant to medical treatment and end-of life-decisions.

1. The starting point is a strong presumption that it is in a person's best interests to stay alive. The *MCA Code* acknowledges this: 'All reasonable steps which are in the person's best interests should be taken to prolong their life' (*Code* para. 5.31). But this presumption is not absolute.

2. There will be a limited number of cases where treatment is futile, overly burdensome to the patient, or where there is no prospect of recovery. Where the patient is close to death, the object may properly be to make his dying as comfortable and as dignified as possible, rather than to take invasive steps to prolong his life for a short while. The decision maker must make a decision based on the best interests of the person who lacks capacity and must not be motivated by a desire to bring about the person's death for whatever reason, even if this is from a sense of compassion. Healthcare and social care staff should also refer to relevant professional guidance when making decisions regarding life-sustaining treatment (*Code* para. 5.31), which would in the UK include relevant guidance from the General Medical Council (General Medical Council, 2010; para. 16, pp. 16–19).

3. Futility should not be confined to questions of whether treatment could cure or at least palliate the life-threatening disease or illness; futility should be considered in a broader sense, recognizing that a treatment may bring some benefit to the patient (and so not be futile) even though it has no effect upon the underlying disease or disability. Furthermore 'recovery' does not mean a return to full health, but the resumption of a quality of life which the patient would regard as worthwhile.

4. In circumstances such as these (where treatment is considered futile, overly burdensome, and where there is no prospect of recovery), it may be that an assessment of best interests leads to the conclusion that it would be in the best interests of the patient to withdraw or withhold life-sustaining treatment, even if this may result in the person's death.

5. At the end of life, the question to be asked is whether it is lawful and in the best interests of a patient for treatment to continue, not whether it is in a person's best interests for treatment to be withdrawn and the patient allowed to die. The legal question to be determined is whether doctors have the 'right to continue lawfully to

Mental capacity and decision-making

invade the bodily integrity of a patient without his consent' (*Airedale NHS Trust v Bland* (1993)).

6. Furthermore, patients (and their families) cannot demand that a doctor administers treatment which a doctor believes is not clinically indicated, although patients with capacity can refuse such treatment (*R (Burke) v General Medical Council* (2005) at para. 50).

The point that an adult with capacity can refuse treatment, even if that refusal would bring about the person's death, was of course established well before the *Aintree* judgment in cases such as *Re B (Consent to Treatment: Capacity)* (2002) where Dame Elizabeth Butler-Sloss stated that a competent patient has: 'an absolute right to refuse to consent to medical treatment for any reason, rational or irrational, or for no reason at all, even when that decision may lead to his or her death'. The case found that doctors had trespassed in providing mechanical ventilation to Ms B, who was paralysed from the neck down following a haemorrhage, when it was her competently made request not to be treated. Dame Butler-Sloss went on to say:

There is a serious danger, exemplified in this case, of a benevolent paternalism which does not embrace recognition of the personal autonomy of the severely disabled patient' (*ibid.*).

It is worth commenting that the circumstances envisaged where it would be permissible not to try to prolong someone's life are those that would be sanctioned by the well-known doctrine of ordinary and extraordinary means. This states that there is a moral obligation to pursue ordinary means, but not extraordinary, where 'extraordinary' is understood to mean those treatments (or investigations) that would be ineffective or burdensome. The law reflects this type of thinking.

Support for decision-making

Various legal mechanisms have been developed over the years to enable those with compromised capacity, or worried by the prospect of losing capacity, to make arrangements in case they should become fully incapacitated. For instance, the MCA amended the previous arrangements for Enduring Powers of Attorney (EPAs) and substituted Lasting Powers of Attorney (LPAs). Whereas EPAs covered only property and financial matters, LPAs come in two forms: they cover property and affairs, like the EPA; and personal welfare, which includes decisions about health and where the person should live. A personal welfare LPA can only be used if the person lacks the ability to make decisions for him or herself; whereas the property and affairs LPA can come into effect at any time. There are two points to note.

First, in the move from the EPA to the LPA we see an enlargement of the field in which the law accepts that we may wish to have the protection of someone of our own choosing making important decisions for us. Whilst the details will be different in other jurisdictions, the inclination to

Mental capacity and decision-making

preserve autonomous decision-making is a strong one in liberal democracies. Second, the law in this regard is acknowledging the importance of proxy decision-making. Under the MCA, however, the attorney appointed by the LPA must act in the person's best interests, so that all of the points made here apply. The attorney, therefore, shoulders a significant burden in terms of protecting the individual's human rights.

What if there is no one to represent the views of the individual who lacks capacity? One of the important safeguards brought in by the MCA is the Independent Mental Capacity Advocate (IMCA). In the MCA's *Code* it states that the IMCA service provides safeguards to those who

- lack capacity to make a specified decision at the time it needs to be made
- are facing a decision on a long-term move or about serious medical treatment and
- have nobody else who is willing and able to represent them or be consulted in the process of working out their best interests (para. 10.1).

In common parlance, it is said that those who are 'unbefriended'—those patients with no relative or carer—require an IMCA at times when critical decisions are being made about health or care, which includes decisions about place of residence. There are cases, for example, where there might be abuse, where an IMCA can be appointed even if family are involved. In addition, the DoL legislation stipulates that an IMCA should be involved where there might be a DoL. Unfortunately, there are still wide disparities in access to IMCAs, which the Department of Health is seeking to ameliorate. Again, the details do not need to detain us. But the principle—that vulnerable people who lack capacity should be 'supported and represented' when they are faced with significant decisions—is surely beyond dispute. Where there is good practice, of course, the person will be supported and represented by those who provide normal care. But the tendency to creeping paternalism, an outcomes-based approach to capacity assessments for instance, albeit benignly inspired, is too prevalent to do away with independent safeguards. If anything, it seems likely that such safeguards should be extended in the future.

Even before the MCA came into force, case law (e.g. *Re T*) had established the legal force of advance decisions. The MCA establishes in statute law that a patient may refuse certain sorts of treatment in the event that he or she loses capacity in the future. Advance decisions must be made when a person is deemed to be capacitated, cannot request anything that is against the law (such as assisted suicide), and must set out exactly which treatments should not be given, and the circumstances under which the refusal would be honoured. The key words are that the advance refusal of treatment must be 'valid' and 'applicable'. Its validity depends on its form and, where it concerns refusal of life-sustaining treatments, it must be in writing, signed, and witnessed, and state clearly

Mental capacity and decision-making

that the decision applies even if life is at risk. Some treatments cannot be refused in advance, especially those for mental illness administered under the Mental Health Act, which, with the exception of ECT, can be given without consent in certain circumstances (see Chapter 58).

More problematic, perhaps, is the notion of ‘applicability’, which suggests that if there has been anything that might not have been anticipated when the advance refusal was made, or if the circumstances were not quite those that now obtain, then the advance refusal of treatment need not be followed. This obviously makes some sense. But it also undermines the surety of the advance directive and places in jeopardy the autonomy it is meant to protect.

In their report on dementia, the Nuffield Council on Bioethics acknowledged the importance of protecting the person’s right to determine what happens to them:

If we are to promote people’s interests in their own autonomy and well-being, and in particular in their *own* notion of what constitutes their own well-being, then it is right that the law should, as at present, permit those who feel so strongly to make those wishes effective (Nuffield Council on Bioethics, 2009, para. 5.40).

However, the report also cautioned that ‘an advance refusal of treatment may not operate in the way that the person in fact envisaged’ (Nuffield Council on Bioethics, 2009, para. 5.41). Hence, the report commended the broader notion of advance care planning, which can take various forms, but which might involve LPAs or advance statements in which the person expresses his or her preferences on a variety of issues. Even if these preferences do not have to be honoured, once established they feed into any judgements about the person’s best interests and cannot simply be ignored.

United Nations Convention on the Rights of Persons with Disabilities

We began this chapter with the notion that mental capacity exists as a threshold concept in law: only decisions made with capacity are regarded as autonomous and therefore worthy of respect; choices made by those who lack capacity can be overridden by others acting in their perceived ‘best interests’ or benefit. However, as we have seen, incapacity is no longer viewed as ‘an ‘off-switch’ for an incapacitated person’s rights and freedoms’ (*Wye Valley NHS Trust v B* (2015), para. 11). Over the past twenty years, the impact of international human rights instruments, most notably the European Convention on Human Rights, as well as broad legislative reform of incapacity laws in the UK, has prompted greater recognition of the rights of the incapacitated adult and a more patient-centred approach to decision-making. So, while this binary ‘capacity/incapacity’ distinction still persists in law, with different legal consequences flowing from each outcome, the idea that incapacity leads

Mental capacity and decision-making

to a complete abrogation of the legal rights of the individual is increasingly difficult to justify (Donnelly, 2014).

The United Nations Convention on the Rights of Persons with Disabilities (CRPD) (United Nations, 2006), in particular, which the UK Government ratified in 2009, challenges established notions of capacity and its legal consequences. The CRPD prohibits discrimination against people with disabilities and promotes the enjoyment of fundamental rights for people with disabilities *on an equal basis with others*. Its purpose is to promote, protect, and ensure the full and equal enjoyment of all human rights and fundamental freedoms by all persons with disabilities, and to promote respect for their inherent dignity.

As a theoretical underpinning, the CRPD poses difficult questions for the MCA and its mental capacity/best-interests model of decision-making. Article 12, in particular, provides that state parties shall recognize that persons with physical and mental disabilities enjoy ‘full legal rights and equal recognition before the law’ (Article 12(1)) and ‘enjoy legal capacity on an equal basis with others in all aspects of life (Article 12(2)).’

The Convention causes us to question whether the functional test of capacity under the MCA, based as it is on a mental disorder, is discriminatory and contravenes Article 12 given that, via the diagnostic test, it is solely applied to people with disabilities. It also causes us to be concerned about the best interests ‘substitute’ decision-making model of the MCA, given this has the potential to deny incapacitated people their ‘will and preferences’ and legal capacity before the law.

Moreover, although the MCA’s presumption of capacity, support for decision-making, respect for the wishes, feelings, and values of the incapacitated individual in the best-interests standard go some way toward achieving the rights conferred by the CRPD, these principles do not go far enough (Donnelly, 2016). Despite the enabling rhetoric that accompanies the MCA, the lack of procedural oversight and safeguards in the Act suggests that it falls short of compliance with the CRPD. Often the reality of clinical decision-making is that ‘the prevailing cultures of paternalism (in health) and risk aversion (in social care) have prevented the Act from being widely known or embedded’ in practice (House of Lords, 2014).

Although the CRPD is not yet incorporated into UK domestic law (in the same way the rights and freedoms guaranteed by the European Convention on Human Rights are enforceable in domestic courts via the operation of the Human Rights Act 1998), we should nevertheless take it seriously. The Convention’s explicit social development dimension is steering the direction of mental health and capacity laws and influencing reform, not just in the UK (Law Commission 2017a,b), but in other jurisdictions worldwide.

Notes:

1 Mrs Murray (as is true of all the vignettes we use) is fictitious, but the wish to die on her own floor rather than in a care home was expressed by KK in the case *Re KK; CC v KK and STCC* [2012] EWHC 2136 (COP), [2012] MHLO 89. She said: 'If I die on the floor, I die on the floor. I'd rather die in my own bungalow, I really would'. The judge did not consider that this meant she lacked capacity, but rather said: 'it is an example of how different individuals may give different weight to different factors'.

2 McFarlane LJ' stands for 'Lord Justice McFarlane'; later we shall refer to 'Peter Jackson J' which stands for 'Justice Peter Jackson'; and so on.

3 Although the MCA lays down no formal ranking or hierarchy between the various factors to be considered in section 4, the courts have repeatedly endorsed the notion that one or more factors may have overwhelming or 'magnetic importance' in influencing or even determining an outcome (see *ITW v Z* (2009) EWHC 2525 (Fam) at para. 32; *KGS v JDS* [2012] EWHC 302 at para. 23; and *PB v RB & Anor* [2016] EWHC COP 12 at para. 29).

Introduction

The occurrence of memory problems is traditionally the most prominent cognitive symptom of dementia, and the illness has, for a long time, been approached as a memory disorder. However, the core of the disorder and the reason why it scares so many does not lie in the reduction of memory function, but rather in the meaning touched upon in the etymology of the word 'de-mentia', which refers to losing one's mind. And since the mind is traditionally viewed as the seat of our identity, dementia is first and foremost feared as a loss of 'self', and consequently of 'self-determination'. People affected by the disorder gradually lose a grip on their own internal processes and control of their own lives. This is linked with a loss of all learnt skills and an increasing and ultimately total dependence on others. Therefore, the last phase often requires admission to a nursing home.

Ethics of living and dying with dementia

We can therefore describe the points of departure for a 'good' (in the moral sense) care policy for dementia on the basis of these summary characteristics:

- The gradual, progressive nature of the illness means that a person with dementia remains actively involved in his or her situation until quite a long way into the disease process, despite cognitive impairment; the person will also actively attempt to adapt to the consequences of the disease, including, for instance, adjusting expectations and a changed outlook on quality of life, as is also observed in other chronic disorders. Offering support in this adaptation process is, therefore, of great importance, requiring adjustment and specification of the ethical principle of 'respect for autonomy'. This 'respect' demands that care staff actively engage in connecting with the perspectives and the current perceptions of people with dementia. A dilemma that may arise here is that the person with dementia may express desires and wishes in the present that are at odds with earlier views communicated about living with dementia—for instance, views that may have been expressed in a written advance directive (AD) prior to dementia arising.
- Dementia, nevertheless, does result in an increasing loss of competence. This means that progressively more decisions (varying from financial matters to treatment decisions and ultimately decisions pertaining to the daily care structure) have to be taken on by others. A good balance between supporting residual opportunities for self-determination and—where this is no longer possible—ensuring proper representation is, therefore, of great importance in all phases of dementia.
- Dementia is an incurable disease with few treatment options. Currently, there is little that can be done other than alleviating symptoms, and perhaps slightly curbing, or delaying, progression. However, what many physicians (and next-of-kin!) do not fully realize is that dementia is also a terminal illness that results in a significant reduction in life expectancy. This prognostic fact justifies an approach towards care policy based on the principles and aims of palliative care.

A number of ethical questions about the care provided to people with dementia are addressed in further detail in the following discussion in light of the three principles for good care outlined here. The meaning of (respect for) autonomy as an ethical principle, the complex ethical issues surrounding the concept of competence, and the position of next-of-kin and proxy decision makers (simply referred to here as representatives) is successively discussed. The role of written ADs in organizing care for people with dementia is also addressed in this context. Central to our argument in dealing with ADs, in supporting autonomy, in anticipating the future, and in providing tailored end-of-life care is the concept and practice of advance care planning (ACP). The chapter concludes with a discussion of a number of ethical questions concerning the end of life.

Ethics of living and dying with dementia

Respect for autonomy

The principle of 'respect for autonomy' may be viewed as an inalienable attainment in modern ethics. This status is attributable to the process of democratization and patient emancipation, which has completely changed the delivery of healthcare since the 1970s and has resulted in a shift in healthcare ethics from medical paternalism to a strong emphasis on patient rights. The most important result of respect for autonomy within medical ethics is the principle of 'informed consent'. Informed consent means that medical treatment cannot, in principle, be permitted without prior permission from the person concerned based on information appropriate to the issue at hand provided by healthcare professionals (Tauber, 2005).

Notwithstanding the achievements of modern healthcare ethics, there is also criticism because of its rather reductionist approach, focusing predominantly on individual autonomy and presupposing an ideal of self-determination, which tends to underestimate the relevance of human relationships as well as in understanding autonomy. From the fields of geriatric ethics and the ethics of care, calls have been made for a more nuanced approach (Spielman, 1986; Walker, 1998; Agich, 2003; Tauber, 2005).

In this connection, it is first of all relevant to underline that 'showing respect' comprises more than just information provision to allow an independent choice. From an ethics of care perspective, attention is called for the layered structure of the concept of 'autonomy', from which at least two meanings may be distinguished (Agich, 2003). These should be viewed as two related, but nevertheless distinct, ethical dispositions. The first may be described as a defensive position—expressed in the desire to be safeguarded against intervention by others. This is also referred to as the principle of 'non-interference'. The second may be expressed as an affirmative position and translates, as it were, into the desire to live life in one's own way and according to one's own standards. From the standpoint of the prevalent rights-based ethics, as well as in the statutory regulations regarding informed consent, the emphasis lies on the former meaning of autonomy, and the provision of appropriate information by healthcare staff is considered sufficient to satisfy the second condition. However, in ethical terms, this is a rather narrow interpretation of the respect for autonomy concept that rests on an understanding of ourselves as, in essence, independent and self-sufficient individuals. Furthermore, it is an interpretation that does not always agree with what people expect from physicians attending them when it comes to health care decision-making. After all, apart from information, people also want advice. Sometimes they require some discussion about the decision to be taken and often need active support, particularly where there is a lot at stake. 'Respect' for autonomy, therefore, does not legitimize a noncommittal approach, but rather demands that healthcare staff actively assist health service users in taking those decisions that they can identify with in such a way that these become their 'own'

Ethics of living and dying with dementia

choices. That is more than simply honouring people's rights and wishes. Especially in care and treatment relationships, the relevance of the second meaning of the autonomy concept becomes clear. After all, autonomy as 'living according to one's own standards' does not mean that people lead their lives by fixed standards, isolated from the world and its uncertainties. On the contrary: autonomy in this sense is a contextual and dynamic concept that reflects a human need and tendency to identify oneself with changing life circumstances, such as illness and other (major) life events (Agich, 2003).

The relevance of this layered structure of the concept of respect for autonomy is evident where this involves caring for people with cognitive impairments, as is the case for (various forms of) dementia. Here, an active approach by healthcare staff, when taking care and treatment decisions, is indispensable from the outset. In this context, good care includes the ability to tailor information carefully to the level of comprehension of the person with dementia, to take into account the speed at which that person thinks and works, to encourage them—where necessary—to be assisted by people they trust, as well as a willingness to offer—or to actively encourage—follow-up discussions in order to provide an opportunity to carefully think the issues through. In any case, health professionals should not rush into assuming that a person with dementia is incompetent (or no longer competent) to make the necessary decisions, and take refuge in consulting with their family or representative. In the past, this was often the indirect route by which the care and treatment of people with dementia was decided, but this is no longer an acceptable approach these days: patient emancipation, which in the past contributed to people with physical illnesses being considered as full participants in discussions with healthcare staff, has now also reached that group of people with dementia. This is primarily the result of a growing interest in the patient perspective: 'a shift away from pathology to people' (Nolan et al., 2002).

Under the dominance of the biomedical paradigm, it was for a long time assumed that people with dementia had no awareness of their condition, whereas we now know that people with dementia are certainly aware of what has befallen them and they try as hard as they can to adapt to the consequences of what is going on in their mind. However, without help and assistance from their environment they will not succeed in doing so, which is why Tom Kitwood (1998)—one of the first advocates of the so-called person-centred care—made a powerful plea for communicative and interactional ethics, and pointed out how the predominantly negative treatment received by people with dementia in our 'hypercognitive' society may undermine their self-image and sense of worth and, therefore, result in 'excess disability'. Proper care for people with dementia stands or falls on taking their subjective experiences seriously, as well as on the search for a link in to their communication and interaction abilities. This may often lead to a relationship of trust where significantly more decisions about care and treatment can be shared than

Ethics of living and dying with dementia

many healthcare professionals had previously believed possible. As part of this 'emancipatory process', it has now gradually become much more common to openly communicate about the diagnosis and significance of dementia with dementia sufferers themselves.

Shared decision-making and care planning

Herein it is very important to encourage 'shared decision-making' by involving next-of-kin and family members where possible at an early stage. This is, first of all, relevant because the sharing of information and decisions is the foundation of psychoeducation and palliative care. Dementia should not, after all, be reduced to a brain disorder with the individual as the sole person affected: it is a disorder that plays out in a social environment, affecting people in their most intimate relationships. It is not just people with dementia who are threatened with losing their identity; their partners also frequently experience a negative impact on self-image as a result of the dismantling of their relationship. However, in addition, the early involvement of next-of-kin is important for establishing a basis for shared aims for future decisions and the planning of care, also referred to as 'advance care planning' (ACP). ACP is a central pillar of good dementia care and can be defined as a dialogical process of supporting affected people and their proxies to think ahead and formulate goals of care as they confront the challenge of a progressive illness trajectory (Messinger-Rapport et al., 2009; Gillick, 2010; Hertogh, 2010). ACP needs to be firmly rooted in doctor-patient communication. It involves clarifying the health status of the person with dementia, determining his or her needs and values, and the subsequent development of treatment plans based on jointly set goals. Two recently developed consensus definitions underscore the relevance of viewing ACP as a dynamic process, encompassing regular reassessment of these goals and plans, in order to accommodate for changes in health and/or in personal values (Sudore et al., 2010; Rietjens et al., 2017). In dementia, the role of family and dear ones will become of increasing significance in ACP as the disease process develops. This will involve decisions around the aims and the limitations of care and medical treatment. Those ethicists who are fearful of paternalism might argue that an early involvement of other parties represents a potential breach of privacy and autonomy. Indeed, in practice, it does occur that some people with dementia insist on secrecy and confidentiality, and occasionally healthcare staff members have no other option than to respect this request (Schermer, 2001). But quite often, people prefer to share the burden of decision-making with others and—more importantly—next-of-kin are much better able to act in future decisions in the spirit of their loved ones' prior wishes and preferences if there has been joint consultation early on in the process. In other words, *shared* decisions set the foundations for *surrogate* decisions at a later stage. This leads us to the concept of competence.

Competence and decisional capacity

Ethics of living and dying with dementia

Respect for autonomy in medical practice is primarily realized, as alluded to earlier, by involving patients in decisions about treatment and care. This process should satisfy two conditions, one external and one internal. The first concerns the quality and adequacy of the information. The second involves the capacity for decision-making. Patients will be unable to make informed decisions if they do not possess information that is relevant to the issue; however, they will also not be able to do so if they have the information but not the mental *capacity* to arrive at a judgment based on this. This capacity is usually referred to as *competence*. Although both terms are frequently used interchangeably (and are in the following sections), under some jurisdictions, 'competence' refers to a formal judicial determination concerning an individual's legal authority to make his or her own decisions, while 'capacity' refers to an evaluation made by health professionals about the functional abilities of patients (Kapp, 1995).

In ethical terms, competence lies somewhere between the principles of autonomy and beneficence (Welie, 2008). Considerations about competence or capacity play a role in searching for the right balance between both principles: the principle of respect for autonomy means that a person's wishes and views cannot simply be ignored. Too lightly doubting someone's competence may result in an unjustifiable restriction on his or her autonomy. On the other hand, holding on to competence too rigorously may result in a patient being put into a position where he or she is not adequately protected.

In clinical practice, the question of competence primarily arises in situations where care staff members are confronted with the question 'Has this (intended) decision been properly considered by the person to warrant it being respected?' The question about competence is, therefore, primarily one about what constitutes 'good' decisions. This highlights the fact that one is not dealing here with a purely clinical problem, but rather a normative judgment, where the physician is given the ultimate responsibility to determine whether or not to accept patients' rights of autonomy in terms of their decisions—nothing more and nothing less. Many shrink back from this responsibility, and this leads to a frequently expressed need among physicians for a greater level of support or more concrete guidance when dealing with issues involving competence and its assessment.

In recent years, numerous ethical and legal studies have been devoted to these subjects, including attempts to produce a better operationalization of the concept (Schermer, 2001; Welie, 2008; Kim, 2009). There is now a reasonable consensus that competence is not a personal characteristic (of people with a particular diagnosis), but rather an evaluation linked to the quality of a decision or choice within a specific context. After all, each decision is different, and complex decisions require greater numbers and different types of skills than simpler decisions. However, in practice, it is not just about the complexity of the decisions, but also and primarily about their practical consequences. For instance, there would be no need

Ethics of living and dying with dementia

for healthcare staff to question a person's competence within an extremely complex decision if there were no consequences tied to it. Healthcare professionals are confronted with this issue as the consequences of respecting a decision become more far reaching and the criteria they set in judging competence become more stringent as the stakes get higher. This is often referred to as the *risk dependency* of competence. For instance, should a person refuse to comply with noninvasive potentially life-saving treatment (e.g. antibiotics for a severe lung infection), higher criteria will be set on his or her level of competence than where treatment refusal does not have serious consequences. A second aspect of risk dependency is the implied *asymmetry* of competence that this entails: agreeing to a medically indicated treatment is considered differently to refusing the same treatment, and this applies more as the stakes get higher. Based on this reasoning, physicians would be more justified in assuming competence where patients request or agree to life-saving treatment than when refusing treatment. Within the ethics literature there is an ongoing debate about the asymmetry of competence. Opponents of this theory have suggested that competence concerns patients' psychological functions. Whether or not these functions are adequate, they argue, may be influenced by the type of decision, but not by the outcome of the decision. This is certainly a tenable argument in theory, but, in practice, care professionals have to deal with the consequences of decisions taken, and sometimes they have to intervene to prevent patients from harming themselves.

As previously discussed, the risk dependency of competence means that the threshold for capacity increases as the consequences of the decision become more significant. This leads to the need for appropriate criteria for assessing (sufficient) competence. It also means that appropriate estimates need to be made in terms of the nature of risks that justify a formal evaluation of competence. The first question concerns 'how' and the second concerns 'when' an evaluation should be made. We only address the second question here; Chapter 52 and Chapter 58 cover the assessment of competence/capacity, respectively, in more detail.

Ethics of living and dying with dementia

When is an evaluation of competence indicated?

It must be said from the outset that a formal evaluation of competence may be burdensome to a person with dementia, and may not always be useful in the context of long-term care. After all, due to the progressive nature of the disease, care and treatment goals constantly have to be adjusted, and the patient's level of competence is anticipated to be gradually decreasing. More important in this connection than evaluating competence is that healthcare staff members remain well aware of a person's remaining abilities in order to enable and 'empower' them to make choices about aspects of care with the right support. In a general sense, the following guidelines may be employed in assessing *when* a formal evaluation of competence is indicated:

- In principle, the care relationship is built upon an assumption of competence. Hence, the decision to make a formal evaluation is not taken lightly. As described previously in this chapter, a person-centred approach implies that staff take each person's experiences and levels of comprehension into consideration, for instance by using comprehensible explanations. There are, of course, limits to simplifying information and providing it piecemeal. This is encapsulated in the term 'appropriate' information, which should, at least, comprise the nature, aim, and consequences of (not implementing) the proposed treatment. If these minimum standards cannot (or can no longer) be satisfied it may lead to doubt as to the level of competence of the person with dementia. Whether this doubt justifies a formal evaluation depends on the following guideline.
- There should always be a 'clear indication' for a formal evaluation of competence, and the burden of proof in this rests with the healthcare professional. Any doubt about the competence of a person with dementia on the part of care staff is, therefore, in itself not sufficient: it should also be related to the consequences of the decision that the person is taking or intending to take. Thus, a formal evaluation of competence is only justified where a behaviour or decision has 'significant consequences'.

Therefore, a person with dementia should be allowed the 'freedom' of choice in many decision scenarios where there are 'no significant consequences', even if there is reasonable doubt as to his or her competence. The advantage of this approach is that people do not have to prove, as it were, their competence for each decision. Some authors have criticized this approach as it is ultimately still healthcare staff who determine what the 'significant consequences' are, which may mean that there is still a level of paternalism lurking in the background. However, the reasoning behind this approach fits well with the views concerning proper care that are prevalent in practice. It has been shown, for example, that formal tests of competence are used infrequently and only used in borderline situations, where there is conflict or an unbridgeable divide between patient and staff perspectives. Therefore, choosing

Ethics of living and dying with dementia

‘shared decision-making’ with adequate decision support for people with impaired decision-making abilities, rather than steering towards a formal competency test, has much to recommend it (Hertogh, 2004; Peisah et al., 2013). This approach offers the option to incorporate the values, life history, and emotions of a person with dementia, as well as contextual factors, into the decision process. It then often becomes apparent that it is not necessary to establish whether or not someone is competent to take the required decision, which not only bypasses many procedures, but also prevents the person with dementia from being ignored in a more or less intrusive manner.

In summary, although there is much good to be said for the notion of competence, formal evaluations of competence should be reserved for borderline and conflict situations where people are sometimes forced to resort to these judgments in the absence of alternatives or where ‘shared decision-making’ has failed or does not appear to be an option. However, such an evaluation is made and underpinned, the result can never be construed as a statement of fact, for such an assessment of competence will ultimately always involve a normative ethical judgment.

Written advance directives and the representative’s role

In situations where people are no longer able to be involved in decisions about their care and treatment, others will act on their behalf as their representatives (or surrogate decision-makers). Who is able to act in this capacity and how this representation is shaped is governed—in most countries—by law. It should be noted that the authority of representatives may differ by country. For instance, in the Netherlands, a representative may not assume responsibility for the most personal decisions of the individual he or she is representing, and the level of responsibility imposed on physicians for those medical decisions being considered with a representative is greater than the responsibility taken directly through consultation with the patient.

It is of primary importance that a representative, in carrying out his or her task, focuses on the represented person’s best interest. Representatives should not allow themselves to be guided by their own views about what is the best and most desirable course of action. It is often believed that a written AD may be of use here in ascertaining the former views of a person who is no longer competent. From a legal perspective, a document like this is the strongest instrument by which someone may attempt to maintain control over care situations and treatment decisions in the event of incapacity, and an increasing number of countries are moving towards anchoring ADs in national law (Hertogh, 2011).

The issue seems, in fact, quite simple: as long as a person is competent, the physician will tailor care directly to suit that person; once the person is no longer able to make known his or her wishes, then the written AD is considered to represent their ‘actual’ wishes. In combination with the

Ethics of living and dying with dementia

proper regulation of representation/surrogate decision-making, the rights of an incompetent person thus appear to be adequately safeguarded. In practice, however, this 'simple' solution may lead to a number of ethical problems.

The dilemmas of the directives

A widely accepted definition describes ADs¹ as:

written instructions executed by decisionally capable adults that pertain to future medical treatment preferences of the party executing the document. These directives take effect only if the patient is decisionally incapacitated at the time that specific decisions need to be made (Kapp, 1995).

ADs can be classified into two categories: treatment directives and proxy directives. A treatment directive (often called a 'living will') refers to a document specifying what kind of treatment the author desires under specific conditions in the event of incapacity, while a proxy directive empowers another person (e.g. healthcare proxy or durable power of attorney) to make decisions on behalf of the author. Both types of directives can also be combined (de Boer et al., 2010). Of relevance here is that most jurisdictions only recognize the so-called negative treatment directive, i.e. a directive containing a refusal of specified treatments in advance. Positive directives, specifying what treatments one would want to receive in case of incapacity, are never legally binding.

Morally, ADs are rooted in the doctrine of informed consent. With expanding technology, they became a key issue of the autonomy-based bioethics movement of the 1970s. In case of incompetence, when contemporaneous autonomy is no longer possible, so-called precedent or prospective autonomy in the form of previous statements and expressed beliefs relevant to the treatment issues at stake should govern the outcome (Dresser, 1992; Winzelberg et al., 2005).

When first introduced (in the US in the course of the 1990s), the enthusiasm for ADs was largely ideological. Empirical knowledge on the subject was largely unavailable at the time and it was more or less taken for granted that ADs would have a positive effect on medical culture and decision-making.

With experience, however, came awareness of the problems, and gradually empirical research revealed that the reality was far from what proponents of ADs had expected it to be, adding to a growing consensus on the failure of ADs (Hertogh, 2011; Perkins, 2007; Fagerlin, 2004).

Since the disappointing findings of the first empirical study into the practice of ADs, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) (Connors et al., 1995), a plethora of research articles and critical reviews have been published and multiple interventions were designed to stimulate AD completion,

Ethics of living and dying with dementia

including several attempts to redesign ADs in order to increase their practicability and relevance to decision-making. Of the problems that all this research has revealed, some are more practical, while others are more fundamental in nature.

First of all, the overall frequency of ADs continues to be low, notwithstanding the existence of legal rules encouraging the completion of directives, such as the Patient Self-Determination Act in the US that came into force in 1990. Approximately one in three US adults has completed an AD (Yadav et al., 2017), but outside the US much lower rates are reported, with a maximum of between 8–10% in the Netherlands (van Wijmen et al., 2010), Germany (Evans et al., 2012) and the UK (Aw et al., 2012). Next, when they are completed, the instructions contained in an AD are often vague or ambiguous, as a consequence of which they are often not honoured (Teno et al., 1997). The concept of advance care planning (ACP) deals with this problem by stimulating consultation with health professionals when one considers drafting an AD.

However, it does not exclude situations in which an AD may conflict with what physicians or surrogates view as a patient's best interest, potentially creating confusion, ambivalence, and/or burden among surrogates and physicians (Smith et al., 2013). There may be circumstances which make it more ethically defensible to override an AD and to respect a person's goals and values rather than following the exact preferences in the directive (Bruce et al., 2016; Sudore et al., 2010; Sulmasy et al., 2010; Winzelberg et al., 2005). Evidence on whether authors want their ADs to be strictly followed or to serve as general guidelines is conflicting and provides no guidance here (Sehgal et al., 1992; Jox et al., 2008). To further complicate matters, it has been shown that proxies do a poor job in interpreting ADs, as they are frequently biased by their own treatment preferences (Fagerlin et al., 2010). Furthermore, the most poignant problems of advance statements pertain to the (in)stability of preferences over time: it is well known that our anticipatory beliefs often fail to recognize our ability to adapt, and that it is extremely difficult to imagine how one's current preferences will hold in a situation (like dementia) one has never really experienced (Hertogh et al., 2007). In general, preferences for life-sustaining treatments are probably most stable in people with a stable health condition. Unstable health, on the other hand, will lead to changing preferences. This phenomenon is often so marked that it has been termed 'the disability paradox': a life that was once despised before the advent of chronic disease, is accepted and even embraced with advancing illness (Albrecht and Devlieger, 1999). With changing circumstances, people change their point of reference. Dementia is no exception to this 'rule', as is testified by a growing body of research on living with dementia from the affected person's perspective (de Boer et al., 2007). People do not develop dementia overnight; instead, the gradual course of the disease allows for adaptation and response shift. But what if they forget to change their AD, or are no longer able to do so? Here we touch upon a key obstacle for complying with ADs.

Ethics of living and dying with dementia

Therefore, a move on from static ADs to the more dynamic practice of ACP is taking place, as outlined in the section 'Shared decision-making and care planning'. Although more research is needed, there is evidence that ACP positively impacts the quality of end-of-life care, and that complex ACP interventions may be more effective in meeting people's preferences than written documents alone (Brinkman et al., 2014). Preference stability for end-of life decisions seem to be larger in those who engage in ACP (Auriemma et al., 2014). It must be emphasized, however, that the process of ACP should be flexible and sensitive to a person's views on autonomy. Not everyone desires to manage and control his or her future. Some people prefer to live life one day at a time and many wish to share the burden of decision-making with others, or even delegate this responsibility to their families and health professionals. It follows that this approach to ACP is time consuming and calls for high quality communicative skills, as well as for a preparedness of doctors to take on a (pro)active role, using their knowledge of the disease trajectory in a tailored way. The framework of a palliative care policy can offer guidance here to people with dementia, their families, and health professionals (Hines et al., 2011).

Palliative care

The issue of so-called non-cancer palliative care has received a lot of attention recently. However, the proposal to conceptualize the care of people with dementia from a palliative care perspective had already been put forward within nursing home medicine in the Netherlands in the 1990s, and with good reason (Hertogh and Ribbe, 1996).

Dementia is, after all, an incurable and ultimately terminal condition. Curative, disease-specific therapy is still not available. Medical treatment is, therefore, limited to alleviating symptoms and complications of dementia, and prolonging life is primarily a consideration in terms of interventions for comorbidities and concurrent disorders. As the disease progresses, questions concerning the aims and limits of medical interventions become more frequent, necessitating a constant search for the right balance between under- and over-treatment. For that reason, it is of great importance to arrive at clear, tailored agreements as a part of ACP. As said, this plan should be periodically re-evaluated and amended if required in line with the disease's progression and important developments within this process. Where possible, this should involve the person with dementia, but in the more advanced stages of the disease—and, therefore, in the majority of people with dementia admitted to nursing homes— treatment planning will be discussed with surrogates. The palliative care concept provides a framework within which this discussion about the aims and limits of medical care may take place and within which ethical questions and treatment dilemmas that have arisen may also be considered and addressed. In Dutch nursing home medicine, this approach is based on the original definition provided by the World Health Organization (WHO, 1990) (see Box 53.1).

Ethics of living and dying with dementia

Box 53.1 Palliative care

Palliative care is integral multidisciplinary care for patients with incurable diseases, aimed at reaching and maintaining optimal quality of life for both patients and their relatives. More specifically, palliative care:

- Affirms life and regards dying as a normal process;
- Neither hastens nor postpones death;
- Provides relief from pain and other distressing symptoms;
- Integrates the psychological and spiritual aspects of patient care;
- Offers a support system to help patients live as actively as possible until death;
- Offers a support system to help the family cope during the patient's illness and in their own bereavement

Reproduced with permission from World Health Organization (WHO). Cancer pain relief and palliative care. No. 804 WHO Technical Report Series. WHO, Geneva. Copyright © 1990.

Of note, a palliative care approach is not exclusively associated with (terminal) end-of-life care. It also comprises care for people who may have a terminal illness but have not yet reached the terminal phase of their disease. Furthermore, within this WHO definition, palliative care also has a place for people with chronic illnesses where long-term management or suppression of the disease is not (or no longer) an option.

The type of care offered to people with dementia in nursing homes is, in essence, palliative in nature and orientation in the broad sense intended here. The focus of this care is on maintaining the best quality of life possible, and extending life should never become a goal in itself. Intuitively this is a clear aim. However, translating it into practice is not always evident. A palliative approach that focuses on maximization of comfort and relief of suffering can be or cannot be combined with treatment of intercurrent illnesses that may prolong life. This approach fits well in the recently proposed model of palliative care for people with dementia (see Fig. 53.1), published on behalf of The European Association for Palliative Care (EAPC) in the White Paper 'Defining optimal palliative care in older people with dementia' (van der Steen et al., 2014). Based on evidence and consensus, the EAPC identified eleven domains for palliative care and defined optimal care for people with dementia.

Quality of life and palliative care

The term ‘quality of life’ has diverse interpretations. In political theory, it is normally related to the material and socioeconomic circumstances in which people live their lives, or to the opportunities they are offered by society to realize a good life (Nussbaum, 2006). Health-related quality of life is frequently defined as the subjective way in which a person appraises his or her present state of life. However, a clear, conceptual definition of health-related quality of life is missing. Researchers have nonetheless tried to make quality of life measurable through the development of several multidimensional questionnaires. So, what is available are operational definitions, which in essence boil down to quality of life as measured on this scale or through that instrument. What is clear, though, is that health-related quality of life does not reflect an external description of an objective entity, but rather a subjective evaluation by the patient of the relevant aspects of his or her health. These types of self-assessment scales have also been developed for dementia, occasionally based on prior, qualitative studies of people with dementia or their carers. An extensive discussion of the methodological aspects of these types of instruments is beyond the scope of this chapter, but it is important to establish that their usefulness diminishes with advancing dementia. We may even ask ourselves whether the concept of quality of life is in itself appropriate in the more advanced stages, since a direct, subjective assessment, of and by the person with advanced dementia, is no longer an option here. The option that does remain is behavioural observations as an indirect measurement. On this basis,

Ethics of living and dying with dementia

observational scales for quality of life in advanced dementia have been developed, such as the QUALIDEM scale (Ettema et al., 2007).

However, the persistent use of the term ‘quality of life’ obscures the presence of another construct, and an observational scale such as this also has a normatively different status than a self-assessment scale. Caution is required here for two reasons. First, research has shown that people with mild to moderate dementia shift their values and priorities in life, and there is no reason to assume that this process of response shift extinguishes in later stages (Hertogh and Ribbe, 1996). Second, other research suggests that caregivers have a tendency to report lower scores on quality of life than people with dementia themselves. This ‘perception gap’ is probably the combined effect of an affected person’s response shift, and caregiver bias as a result of their care burden (Sands et al., 2004). The conclusion, therefore, must be that the term quality of life is applied with a necessary amount of caution in the care of people with advanced stages of dementia, where quality of life appraisals are necessarily based on observations and interpretations by others than the person him/herself. In practice, care and treatment will be primarily focused on a person’s wellbeing or (dis)comfort. For example, nursing home residents with dementia frequently have burdensome symptoms such as pain and these burdensome symptoms frequently persist over the disease trajectory, with a peak shortly before death (Hendriks et al., 2015, 2014).

Observational scales for discomfort, counting frequency, intensity, and duration of behaviour, such as the Discomfort Scale—Dementia of Alzheimer Type (DS-DAT), pose a different and less value laden approach and may be of some assistance here (Hurley et al., 1992). Similarly, there are dementia pain scales observing behaviour directly during a few minutes, such as the Pain Assessment in Advanced Dementia (PAINAD), and those rating behaviour over the last week, for which familiarity with the affected person is required, such as the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC) (Warden et al., 2003; Fuchs-Lascelle and Hadjistavropoulos, 2004). However, the end estimations of a person’s state of wellbeing strongly depend on (formal and informal) caregivers’ appraisal of behaviour and nonverbal communication, which are always more or less biased by their own situation and their emotional ties. This dilemma needs to be addressed openly as an integral part of palliative care and ACP.

Prolonging life

When talking about life-prolonging treatment, it is important to make the distinction between the intention and the effect of medical treatment. Although prolonging life is not the aim or intention of medical treatment in the context of palliative care, it does not mean that palliative medical treatment cannot or should not potentially lead to a prolongation of life as a side or co-intended effect. It is highly likely that people with dementia will live longer as a result of treatment that is primarily aimed at

Ethics of living and dying with dementia

maintaining or improving their wellbeing. A person with cancer for whom meaningful life extension through disease-specific treatment has become an illusion, but who is not yet in the terminal stages of his or her disease, is certainly still entitled to antibiotic treatment for a respiratory or urinary tract infection, and, furthermore, regular monitoring and adequate control of his or her blood sugar levels will not be omitted should he or she also be diabetic. The aim of this is not to keep someone alive as long as possible, but rather not to burden the last phase of life with, in principle, readily treatable discomfort, even if the medication used has the potential side effect of extending life. However, it is advisable to evaluate critically the use of preventive medication. After all, medication used for primary or secondary prevention may have a time-until-benefit extending beyond a person's actual life-expectancy. Therefore, treatment with this type of medication must be critically assessed and may be best discontinued (Holmes et al., 2006; Hendriks et al., 2017a).

There is, in principle, no reason for treating individuals suffering from incurable and progressive dementia differently. Still, there are important differences compared to the situation of someone with cancer. The root of this lies in the problem of a decline in communication possibilities and the increasing lack of competence of patients with dementia. In the advanced and terminal stage of the disease, signs of (dis)comfort can only be derived from observations. Furthermore, as the disease progresses, the issue of whether the life-extending side effects of palliative treatments are still morally acceptable becomes a more significant question. After all, any successful treatment of a respiratory tract infection or other potentially life-threatening development exposes a person to a further progression of his or her dementia, along with the associated mental and physical decline. Hence, instead of asking what constitutes good quality of life, the question more and more becomes how to arrange for a good quality of dying. Discussion of this question with surrogates in the context of ACP may lead to a more restrictive treatment policy, focusing on comfort care only. If planning was started well in advance, this decision may be well prepared for and relatively easy to make (Hendriks et al., 2017b). Research suggests that informing nursing home residents and families about the course of dementia, the short average survival time, burdensome symptoms that can occur, and the occurrence of pneumonia and intake problems, which have a poor prognosis, may help formulate realistic overarching care goals to help prevent burdensome, unnecessary treatment in acute situations. (Hendriks et al., 2017b, 2017c, 2015, 2014). However, it remains an important responsibility of the physician to choose the proper moment. He or she should have the sensitivity to recognize how and where in the course of the disease trajectory an additional disease or complication offers an opportunity to arrange for—from a palliative care perspective—an acceptable end-of-life scenario by abstaining from life-sustaining treatment and focusing on active symptom control only. This, however, implies that a particular responsibility rests on the physician, together with the family/representative, since here,

Ethics of living and dying with dementia

more so than in other domains of palliative care, it is in effect the physician and the representative who direct the actual end-of-life scenario. In taking on this responsibility, surrogates as well as care professionals can find support and guidance in decision aids and written information on the course of the disease, the complications to be expected, and the burdensome decisions the illness trajectory holds in store for them: for example, regarding the use of antibiotics, feeding tubes, and artificial (re)hydration. In this respect it is worth noting that the evaluation of a booklet on comfort care in end-stage dementia demonstrated that written information on the options of palliative and comfort care are welcomed, not only by family members and surrogate decision-makers, but also by practitioners and—in particular—by nurses (van der Steen, Arcand et al., 2011; van der Steen, Toscani et al., 2011). Through such written decision support instruments, all parties feel better equipped to address the ethical issues at stake and engage in shared decision-making and care provision.

Conclusion

This chapter has discussed a number of ethical questions arising in the care of people with dementia. The progressive nature and consequences of the disease for the individuals affected and those in their environment require specific ethical deliberations and a focus on shared decision-making and (advance) care planning. Prevalent rights-based ethics do not always offer the most appropriate guidelines within this context and may even occasionally create new ethical problems, as is the case with ADs. Apart from refining current views on autonomy, additional guidelines are required from a person-centred ethics of care perspective to help make relevant decisions about (current and future) care and treatment.

Carers and dementia

Chapter: Carers and dementia

Author(s): Jan Oyeboode and Sahdia Parveen

DOI: 10.1093/med/9780198807292.003.0054

Introduction

People living with dementia inevitably need increasing support as dementia develops and progresses. The bulk of this support is provided by family members, who often step into caregiving as a matter of course and, over time, take on more responsibility until many are full time carers. Family carers are of vital importance to the quality of life of many people living with dementia and to sustaining their ability to live in their own home in the community (Smits et al., 2007). When assessing care and support needs, family carers need to be explicitly considered. Carers need to be given the tools, in terms of information, skills and support to take on caring, and be supported to continue over time as care needs change or expand. Taking on caring responsibilities has a far-reaching impact whether physical, psychological, social or financial. So, carers may require emotional and practical support to care in a way that minimizes

the impact on their own health and avoids placing their own wellbeing at risk.

In this chapter, we aim to provide information about dementia caregiving that is useful to health care professionals, to raise awareness of carer issues and to give evidence-based ideas about how to involve and support carers effectively as they care for their relatives. The chapter opens with an overview of the extent and nature of family caregiving, followed by information about the impact of caregiving on carers and the caregiving trajectory over time. We introduce models that provide a useful way of formulating the issues to help planning care to meet the needs of carers encountered in practice; and we summarize the research evidence regarding interventions that are helpful to carers.

Facts and figures

There are approximately 46 million people living with dementia worldwide and this is estimated to cost the global economy £450 billion per year (ADI, 2010). Within the UK, there are 24 million people who know a family member or friend with dementia (ADI, 2010). A report by Alzheimer's Research UK in 2015 revealed that there are approximately 700,000 family members actively providing care and support, worth £8 billion per year, for a relative with dementia. This is half of the dementia care provided in the UK (National Dementia Strategy, 2009). A more recent UK-based survey by the Alzheimer's Society (Alzheimer's Society, 2017) found that 87% of 966 people living with dementia were assisted by family members, whereas only 14% had help with their day-to-day life from a paid carer. Figures from the US suggest that families and friends provide about 18.1 billion hours of care at a cost of over \$221 billion (Alzheimer's Association, 2016). As well as providing economic benefit, research suggests that having a co-resident carer can improve the person living with dementia's quality of life (Farina et al., 2017) and can produce a twenty-fold reduction in the risk of institutionalization (Banerjee et al., 2003).

It is estimated that 39% of carers spend over one hundred hours per week providing care and support, a level which has been found to predict negative carer outcomes (Alzheimer's Research UK, 2014). However, it is worth noting that the more time spent providing care can also increase the number of gains a carer experiences in their role (Parveen & Morrison., 2012). Women are more likely to provide care for a relative with dementia, with figures suggesting that 60 to 70% of carers are female (ARUK, 2015). Women are also more likely to provide support for more than five years. Responsibility for caregiving tends to fall upon spouses, followed by daughters, daughters-in-law, and sons (Aneshensel et al., 1995; O'Rourke et al., 2000). Although carers provide a significant amount of support for those living with dementia, it is striking that 44% of carers themselves are living with a chronic illness or disability (ARUK, 2014). Approximately 61% of carers state that they lack support from other family members, friends, and dementia services (ARUK, 2015).

Carers and dementia

Busy health and social care providers may over-estimate the reach of support provided by services but surveys of this sort show how vital family carers are and therefore how important it is that family supporters are considered whenever care is being planned for someone with dementia.

Currently 58% of people living with dementia reside in low-income countries, a proportion predicted to increase to 71% by 2040 (Prince et al., 2013). Whereas there is an expected 100% increase in prevalence in developed countries, there will be a 300% increase in countries such as India (Prince et al., 2009). Formal care may not be widely available in such countries and family members traditionally provide support for those with care needs (Ahmad, 1996; Katbamna et al., 2004). Family care indeed accounts for 56% of societal costs in low-income countries (Wimo et al., 2007) and family carers are at an economic disadvantage. The 10/66 Dementia Research Group (Prince, 2000) report that family carers in low income countries are forced to cut down on paid work yet compensatory benefits are non-existent within these countries' welfare systems. Considering the expected increase in the number of carers being relied upon to provide support for relatives, there is an urgent need to develop services in low-income countries that will support families to continue to care.

Carers—basics

The term carer or caregiver is difficult to define as it is used in different ways by health and social care professionals and families. The term 'carer' is more commonly used by UK care-based organizations, whereas the term 'caregiver' is more often used in the American context. Carers Trust in the UK defines a carer as an individual who provides care and support without financial compensation for a family member who due to illness, disability, a mental health problem, or an addiction cannot cope without support. Similar definitions can be found within the research literature, although the term 'informal carer' is often applied to family members. The problem with this term is that it implies the care provided by family members is casual and perhaps of not high quality. The term has therefore not been favoured by carer services and carers themselves (Farina et al., 2017).

Although the term carer is widely used by health care professionals and service providers, it can be problematic when used while talking to families. Most caregiving relationships are extremely complex, as they are based upon long shared histories, for example, marriage. Many family members therefore don't perceive themselves as 'carers', but as wives or daughters (Parveen et al., 2011) and provide support as a natural part of community or family life. The term also places emphasis on the care partners as 'helper' and 'helped', whereas in some relationships, e.g. spouses, the care is a mutual exchange of support. Within the context of dementia, the term can place the person with dementia as 'cared for' and thus undermine his or her independence and identity. Despite the

Carers and dementia

limitations of the term, it can be useful when used in connection with carers' assessments, registers and groups, but should be used sensitively.

Who provides care is often influenced by the position of the person with dementia within the family, as well as by availability and according to culture. The spouse is the most likely person to provide care and support, and if a spouse is not available or requires additional support from family members, daughters, and daughters-in-law usually step in. As caregiving is predominantly a female role, sons often find themselves in a minority. Spouse caregivers may not consider that they are providing care per se but simply acting out of mutual marital obligations. Filial carer is a term used to describe adult children or children-in-law providing care for a parent/parent-in-law. Non-kin carers include neighbours and friends providing unpaid care and support in the community.

The support provided by carers is wide ranging. Nolan and colleagues (1996) describe the following types of caregiving: anticipatory care, preventative care, supervisory care, preservative care, instrumental care, protective care, reconstructive care, and reciprocal care. These types of care are thought to overlap considerably. Nolan and colleagues (1995) state that by providing a typology of care, health care professionals are enabled to provide services to be facilitative, rather than obstructive.

Impact of caring

Caring for a relative with dementia impacts on carers' lives in many ways. Witnessing decline in a relative frequently changes the nature of the relationship, causing grief, anxiety, or emotional upset. In addition, taking on extra tasks and responsibilities may have an impact on sleep, energy levels, physical health, and time available for work, hobbies, and social life. Yet, many family members who become carers gain satisfaction from fulfilling their vows and values and from the opportunity to develop new skills or discover previously untapped personal qualities.

Impact on fulfilment of needs

In a recent study of how caring facilitated or impeded fulfilment of carers' needs (Pini et al., 2017), a thematic analysis of interviews with a diverse sample of 42 current carers of a relative with dementia produced nine themes. These themes, shown in Table 54.1, highlight the impact of caring on the relationship between carer and cared-for, as well as demonstrating that the carer may feel he/she lacks control over his/her own life in the face of caring for someone with dementia. The themes also show that caring often impacts on the carer's sense of identity and ability to connect with others.

Table 54.1 Nine key themes on the way caring for a person with dementia impacts on fulfilment of the carer's own needs.

Carers and dementia

Being a carer impacts on fulfilling my need to/for ...	Illustrative quotes of the way caring impacts on the need.
feel close to my relative	You've got to find those little glimmers, those little moments where you get the person back just briefly. Those little glimmers, and you just think, 'Oh right, yes, that's how it was ... It's bittersweet, isn't it?' (Abbie).
feel in control	I think if you look too far into the future you frighten yourself and wonder how you will cope, and I genuinely don't think too far ahead (Theresa).
freedom	I feel I'm attached on a piece of string to my husband and that string is getting shorter and shorter and shorter (Beatrice).
feel connected to the people around me	They're my medicine, my friends (Beatrice).
protect my relative	When I see her in those moments when she's like a child or when she's lost and she's looking to me to guide her, just those few moments then everything becomes secondary and I just think, I'm going to help you and that's all there is to it (Karl).
take care of myself	I've not really focused on my own physical, well physical and mental health needs so, I find that, you know, health problems have cropped up all of a sudden, that needed my attention but I was, you know, not paying attention on that side and focusing on my mum (Jayda).
be my own person	I would go mad if I wasn't working. I think you have to; I think if you can maintain some normality, you're also looking after yourself, I suppose it's like putting your life jacket on first isn't it before you deal with your child (Charlotte).

Carers and dementia

share/express my thoughts and feelings	It's almost a self-protection thing, isn't it? Maybe it's just me, some things you just keep, keep closed because it's, maybe you make yourself vulnerable to, if you say something in an unguarded moment, you can't take it back (Abbie).
get things done	Some days all those plates come crashing down at the same time, 'cause the plates stopped spinning. Fortunately, it's rare, but it can happen and when it does happen then, yeah, I have a meltdown (Isobel).

Source: data from Pini, S., Ingleson, E., Megson, et al, 2017. A needs-led framework for understanding the impact of caring for a family member with dementia. *The Gerontologist*.

Impact on relationships

Reviews of research on the effects of dementia on family relationships indicate that dementia makes communication more difficult and takes away opportunities for shared activities (Ablitt et al., 2009; La Fontaine and Oyeboode, 2014; Quinn et al., 2010). Such changes often lead to grief, with almost 75% of carers experiencing grief related to the diagnosis, the loss of past roles of the person with dementia, and the loss of intimacy (Diwan et al., 2009; Sanders and Corley, 2003). Where children or young people are involved, as in many cases of young onset, they may find having a parent with dementia a very difficult experience, as shown in a recent study of 19 children and young people, aged 8–31 years, with a parent with dementia (Hall and Sikes, 2018; Sikes and Hall, 2017). In families where one parent had young onset frontotemporal dementia, 75% of parents reported their children experienced conflict with the parent with dementia, had problems at school, and suffered psychological/emotional problems (Passant et al., 2005).

This evidence indicates the need for health care professionals to pay attention to the relational aspects of caring as well as the practical aspects, and reminds us that health and social services not only need to consider the role and wellbeing of the primary carer, but also the respective roles and wellbeing of the wider family. The latter may be especially pertinent when considering young onset dementia, since young people may be involved in caring, and it is also of relevance when supporting families from cultures that have more extended family structures, such as those from 'black and minority ethnic' populations, since in these families caring may be more often shared between a number of relatives.

Carers and dementia

Positive impacts

Although approximately 50% of primary carers experience high levels of burden (Brodaty et al., 2014), it is worth remembering the corollary of this: that therefore about 50% do not. Many carers report that, despite some distress or stress, love and happiness often remain (La Fontaine and Oyebode, 2014; Ablitt, et al., 2009; Quinn, et al., 2010) and some carers report that they have developed a closer relationship as a result of caring (Netto et al., 2009). Many carers find that supporting their relative with dementia gives them a sense of pride, satisfaction, or fulfilment. Some develop new skills or find that caregiving leads to personal growth (Sörensen et al., 2006; Lloyd et al., 2016). In a review of 14 qualitative studies aimed at understanding positive aspects of caring for someone with dementia (Lloyd et al., 2016), the authors propose that positive facets of caregiving have been found to relate to: role satisfaction (from doing a good job in ensuring the person is well cared for and safe), emotional rewards (e.g. from feeling appreciated), relationship gains (from feeling close to the person cared-for), personal growth (e.g. developing a capacity for patience or becoming more self-aware), increased faith or spiritual growth, a sense of competence and mastery in the face of challenging circumstances, fulfilling a sense of duty, and 'giving back' to the person being cared for.

Positive caring experiences seem to be more likely in those who are committed to the relationship, who find a way of accepting the changes dementia brings, and who make a conscious effort to see things positively. In addition, carers who find ways of creating opportunities for the person with dementia to take part in activities, and those who have ways of drawing strength from faith, social support, or their own past experiences, seem to be able to remain positive (Lloyd et al., 2016). Among spousal carers, those who believe the person with dementia and the relationship are essentially the same as they used to be seem to have more positive and fewer negative feelings (Riley et al., 2016). Ott and colleagues (2007) conducted a quantitative study with over 200 dementia carers focusing on personal growth in particular and found that 46% of the variance in levels of positive growth was explained by higher levels of social support, lower levels of depression and coping by reframing and by religion.

Not only is being able to adopt a positive perspective helpful to carers' wellbeing, but also carers who experience gains or satisfaction are less likely to move the people with dementia into care than relatives of those who feel burdened (Roff et al. 2004; Luppia et al., 2010).

Impact on mental and physical health

The negative impact of caring can produce mental health problems. In a review that summarized the current state of knowledge, Pinquart and colleagues (2006) synthesized the findings of several meta-analyses and concluded that 'carers of people with dementia have more symptoms of

depression, higher stress scores, lower self-efficacy, and lower subjective wellbeing than non-carers' (p. 962). In a systematic review of studies of depression in caregivers, Cuijpers (2005) concluded that there is evidence that over one in five carers becomes depressed and the odds of developing depression are significantly increased compared with non-carers. Conclusions from Schoenmakers and colleagues (2010) systematic review concur that dementia carers have higher levels of depression than non-carers or carers for those with other chronic or psychiatric conditions. They summarize past research as indicating 30–80% of carers are depressed. Unsurprisingly, higher levels of depression in carers are associated with higher health service usage (Zhu et al., 2015). Anxiety has been less researched but Cooper and colleagues (2007) reviewed 33 studies, and concluded that anxiety levels were higher among carers than matched non-carer control groups, with significant levels of anxiety affecting about 25% of carers. These relatively high levels of depression and anxiety suggest that professionals should routinely enquire about carers' wellbeing and be prepared to suggest treatment that may help where necessary.

Physical health can also be affected. The physical health of carers has been found to be poorer on average than the health of non-carers, and that of dementia carers has been found to be worse on average than that those supporting a relative with another health condition, even when the samples are age-matched (Sörensen et al., 2006). Pinquart and Sörensen (2003) conducted a meta-analysis of objective health from 39 studies, covering responses from over 3,500 carers compared with more than 12,000 non-carers and found that carers on average had poorer objective health than non-carers. They also found there were no significant differences between the findings of studies that used objective and subjective health reports. This implies that it is valid to ask carers how they feel about their state of health as a marker of whether the person is physically suffering from caring.

It is often assumed that how dementia affects family carers is related to the severity of cognitive or functional impairment of the person with dementia. However, correlational studies show this is not necessarily the case (Pinquart and Sörensen, 2003). How carers cope depends on the carer's physical and mental health and personality (for example, whether the person has a propensity to be anxious), the nature of their prior relationship with the person cared for, and the behaviour and specific care needs of the person with dementia (Ablitt et al., 2009; Brodaty et al., 2014; Joling et al., 2015; Lloyd et al., 2016). Coping with the behavioural issues of the person with dementia is consistently found to have more influence on carer outcomes than cognitive functioning and functional disability. In a meta-analysis of findings from 228 mainly American studies Pinquart and Sörensen (2003) found that behavioural issues, such as day and night-time restlessness of the person with dementia, and emotional or behavioural disinhibition, were moderate predictors of carer burden ($r=0.37$) and carer depression ($r=0.27$), respectively, whereas functional

impairment ($r=0.22$ and 0.14) and cognitive impairment ($r=0.18$ and 0.16) showed only small correlations. Whether the carer believes he or she has the capacity to cope (i.e. the carer's self-efficacy beliefs) also seems to be a major influence (van der Lee et al., 2014, 2017). These findings imply that interventions that enable carers to understand and respond effectively to the behaviour of the person with dementia and which enhance the carer's belief in his or her ability to cope have potential to be beneficial to carers.

Impact on particular groups

Much research into caring for a relative or friend with dementia has focused on white, female, spousal carers, caring for a relative with late onset Alzheimer's, vascular, or mixed dementia. However, caring poses different issues and has different meanings and impact for different sections of society, including men, and people of different cultural backgrounds or ethnicities, as well as for those caring for a relative with young onset dementia or a rare dementia, or looking after a relative with learning disability and dementia.

Ethnicity

Of particular relevance to caregiving experience in diverse multicultural societies such as modern Britain, the US and much of Europe, is ethnicity. Research has shown that, on average, those from minority ethnic populations receive their diagnosis of dementia later than the majority ethnic population, and have a different trajectory of care, being less likely to be prescribed medications for dementia and less likely to use residential or nursing home care (Cooper et al., 2010). The corollary of these patterns of care is that families are often caring for someone until a later stage of dementia before they have a diagnosis or access to services and support and also that many families continue to provide support in the family home, even when there is severe disability due to dementia.

Qualitative research, mainly with South Asian carers in the UK, has found that there is lack of awareness of the nature of dementia, with memory problems often seen as a sign of normal ageing rather than an early symptom of dementia (Giebel et al., 2015). Dementia may also carry a greater stigma in minority ethnic populations, being seen as a sign of madness or sometimes being explained by notions of possession or being seen as a 'white person's illness' (Berwald et al., 2016). Family carers may either share or have to contend with these illness beliefs, so may benefit from provision of accurate information. Many family members assume caring as a natural extension of family responsibility, and may feel pressure from other family members or the wider community to continue, despite their own feelings of stress (Johl et al., 2016; Tilkie et al., 2010, Parveen et al., 2017b, Berwald et al., 2016). On the other hand, some carers may feel less resentment or entrapment resulting in positive consequences for carer wellbeing, with research in the US consistently finding 'black' Americans report less caregiving stress and retain a close

Carers and dementia

emotional bond with the person with dementia (e.g. Haley et al., 2004). Religion and spirituality are often used to enable coping, both in black American samples and South Asia carers in the UK (Haley et al., 2004; Lawrence et al., 2008). Consideration of the centrality of ethnicity to the impact of dementia on carers, has led Knight and Sayedh (2010) to position this as a fundamental aspect of their sociocultural model of caregiving (see Sociocultural model of caring).

Gender

A further attribute that has a fundamental impact on carers is gender. Although 41% of spousal carers are male (Brown et al., 2007), most adult child carers are daughters or daughters-in-law, and caring is often assumed to be a female role. A review by McDonnell and Ryan (2013) of 56 studies related to men as carers, found that male carers often experienced a sense of isolation. However, many husbands saw their role as an opportunity to repay their partner for the care given to them earlier in life, and many men gained satisfaction from learning new skills and discovering a side of themselves they had not previously developed. Male carers have been found to use a different style of caring from women, using a 'management' or problem-solving approach to make best use of resources. Consistent with this, one review of male experiences of educational support groups found that men preferred terminology such as 'workshops' to 'support groups' (McFarland and Sanders, 2000). Studies suggest that male carers place more value on the informational aspects and skills training, rather than sharing of experiences and emotions.

Young onset dementia

When dementia is of young onset (under 65 years), the carer is usually the spouse, sometimes assisted by children or young people in the family, or if there is no spouse, parents or siblings. The impact for spousal carers is different due to different stage of life of the person and the carer. Since both partners are likely to be of working age, dementia can mean a substantial loss of income with both parties relinquishing work at a time when there may still be considerable household outgoings to pay a mortgage or support young people through their education. Financial advice therefore can be particularly important for families in this position. In addition, any children and young people in the family may have emotional support needs of their own, in addition to the needs of the person with dementia, placing an extra sense of responsibility on the carer at a time when he or she can no longer depend on his or her life partner. Furthermore, as young onset dementia is relatively rare, it may be hard for the carer to meet others in a similar position to break through any sense of isolation. Where young people provide care for their parent, it has been found that this is often invisible if a spouse is seen as the primary carer. Young people may worry about the health of their well parent as well as the parent with dementia, and may feel alienated from their peers, who do not carry similar responsibilities, yet they may not receive services or support in their own right (Allen et al., 2009). This is

Carers and dementia

an area where a family approach following diagnosis can be helpful to consider the family's resources and coping strategies and help them to prepare for the future.

A special group among those with young onset dementia are people with Down syndrome, up to a third of whom develop Alzheimer's disease by the age of 55–59 years. Their carers are often ageing parents or siblings who may have supported the person all his or her life. While these carers are often used to caring and know their way around learning disability services, it can be stressful for them to find out that a child, who has already faced adversity due to disability in life, now has to face life with dementia (Foster, 2012). Family carers surveyed indicate that their main concerns are to have full information, to remain fully involved with their relative's care, and to have a chance to meet other carers and other people with dementia (Furniss et al., 2012).

Less common forms of dementia

Finally, carers' experiences are also influenced by the type of dementia. For those dementias that affect language (such as semantic dementia), vision (such as posterior cortical atrophy), social cognition or inhibition (such as behavioural variant frontotemporal dementia, bvFTD), the day-to-day challenges may be quite different from those faced by families where an individual has, for example, memory problems or disorientation. It has been found that carers of people with bvFTD have greater levels of stress and burden than those caring for a relative with Alzheimer's disease (Mioshi et al., 2013). Yet since these dementias are not as common nor as widely known, carers may find themselves lacking information about the meaning of the symptoms and advice about how to best respond. They may benefit from being linked with others through Internet-based groups, overcoming the problems of rarity and distance.

Caregiving over time

Recently there has been an increasing interest in exploring and understanding the 'journey' of caregiving. Within the context of dementia, there are a number of transition points for families and those living with dementia, with each transition representing specific challenges for families, and presenting additional risk of medical errors (Rose & Lopez, 2012). Transitions are defined as 'a passage between two relatively stable periods of time' (Swanson and Tipp-Reimer 1999). Meleis (Meleis et al., 2000; Meleis, 2010) presents the 'Middle Range Theory of Transitions' which provides a useful guide to understanding transitional points for carers and enabling the development of anticipatory interventions to facilitate transitions. Transitions are often triggered by significant events, e.g. when the carer develops health problems, and require new ways of coping and managing. Transitions can be location based, e.g. moving from home to nursing home care, or psychological, e.g. the needs of the person with dementia become more complex.

Carers and dementia

Within the context of dementia, carers may experience several different transition points. A number of models and pathways have been proposed which attempt to describe the carer journey. The Global Deterioration Scale (Reisberg et al., 1982) describes transitions in care in terms of the person with dementia's cognitive decline. The scale ranges from 'No subjective complaints of memory' to 'Very severe decline'. Although the scale has some use for describing the transitions in cognitive decline for the person with dementia, it does not explicitly state transition points specific to the carer. More specific to the UK context, the NHS England Transformation framework presents the Well Pathway for families and relatives living with dementia (Department of Health, 2009). The framework outlines and sets the standards for five stages where people with dementia have the right to receive the best care and support. The five stages are: Preventing well, Diagnosing well, Living well, Supporting well, and Dying well. Similar to the Global Deterioration Scale, the Well Pathway does not explicitly describe the carer journey and how to facilitate transitions. This has been found to be the case in a number of countries as described by Fortinsky and Downs (2014), who conducted a review of national dementia strategies within Australia, England, France, Netherlands, Norway, Scotland, and the US. The review found that national dementia strategies tended to focus on transitions in the early part of the journey, and the strategies varied greatly in terms of specific action plans. The strategies were generally focused on preventing or delaying transitions as opposed to facilitating transitions and very few strategies made use of evidence-based approaches to improve the transition process for families. Fortinsky and Downs (2014) proposed six transition points based on their review of national dementia strategies: i) symptom recognition to diagnosis; ii) diagnosis to links with community services; iii) home to hospital and back; iv) home to residential care; v) residential care to hospital; and vi) home or residential care to end-of-life/palliative care.

Although based on the American dementia care context, Rose and Lopez (2012) describe a framework of transitions which is more specific to carers. They outline the following stages at which carers may need more support: the obtaining of the initial diagnosis, advance care planning for financial issues and health care, driving cessation, managing behavioural symptoms, changes in settings (locations), and end-of-life care. Research in the UK by the Carers Trust and University of York (Newbrunner et al., 2013) led to a similar description of the care trajectory in the dementia context. The report 'A Road Less Rocky' describes ten transition points which are termed as 'stress trigger points' for carers. The report highlights the need for timely information and support at each of these ten stress trigger points:

1. when the dementia is diagnosed;
2. when the carer takes on an active caring role;
3. when the capacity of the person with dementia declines;

-
4. when the carer needs emotional support and/or a break from caring;
 5. when the person with dementia loses their mobility;
 6. when the person with dementia has other health problems;
 7. when the carer has to cope with behavioural problems;
 8. when the carer's own circumstances change;
 9. when the person with dementia becomes incontinent; and
 10. when decisions about residential and end of life care have to be made.

It is worth noting that all the frameworks emphasize that it is important to note the individual variability within dementia, and therefore not all carers will experience the same transition points in their journey or navigate the points within a specific time frame.

Fortinsky and Downs (2014) note that current dementia strategies focus on preventing transitions as opposed to facilitating carers to navigate through transition points. Recent research has therefore focused on developing interventions to facilitate transitions. A concept that has been particularly useful within this research has been the construct of 'preparedness'. Preparedness has been defined as perceived readiness to assume the role of carer across multiple domains, including meeting the physical and emotional needs of the care recipient and being able to identify relevant services and information (Fujinami et al., 2015). A number of studies have illustrated that low preparedness in caregivers leads to poorer outcomes such as caregiver burden and distress (Fujinami et al., 2015; Yang et al., 2014; Henriksson et al., 2012, 2013; Mak & Sörensen, 2012; Ducharme et al., 2011; Pinquart & Sörensen, 2002). However, most previous preparedness research has been conducted in the fields of cancer and stroke care, and little is known about the impact of preparedness on carers of people with dementia.

Recent research has focused on preparing carers for dementia care, for example a team of Canadian researchers (Ducharme et al., 2011) describe an information intervention designed to facilitate the transition to the point of receiving a formal diagnosis. The research involved 62 carers in the intervention group attending an information programme, with the resulting outcomes being compared to those of 49 carers who did not receive the intervention. The results indicated that the carers who received the intervention were more confident in their role, more prepared, better able to plan for the future, and more likely to use problem-focused coping. The intervention did not have an effect on stress management, perceived support from friends and family, or family conflict. Huang and colleagues (2013) also aimed to improve carer preparedness via a home-based training programme delivered by a registered nurse over two weeks. Unlike Ducharme and colleagues' (2011) study, this intervention was not designed for a specific transition point. The randomized control trial found that the programme improved preparedness, competence, and self-efficacy, but did not have an impact on anxiety or depression. Gonzalez and colleagues (2014) also

aimed to improve preparedness for the care journey through the delivery of six two-hour sessions of resourcefulness training in a group setting. The intervention was tested on 50 carers, with 52 carers in the control group not receiving the intervention. They report that the carers who received the training had higher levels of preparedness and resourcefulness and lower levels of anxiety when compared to the control group. There has been very little research focused on specific transition points in dementia caregiving (with the exception of Ducharme et al., 2011). Further work is required to develop evidence-based interventions to facilitate carer progression through transition points.

Models for understanding caregiving

There are a number of explanatory models or conceptual frameworks, that are used to understand the impact of caring on carers' lives. These are useful because they can lead to an individual formulation of the sources of impact for specific carers, and inform tailored support to address the particular pressure points for different individuals. One fundamental generic caregiving model, which can be useful to keep in mind, was put forward almost 30 years ago by Hall (1990). He proposed that carers are guided by underlying beliefs and values, even though these are not necessarily explicitly articulated or acknowledged. These values come into play alongside the needs of the person with the diagnosis and jointly influence the carer's goals or objectives; for example, the carer's goal could be: 'To care for her, as well as she cared for me' or 'To fulfil my vows by looking after him' or 'To do my best but my children have to come first'. The goals and objectives then influence the carer's practices or acts, i.e. what they actually do in the way of providing care, and these acts are accompanied by emotional responses and feelings. Since living with dementia places many extra demands for support on those around the person with the condition, it is not surprising that stress can result, nor that stress-and-coping theory commonly underpins models used to understand the response of carers to caring. Other models incorporate grief theory, or give greater consideration to positive outcomes or the role of cultural values. In this section, we introduce stress and coping theories in some depth and give a briefer description of other models.

Stress, appraisal, and coping models

The basic tenet of stress and coping theories is that when demands or stressors arise, people use various coping strategies to respond and adapt. Stress arises when the demands that are experienced outstrip the coping resources that a person has available to draw on. Mediating the relationship between demands and stress is the person's appraisal of their situation. In the well-established transactional model of stress, Lazarus and Folkman (1984) proposed two steps of appraisal between stressors and outcomes. Firstly, the person judges whether an event (e.g. the diagnosis of dementia or the development of a new need for support) is relevant to his or her own position. Secondly, the person appraises his

or her own ability to respond effectively, that is to cope, with the perceived threat or challenge. The application of stress and coping theory to dementia care was pioneered by Haley and colleagues (1987) and Pearlin and colleagues (1990), and updated by Sörensen and colleagues (2006) in the light of more recent evidence.

The latter's model is shown in Fig. 54.1, and illustrates four key domains, which are seen as playing a part in determining the outcomes for the carer. These are the background and context, the stressors, and the carer's appraisal of the situation, as well as a number of moderating influences. The background contextual factors include the socio-demographic dimensions of gender, age, ethnicity or culture, and socioeconomic status, all of which set the general scene onto which dementia caring is superimposed. Sörensen et al. divide the stressors into two types: primary and secondary. Primary stressors are those that relate directly to the impact of dementia. As noted earlier, primary stress tends to be more connected with carers' response to behaviour than to cognitive or functional abilities. The secondary stressors include the knock-on effects on other areas of a carer's life, for example, on work or hobbies, finances, or relationships. Dementia frequently challenges the cohesiveness of family relationships. Pearlin and colleagues (1990) proposed that providing care for a relative with dementia could cause family conflict through three routes: i) when there were differences between family members in their beliefs about the nature of dementia and the disability it causes; ii) when there were disagreements about the amount and quality of care required from various family members; and iii) when there was a lack of acknowledgement accorded to the primary carer by other family members. The connections between primary and secondary stressors are seen as being a cascade, as the demands posed by dementia in turn cause other stressors so that there is a proliferation of stress.

Carers and dementia

Fig. 54.1

A stress-appraisal-coping model of dementia caregiving.

Reproduced with permission from Sörensen, S., et al. Dementia care: mental health effects, intervention strategies, and clinical implications. *The Lancet Neurology*, 5(11): 961-973. Copyright © 2006 Elsevier Ltd. All rights reserved. DOI:[https://doi.org/10.1016/S1474-4422\(06\)70599-3](https://doi.org/10.1016/S1474-4422(06)70599-3).

The appraisal process draws attention to the way that carers' subjective beliefs about the nature of the stressors and their ability to cope influence their wellbeing. It includes both negative appraisals, such as perceptions of lack of control, role conflict, or role captivity, and positive appraisals, such as finding meaning or having high self-efficacy for caring. Finally, Sörensen and colleagues (2006) include moderators that influence the stress-appraisal process, and these also include factors that can increase or decrease the risk of adverse outcomes. Good levels of information, having available resources, support, or services, and ability to use adaptive coping strategies such as problem-solving may all buffer or attenuate the impact of stress. The outcomes, influenced by these four precursors, are whether the carer experiences physical or mental health problems.

Stress and coping frameworks such as these are quite comprehensive, understandable and clinically relevant. They can provide a useful way of making sense of carers' individual situations and may help to suggest areas for intervention. Some key implications of Sörensen and colleagues' (2006) model are that:

- It is important for clinicians to bear in mind the background variables, which are very significant as they have a strong influence on values, expectations, and resources. It is worthwhile discussing their influence with a carer when establishing his or her response to caring.
- Where there are primary stressors that the carer appraises as a major threat, especially if these relate to behavioural issues, working on how these could be managed can be a valuable focus of intervention.

Carers and dementia

- Secondary stressors should be taken seriously as they may push a carer to a point where he or she can no longer tolerate caring. If these arise from family conflict, then problem solving using a family perspective can be helpful.
- Appraisals are powerful. Where these are negative, work to help a person adopt a more positive perspective can make a big difference to the carer's mood. This could be through a cognitive behavioural approach but equally through psychoeducation or through having an opportunity to connect with carer networks that may foster coping and positivity.
- Systematic enquiry about moderating influences may help to identify barriers to coping well, e.g. lack of particular information, that can be addressed.

Sociocultural model of caring

Ethnicity is included as a background variable in Sörensen and colleagues' (2006) stress-appraisal-coping model but is given a more central position in the updated socio-cultural coping and stress model put forward by Knight and Sayegh (2010). They suggest that across all cultures the core of the stress-appraisal process holds true, in that carers experience stressors arising from caring, often perceiving these as burdensome. However, they propose that cultural values influence the resources available to enable coping, through impacting on perceived social support and coping strategies available to carers. For example, in a culture that places a strong emphasis on the obligation to provide care, they propose that the carer may be less likely to perceive others as offering social support; and may be more likely to cope using cognitive coping strategies (for example, positive reappraisal or acceptance) rather than problem-solving strategies. In Fig. 54.2, illustrating their model, they place in bold the three areas that are culturally related and in non-bold the areas they view as being more universal and less culturally determined.

Carers and dementia

Loss and grief

In addition to stress-appraisal and coping processes, a further key process in play for many carers, alluded to in the earlier discussion on impact, is the cumulative and ongoing experience of losses which can give rise to mourning and grief. This area has not been as fully explored as the stress process but nonetheless there is research evidence on this area. In one significant study, Ott and colleagues (2007) looked at predictors of grief and personal growth in over 200 carers of people with Alzheimer's type dementia. A small number of factors explained almost 60% and 58%, respectively, of the variance in degree of grief in carers of people with dementia who were living at home or living in care. Where the person was living at home, three variables predicted the degree of grief: i) being unable to achieve a positive state of mind, ii) feelings of depression, and iii) coping by venting distress. For those in care, spouses experienced significantly higher grief than adult offspring. Being unable to achieve a positive state of mind and depression were again associated with levels of grief but coping strategies of self-blame and planning for the future were also significant influences.

Noyes and colleagues (2010) summarize research literature on grief and dementia care, and propose the grief-stress model of caregiving, which adds processes of loss and grief to the stress and coping model. In parallel to overload-related primary stressors, secondary stressors, and stress-related outcomes, they propose a process of loss-related primary stressors that create secondary relationship losses, affecting the sense of closeness and contact with the person cared for. The relationship losses are seen as leading to grief related outcomes such as loneliness, regret, and hopelessness.

Very often in service provision, the stresses associated with caring are more obvious, or more accepted, than the elements related to grief, partly as it may be felt to be taboo to grieve when the individual with dementia is still living, and as the carer may want to protect the person with dementia from realizing the distress she or he is feeling. Nonetheless, it can be helpful for carers to be given space to express their feelings of loss.

A model of the positive aspects of caring

As noted, positive aspects, often referred to as gains or uplifts, are part of the experience for many carers of people with dementia. Carbonneau and colleagues (2010) put forward a conceptual framework for consideration of these aspects. They suggest that, in addition to focusing on the reduction of stressful aspects of caring, psychosocial interventions need to find ways to enhance positive and satisfying aspects of caring. A stress-coping model cannot readily facilitate this and so a means of analysing and understanding the positive aspects becomes necessary. Carbonneau and colleagues based their model on an integrative review of just over 40 research papers. They proposed that the positive aspects of caregiving

are derived from three domains: i) the quality of the daily relationship between carer and cared-for, ii) the meaning of caring to the carer, and iii) the carer's sense of accomplishment from providing care. Whether these positive aspects are experienced are seen as being strongly influenced by both the occurrence of enrichment events in everyday life and the carer's sense of self-efficacy. Carbonneau and colleagues characterize enrichment events as those that leave the carer feeling content, pleased, or joyful. They may arise from a moment of contact, such as a shared joke, or from engaging together in an activity, such as singing in a choir or going for a walk. They may also come from seeing the person with dementia looking relaxed or smiling. It is proposed that such moments of uplift counteract the stresses of caring, but they may dwindle due to the carer lacking the energy, time, and hope needed to bring them about. Here, the carer's self efficacy plays a part, as carers with a stronger sense of self-efficacy who believe that they are capable and can be effective in their caring role, can use this belief to help them set up enriching moments. A recent review of research on the role of self-efficacy beliefs (Crellin et al., 2014) adds evidence to the Carbonneau model, finding across nine studies that higher levels of carer self-efficacy correlated with carer reports of finding meaning, levels of satisfaction and resilience, gain, and positive affect. They noted that carers with high self-efficacy beliefs developed new skills, which in turn led to carers and cared-for enjoying joint activities, that themselves generated positive caregiving experiences (Sanders, 2005; Narayan et al., 2001; Peacock et al., 2010). With the turn to positive psychology, an increasing number of studies are looking at ways to intervene to help carers enhance the gains of caregiving (discussed further on).

Interventions for carers

In preparing this chapter, we asked several carers for their opinions about the most valuable thing that a health professional can do for a carer and that a health professional had done for them (see Box 54.1). They advised that carers should be fully informed and involved in care decisions about their relative; they should be treated with honesty, openness and respect; and carers' needs should be considered as well as those of the person with dementia. All family situations and relationships differ, and it cannot be assumed that all people with dementia wish a close relative to be involved, nor that every person with dementia has a close relative who would want to take on caring. However, given the way that dementia affects the support needs of the person and the impact this then has on the primary carer's life and other family relationships, it is essential for clinicians to consider how to involve whoever is closest to the person with the diagnosis, so that care can be planned and support put in place. Sørensen and colleagues (2006) propose that, when diagnosing dementia, the diagnosing professional should: screen for safety, risk issues, and carer distress; offer acute intervention, dependent on the care dyad's needs, ensuring any intervention is culturally appropriate; provide information and education about dementia and its

management; know how to make appropriate referrals to local or national resources for carers and couples, including support groups, psychoeducational interventions, mental health care for the carer, and case management; and ensure maintenance of gains and review of changing needs over time, as transitions in care arise.

Box 54.1 Responses of family carers to two questions on service provision

The most valuable thing a psychiatrist/psychologist can do for a carer is:

'... to give an accurate diagnosis and explain what that means.' (Barbara Carlton, former carer for her mother).

'... to listen to the carer and also look at things from their view as well as from that of the Service User' (former carer).

'... to look after the carer's mental health as well as the service user' (former carer).

'... listen and try to understand ... not be rude and off-hand about our loved ones. Not force a person with a diagnosis to give things up—try and help us persuade the person it's their choice to stop doing something, for example, driving' (current carer).

'... to be open, honest, and to give relevant, up-to-date information about accessing the various services and help available for both carer and their loved one' (Rachael Norris, carer for her husband).

'... to know I have somebody I can turn to when things get tough.' (Andrea Ryan, carer for her husband).

The most helpful thing that my relative's psychiatrist/psychologist, healthcare team did for me was:

'... to make a diagnosis which meant that I understood what was wrong and then to arrange for a community psychiatric nurse to visit my mother once a month' (Barbara Carlton, former carer for her mother).

'... to include me in all conversations related to the diagnosis, ongoing plans, and strategies available to us' (Rachael Norris, carer for her husband).

'... to help me through changes by explaining things to me and finding ways around them' (Andrea Ryan, carer for her husband).

Carers and dementia

'... my father's psychiatrist saw me, recognized me, and valued me to support the lead with my father's care. Her approval validated me' (former carer).

With thanks to TIDE (Together in Dementia Every Day) for the anonymous quotes.

Sörensen and colleagues (2006) identify nine types of intervention that impact on carers. Clustering these by the aspect of the stress-appraisal-coping model through which they impact on carer stress, four intervention types (pharmacotherapy, training for the person with dementia, respite care, psycho-education) aim to reduce the primary stressors of dementia care. Although medication and training for the person with dementia are primarily targeted at the person with dementia, they may have positive knock-on effects for the carer also. A review of pharmacotherapy found that acetylcholinesterase inhibitors provided a small but statistically significant benefit to carers in terms of reducing the hours they spent in caring and their sense of burden (Linger et al., 2005); and a review of training for the person with dementia, for example, through cognitive stimulation therapy, found evidence that active involvement in delivery of therapy for the person with dementia led to significant improvements in carers' quality of life and reductions in carer depression, although there were no changes in caregiver burden or in the quality of the relationship (Leung et al., 2017). Respite care and psychoeducation are principally aimed at removal or reduction of the primary stressors of caregiving, through providing a direct substitute for care that would have been provided by the family carer or by offering carers information and techniques to manage primary stressors more effectively. Psychoeducational interventions are defined as involving the structured presentation of information and techniques to help carers manage the demands of caring. The fifth type of intervention for carers, described by Sörensen and colleagues (2006), is support groups, described as providing a forum to share feelings and concerns and to overcome isolation, and so primarily targeting secondary stressors, such as social isolation. Sixth, are psychological interventions (referred to as psychotherapy). This group of interventions is the only one to overtly focus on appraisals, with the psychological therapies, including cognitive-behavioural therapy, seen as addressing beliefs about dementia and its effects and management. Finally, Sörensen and colleagues' typology includes consultation or case management, multicomponent interventions, and lesser-used interventions (within which they include approaches such as yoga, employer-based interventions, and phone groups).

There is considerable and growing research evidence that respite care and psychosocial interventions can be effective in producing positive outcomes. In their review of 127 studies conducted between 1982 and 2005, Pinquart and Sörensen (2006) concluded that carer interventions

have positive impacts on carer burden and depression, wellbeing, ability, and knowledge, and on the symptoms of the person with dementia. However, while impact is significant, it is also modest and domain specific, highlighting the importance of carefully identifying needs and planning interventions to meet those needs. Needs assessment could be based on a formulation for an individual carer of family around the nine ways in which carers report that dementia impacts on their fulfilment of needs, as described earlier (Pini et al., 2017), or on a systematic consideration of the models of caring.

A meta-analysis by Sörensen and colleagues (2002) considered 87 studies of interventions for carers of people with dementia or elderly relatives with physical health problems. They concluded that day or residential respite care was more effective in reducing subjective burden for carers than psychoeducation or supportive counselling, and respite care and psychoeducation both reduced carer depression and improved carer wellbeing. On the other hand, a review by Maayan and colleagues (2014) concluded that there is insufficient evidence that respite care is an effective approach to management of carer stress. A review of nonpharmacological best practice for family carers of people with dementia (Gallagher-Thompson et al., 2012) concluded that skills training, psychoeducational programmes, individual and family counselling, cognitive behavioural therapies, and multicomponent programmes can all effectively reduce the stress that carers experience. Interventions that are effective have in common that they involve both the person with dementia and the carer, they are flexible enough to be individually tailored and they are intensive or involve active participation (Brodaty et al., 2003; Pinquart and Sörensen, 2006).

Most of the interventions that have been well researched have been designed for use around the time of diagnosis, to assist the person with dementia and carer to be prepared for the future. Brief interventions delivered at this point, for example, six-session skills-training programmes can have positive effects for carers, sustained for up to 32 months afterwards (Selwood et al., 2007). In addition, intensive programmes, such as a 12-day joint residential programme for care dyads, have been found to delay moves of the person with dementia to nursing home care (Brodaty et al., 1997).

One example of an effective short-term intervention that combines psycho-education, skills training for carers, and appraisal-focused work, is the START (STrategies for RelaTives) intervention (Livingston et al., 2013), a UK adaptation of the US-developed Coping with Caregiving programme (Gallagher-Thompson et al., 2003). The UK-based programme consists of an eight-session intervention delivered by non-professionally qualified staff, and accompanied by a manual that carers use to put learning into practice between sessions. The programme covers psychoeducation about dementia; carer stress and sources of emotional support; understanding and managing behaviour of the person with dementia; changing unhelpful thoughts; promoting acceptance; assertive

communication; relaxation; planning for the future; increasing pleasant activities; and maintaining learned skills. Both Coping with Caregiving and START have been found to lead to significant reductions in depression in carers.

An effective supportive intervention is a five-session plus phone support, family-oriented emotional support programme, which is delivered over three months, with the first and fifth sessions of the programme being for the primary carer and the other sessions open to others in the family as identified by the primary carer. The programme has been researched across three countries (US, UK, Australia) with significant reduction in depression in carers being sustained across the two years of follow-up (Mittelman et al., 2008).

Few interventions for carers that focus on later transitions in care have been rigorously evaluated. However, the SHARE (Support, Health, Activities, Resources & Education) intervention (Whitlatch et al., 2015) is an example of an approach designed to enable care dyads to think ahead to some of the difficult situations that may arise as the person diagnosed needs more care. This six-session intervention, developed in the US, involves structured discussions and exercises to facilitate communication between couples about their care values and preferences for future care. A recent randomized controlled trial found that dyads who took part were able to construct a future care plan, and carers experienced improved relationship quality.

As noted, it is important for interventions to be culturally appropriate and some of those described have been tested across ethnic groups with the US (e.g. Coping with Caregiving, Gallagher-Thompson et al., 2003) or across countries. Within the UK, work has been done to adapt and evaluate a carers' programme for South Asian families (Parveen et al., 2017a) but further work needs to be done to develop, adapt, and evaluate interventions to meet the needs of all sections of society, including carers of different ethnicities, sexualities, ages, and carers of those with rare dementias. However, overall, there are many evidence-based ways that health professionals can involve and support carers, treating them as genuine 'experts-by-experience' and as partners in care planning and provision. Interventions that are shown to be effective involve the person with dementia together with the carer, are flexible enough to be individually tailored, and are intensive or involve active participation.

Elder abuse

Chapter: Elder abuse

Author(s): Jill Manthorpe

DOI: 10.1093/med/9780198807292.003.0055

Introduction

From national to local newspapers (see Box 55.1) there are regular accounts of the neglect and abuse of older people, including those with mental health problems. Old age psychiatrists will be readers of such reports; likewise, their patients and their families will see such 'horror stories' fairly regularly. The professional role is evident. Old age psychiatrists may be the first to hear of people's experiences or may learn of incidents from patients' families that cause them concern.

Furthermore, they may be called upon by other concerned professionals, including the police, or their involvement may occur much later when trying to help people survive or cope with a distressing incident or a service to come to terms with an allegation, incident, or scandal.

Elder abuse

The chapter describes some of the challenges that confront old age psychiatrists working within contexts where abuse and neglect of older people are of rising concern. This chapter *could* focus entirely on definitions, quantifying the nature of the problems, or risks, but knowledge here is still partial. While presenting some discussion of these matters, the chapter also draws attention to practice responses and interventions that appear to have some success in reducing risks and minimizing harms. The chapter also points to new areas of concern beyond interpersonal violence that are beginning to threaten the wellbeing of vulnerable older people, particularly online threats. It is important to note that, while some mental health problems such as depression may be a risk of heightened vulnerability, there is room to explore if depression is linked in other ways to victimization, or is a response to it. Old age psychiatrists could assist researchers in exploring the links between expressions of distress and elder abuse to promote survival and resilience among older people. They could also assist in the development of interventions to treat perpetrators for whom there is currently little help and about whom we have little understanding.

Elder abuse

Defining elder abuse

It is no exaggeration to say that definitional variations plague the subject of elder abuse and adult abuse generally (Dixon et al., 2009). As yet there is no universally accepted definition of elder abuse, but the following is often used:

A single or repeated act or lack of appropriate action occurring within any relationship where there is an expectation of trust, which causes harm or distress to an older person or violates their human and civil rights (World Health Organization, 2002).

There is general unanimity that elder abuse, of whatever type, may result in serious adverse consequences for older people but increasingly it is merged with infringements of dignity or of other human rights where harm is less easy to quantify and often more subjective. A recent systematic review concluded that elder abuse may affect one in six older people worldwide, approximately 141 million people (Yon et al., 2017). Evidence from most low-income and middle-income countries is also growing; see studies from India (Chokkanathan et al., 2013; Evandrou et al., 2017) and Malaysia (Sooryanarayana et al., 2017).

Less commonly referred to are instances where older people are the 'perpetrators' of abuse and neglect. This is a group about which we know very little; indeed, studies of 'perpetrators' in this area are few. One feature of elder abuse has been its relative isolation from other research and practice debates, including, until recently, domestic violence and 'hate' crimes. Researchers in the US have commented that a better understanding of domestic violence may help in understanding, and then addressing, the reluctance and often refusal of older victims to take action or to accept protective services (Jackson and Hafemeister, 2012).

Generally, elder abuse is a term used to refer to the ill-treatment of an older person (usually defined as over age 65 years) by commission or omission. Terms such as maltreatment or mistreatment are also commonly used. Abuse may occur both in home or domestic settings (the older person's own home, a relative's home, or supported or sheltered housing) and in other settings (day-care centres, sheltered or assisted living facilities, care homes (residential and nursing), and hospitals). Some kinds of behaviour definable as abuse are criminal acts, such as assault and theft, or wilful neglect of a person lacking mental capacity (in England and Wales). There are other actions or behaviours that may be more contingent upon particular circumstances, such as restraint. More commonly, classifications centre round psychological abuse (bullying, shouting, or swearing), physical abuse (hitting, shaking), sexual abuse, financial abuse, and medication or institutional abuse. In addition, people may experience several types of abuse; an Irish study (Clancy et al., 2011) found that the most frequent combination was psychological and financial abuse (20% of all reports). There have been claims that physicians consistently underestimate the prevalence of elder abuse

Elder abuse

(Cooper et al., 2008), and while general estimates of around 5% of the older population may be a reasonable conclusion; this may be much higher among people with mental health problems. However, Gilhooly and colleagues (2016, p. 9) have reported that professionals are more likely to decide that financial abuse is definitely taking place, and are more likely to act if the victim is 'mentally incapacitated'.

Definitions are important—they not only determine who will be counted as abused and who will not, but they also affect the legitimate interventions by professionals and the powers of the criminal justice and regulatory sectors to intervene in family life, in care and health activities or businesses, and everyday transactions. Governments have also given powers to older people to hold other people to account if they abuse or neglect them. Recourse to action may be by complaint or by authorizing others to act on their behalf; old age psychiatrists need to be aware of such systems.

Financial abuse is one area where these definitions and risks are controversial and this may be expressed in calls for professional assistance or action. At one level it can be seen as a crime and sheer exploitation. Gilhooly and colleagues (2016) have classified possible motivations:

- Malicious—deliberately not spending assets for the wellbeing of the donor to protect an inheritance
- Malicious—deliberately spending or taking assets for their own personal benefit
- Opportunistic—a spur of the moment, unplanned act
- Misplaced moral justification—believing the victim would have wanted them to use the assets for their own benefit
- Neglect
- Incompetence

There is increasing concern about the targeting of older people or vulnerable adults from afar (email and telephone scams), as well as sophisticated and aggressive door-to-door theft, deception, exploitation, and repeat victimization (Alzheimer's Society 2011; Manthorpe et al., 2012). Oliver and colleagues (2016) have recently outlined the vulnerability of some older people to mass marketing fraud and the techniques used to entrap them.

In most developed states, policies and procedures outline the expected response of national and local government to incidents and allegations of elder abuse (see, for example, Sethi et al., 2011). In England, the term safeguarding describes multi-agency arrangements to prevent and respond to the abuse of vulnerable adults. This term was adopted to mark a shift in emphasis from reaction and rescue to prevention and harm minimization, in the hope that outcomes for the older person might be

Elder abuse

better and of their own choosing. English law was recently updated, and the Care Act 2014 clarifies the responsibilities of professionals and organizations and prompt more consistent responses. Local authorities must lead a multi-agency local adult safeguarding system (including the NHS) to prevent or stop adult abuse and neglect. They are required to make 'enquiries', or ask others to do so, when they think an adult with care and support needs may be at risk of abuse or neglect. Furthermore, they need to determine what action may be needed and acceptable to safeguard the person. In each area they must set up a Safeguarding Adults Board (Board) that includes representatives from both the NHS and the police and create a joint safeguarding strategy. The Board must undertake a Safeguarding Adults Review when someone with care and support needs dies as a result of neglect or abuse and there is a concern that the local authority or its partners could have done more to protect them. Finally, the local authority must arrange for an independent advocate to represent and support someone who is the focus of a safeguarding enquiry or review, if required. The implications for professionals such as psychiatrists are clear—starting with their responsibility to raise concerns or to prompt an enquiry; to offer advice about a person's ability to make decisions or give evidence, to take part in planning for support, and to cooperate with any Safeguarding Adult Review. In some instances, they may be asked to provide specialist or expert opinions or to support colleagues. While there is not mandatory reporting in the UK, professionals must abide by their codes of conduct, and may need to break confidentiality.

How much elder abuse is there?

For many years, researchers maintained that abuse of older men and women was not a rare phenomenon and that societal action was not required. Wilson (1994) argued that high rates of elder abuse and neglect existed among elderly mentally ill (EMI) clients of health and social services. She concluded that EMI services might expect abuse rates of 30–50% among users. Other studies have asked family carers about their behaviour where it may be hard to ask older people directly and where carer emotions and behaviour are a focus of professional activity. For example, Cooper and colleagues (2010) undertook longitudinal research among family carers of people with dementia who had been referred to community mental health teams. As many as half of these carers admitted abusive behaviour at baseline:

The psychological abuse items asked were whether they had: screamed or shouted at the care recipients, used a harsh tone of voice, insulted, swore at them or called them names; threatened to send them to a care home, to stop taking care of or abandoning them; or used physical force on them. The physical abuse items were: whether they had been afraid they might hit or hurt them, whether they had withheld food, hit or slapped, shaken or handled them roughly in other ways (Cooper et al., 2010, p. 482).

Elder abuse

The proportion of family carers who reported such behaviours had not only increased to nearly two-thirds one year on, but also this had persisted or worsened, despite carers' use of specialist mental health and other services (and their use by their relatives). The researchers concluded that targeted therapeutic interventions were needed to change carer abusive behaviour, particularly focused on reducing carers' depression and anxiety.

Who is at risk?

Patterson and Malley-Morrison (2006) have maintained that older people are universally susceptible to abuse, explicable by several individual and social, or ecological, factors. Community-based studies that surveyed large representative groups alerted professionals to potential hazardous situations, 'risky people', and client frailty. For example, the UK National Elder Abuse Study (O'Keefe et al., 2007) pointed to the risks faced by disabled older people being cared for by their partners. They concluded that this situation might lead unintentionally to poor-quality care and neglect as these family carers found their responsibilities increasingly difficult and when they perceived, rightly or wrongly, that services were inaccessible or inappropriate. Biggs and colleagues (2010), undertaking further analysis of this UK survey (which did not include people living in care homes or who used proxies for those unable to participate), found that the ways in which risk factors affected the likelihood of reported mistreatment and neglect were varied and complex. They concluded that a risk factor could have a causal influence, be the result of mistreatment, abuse or neglect, or some other factor might be more influential. Using the example of depression, which emerged as one of the risk factors associated with mistreatment (regardless of definition used), they found that, although depression may increase the likelihood that older people perceive and report mistreatment, it may also be a consequence of experiencing mistreatment or indeed a response to some common factor, such as mobility problems.

There is not great evidence that particular individuals are more at risk than others. Claims are made about some factors (gender, socioeconomic status, location, and so on). Not surprisingly, professionals working in different areas often conclude, with the apparent support of associated researchers, that their clients are at greater risk than others. There is some evidence that older people with cognitive impairment are at greater risk than other older people (Choi et al., 1999; Alzheimer's Society, 2011) but it may be that they are more likely to be referred for interventions. The Chicago Health and Aging Project (CHAP) (Dong et al., 2011) found an increased risk of reports of elder abuse to a social services agency among older people (aged 65 years and over) who had lower levels of global cognitive function, lower scores on the Mini-Mental State Examination (MMSE), and reduced episodic memory and perceptual speed. They recommended that relevant health professionals should screen for elder abuse alongside the cognitive screening and that 'red flags' for potential elder abuse 'should be raised for vulnerable,

Elder abuse

cognitively impaired individuals, especially those without the support needed to meet their most basic day-to-day needs' (p. 214). They further advised more discussion of elder abuse and dementia among and between relevant agencies.

It is now generally accepted that elder abuse affects or potentially affects a wide variety of older people. Moreover, what might be protective might be hazardous (e.g. living with family members or being in a care home, may protect or evoke new risks). The use of terms such as 'place of safety' is now generally avoided since no location or relationship has emerged as beyond reproach.

Prevention

While there may need to be a dual focus on prevention and response when addressing the abuse and neglect of older people with mental health problems in settings of all types, examples of prevention have not greatly been researched and so the evidence base for practice is thin. Nonetheless, old age psychiatrists need to be aware of local systems and resources that may assist with primary prevention—services which enable older people to seek help with worrying family relationships, or enable them to raise concerns about care workers or 'false friends' in person and remotely (promising romance, or lottery windfalls). Such opportunities for informal advice or counselling may be found in community, faith, and voluntary sectors, and part of prevention lies in informing social networks that there is help available, but also that they have a role in reducing loneliness and tackling feelings that nothing can be done. The fear and shame associated with admissions of elder abuse or even suggestions that independence is threatened need to be considered. As with primary care professionals, if approached by individual older people about their distress or fear, old age psychiatrists need to listen carefully to what is being said or what is *not* being said. The views of other members of the multidisciplinary team can provide different insights into family or care settings. Somatic complaints or expressions of anxiety, depression, apathy, and distress may be symptoms that suggest matters are slipping out of control and that previous coping strategies are inadequate. The situation of older parents supporting an adult child with addiction problems is often seen as an example where, to some professionals, the parent may be a resource, but to other professionals the older person may be at risk of exploitation since their ability to call for help may be undermined by their loyalty to their child.

Elder abuse

Further work on strategies to prevent abuse would be timely because many public educational initiatives may not be easy for older people with dementia (and many others) to comprehend or recall. Other multidimensional approaches that are part of public policy in the UK and contribute to prevention of abuse include:

- Setting up requirements for checks of care workers and volunteers to see if they have a criminal record that might lead a person not to take the risk of employing them (UK);
- Establishing a 'vetting and barring' list of people who must not be employed to work with vulnerable adults and criminalizing an employer if they do employ any person who is barred (England);
- Criminalizing the wilful neglect or ill-treatment of people who do not have mental capacity (Mental Capacity Act (MCA) 2005) (England and Wales);
- Amending sexual offences law to criminalize the sexual abuse of vulnerable adults;
- Setting up higher expectations that staff will be trained to support vulnerable adults;
- Learning from inquiries or reviews of professional or system failures (Manthorpe and Martineau 2016).

Internationally, a recent systematic review concluded that the most effective place to intervene to prevent elder abuse would be to focus on reducing physical restraint by long-term care workers (Ayalon et al., 2016). Old age psychiatrists may be able to play their part in such initiatives. Their roles in leadership and team work when responding to 'incidents' or encouraging preventive measures have not been much researched but their expertise may be useful in avoiding scapegoating, blame, and loss of morale. More proactively, they could model behaviour that encourages the voicing of concerns and supports staff who are facing ethical difficulties.

Preventive measures that can be recommended by old age psychiatrists include giving information to older people about the potential to plan in advance of loss of decision-making capacity, whether this is temporary or permanent. Such information may be useful to people newly diagnosed with dementia as it enables them to consider their options and ways in which they can protect themselves from abuse to some degree. Practitioners' roles can encompass providing information about advance care and financial planning, what to do when decision-making capacity is declining as well as absent; helping family members and the wider care team assess decision-making capacity; recommending specific support services and expertise to people with dementia and carers; and referring them to sources of help (Widera et al., 2011). For older people with fluctuating mental health problems, being able to set out their choices

Elder abuse

about care and treatment that can be taken account of if they are in great distress is a further matter that professionals can discuss.

One key point that has exercised professionals working with people who are able to make their own decisions is that of patient confidentiality. Old age psychiatrists are likely to have to advise team members on such matters, and should be aware of local policies and their responsibilities. Practitioners, of course, do not generally share information with other agencies or take action without the consent of a person who has the capacity to make this specific decision where there is no overriding duty above the normal duty of patient confidentiality. However, in England, such a duty may apply when someone else without mental capacity is at risk (e.g. another member of the family or another resident in the day centre might be at risk from a malevolent volunteer or care worker) where a 'safeguarding adults' referral should be made about that person. The duty also applies when someone publicly employed in a position of trust is apparently responsible for neglect or abuse.

Action and response

This chapter identifies that elder abuse may be unreported, undetected, and underestimated by professionals overall and suggests that old age psychiatrists have particular roles in supporting older people at risk of such harm (including perpetrators) and as leaders of services and teams. What can be done? This chapter concludes by exploring three areas illustratively.

First, there is some evidence that educational interventions with practitioners can be effective. Cooper and colleagues (2012) reported on an educational elder abuse intervention and its impact on practice. Forty trainee psychiatrists in two London National Health Service (NHS) Trusts completed the KAMA (Knowledge and Management of Elder Abuse) and the CSQ (Caregiver Scenario Questionnaire) to measure their knowledge about managing and detecting elder abuse, before and immediately after a brief group education session. The researchers asked how often participants considered, asked about, detected, and managed cases of possible elder abuse. They measured the psychiatrists' confidence in doing so, at baseline and three months post-intervention. Immediately post-intervention, the participants scored significantly higher on knowledge, compared with baseline, and identified more items that were either definitely or possibly abusive. At three-month follow up, 24 (60%) participants reported higher confidence in managing abuse and considered it more frequently, but despite this they indicated that they did not ask older people and their carers about abuse more frequently. There was no significant change in detection of abuse cases compared with a three-month period before the intervention (Cooper et al., 2012).

The researchers concluded that the value of this brief educational intervention lay in the increase of the trainee psychiatrists' knowledge and greater vigilance for abuse immediately and after three months.

Elder abuse

However, the trainees still remained reluctant to ask patients about abuse, citing reasons such as fear of causing offence or harming the therapeutic relationship, as well as being unsure how to ask people with dementia about the subject. The researchers suggested that changing professional behaviour may require a more complex intervention than education alone, and recommend that this is devoted to improving communication skills. This may be equally applicable to other professionals.

Second, at policy level, measures to enhance self-efficacy and learned resourcefulness could be promoted by old age psychiatrists to increase resilience among older people, possibly working more collaboratively with domestic violence organizations that offer refuge and rebuilding of confidence, but also working with perpetrators and with survivors' networks. Action on elder abuse means addressing social isolation as well as enhancing existing social networks. The multiple risk factors of isolation and loneliness are found in many studies of elder abuse, and appear applicable to stressed carers and some perpetrators, as well as victims of abuse. It is well recognized that older people are easily isolated as a group from public policy strategies unless specifically identified. A simple focus on abuse neglects other aspects of social connectedness.

Lastly, as a result of media reports there may be urgent work to do in persuading families and older people that not all care providers are characterized by poor or abusive practice. Otherwise people may choose not to seek early support. One area where old age psychiatrists may be able to offer meaningful reassurance is by explaining to relatives that their patients living in care homes are still entitled to NHS services and they should be able to outline how residents and care home staff are still able to access their support when needed.

Care workers are often unfairly described as under-skilled and lacking training and their work is seen as low status, poorly paid, and difficult (Hussein and Manthorpe, 2012). Effective support from health services is crucial for care homes. Gordon and colleagues (2018) found that working between healthcare services and care home staff was enhanced by: i) investment in care home-specific work; ii) relational working which over time builds trust between practitioners; iii) care which 'wraps around' care homes; and iv) access to specialist care for older people with dementia. Under these circumstances, there are likely to be positive outcomes in terms of reduced hospital admissions and overall care. These strong relationships may also have an important part to play in preventing abuse and neglect.

Conclusion

Older people with mental health problems often have great strengths and resilience, but their frailty may place them at increased risk of harm from others. As with other facets of their care and treatment, minimizing undesirable risks is an ongoing process and requires good partnership

working between health and social care, between formal and informal networks, and may involve experts from other areas, in prevention, befriending, evidence collecting, care coordination, and monitoring. This chapter has outlined aspects of the risks of elder abuse affecting older people. There is international interest in how to manage the tightrope of over- and under-protection and a sharper focus on interventions that limit perpetrators' ability to exploit or harm older people. Other interests include searches for effective and acceptable interventions. The prevention of abuse, the minimization of harm, and the provision of effective responses all require good working relationships, record keeping, analysis, observation, and listening skills, as well as being able to 'think the unthinkable'. These skills can be fostered among local services and communities by old age psychiatrists.

DOI: 10.1093/med/9780198807292.003.0056

Older people as victims

Crime against ageing individuals is recognized as a worldwide phenomenon, which transcends cultural values and societal attitudes (Ryan, 2009). It is predicted that by 2050 the global population of individuals over 60 years old will reach two billion, from the current 900 million (WHO, 2017). At the current prevalence rates, 320 million older people will be the victims of crime (WHO, 2017). A large proportion of these will be located in low- and middle-income countries, where resources to deal with these issues are often inadequate (WHO, 2017).

This section of the chapter focuses on older people as victims. We do not want to restrict our discussion solely to those actions that are identified as crime as these constitute only a small part of all the types of harmful acts against older people, such as abuse, which are not necessarily detected and pursued through the criminal justice system. This section is in three parts. The first focuses on older people as victims of actions that

Older people as victims and perpetrators of crime

are regarded as crime; the second on abuse of older people, which may not necessarily be reported as crime. The final section reports on issues of identification, reporting, prevention, and intervention, which apply to all types of victimization of older people.

Older people as victims of crime

This section focuses on the existing evidence around criminal acts against older people by reporting on criminological data and by making comparisons with offences against younger victims. It also discusses data regarding violence in residential and institutional care settings. Most research data concern violent crimes (i.e. murder, robbery, and assault), sexual violence, and financial fraud.

Violent crime

Statistics show that violent crime perpetrated against older individuals, aged 50 years old or above, occurs 20 times less frequently than violent crime against younger people (Bachman and Meloy, 2008). However, this may be a considerable underestimate, given that prevalence data rely on police reports and adult protection services, and these crimes may often be undisclosed to the authorities (Bachman et al., 1998). However, it may also be the case that older people make fewer interactions outside their home and are therefore less at risk of some types of violence. Despite the lower rates of falling victim to violent crime, it should be noted that older people may be disproportionately fearful of such crimes and, if they are attacked, may find it more difficult to recover from the incident than younger people.

The risk of being murdered is lower among older people than at any age and its incidence has remained stable in the last few years (Klaus, 2005). Compared to violence against younger victims, there are differences in relation to the method and context of killing, as well as the perpetrators' characteristics. In the UK, while the prevalence of murder among the over 50s is similar to that in younger people, there are some gender differences. In 2015, 13% of female victims of homicide were aged 75 and over, 9% of the UK female population being in this age group. Conversely, 4% of male victims were over 75 years old, 7% of the UK male population being in this age group (ONS, 2016). Older victims are more frequently killed during robbery, while younger ones more often following interpersonal conflicts (Bachman and Meloy, 2008). While overall homicide statistics report that perpetrators are more likely to be known to the victim, for elder homicide strangers account for a large proportion of the perpetrators (Bachman and Meloy, 2008).

As with homicide, the risk of falling victim of robbery decreases with age (Bachman and Meloy, 2008), except for street robbery and handbag snatching (Klaus, 2005). While younger victims of robbery are more likely to be male, victims in the older group are equally shared in terms of gender (Bachman et al., 1998).

Older people as victims and perpetrators of crime

The prevalence of assault is lower for older victims compared to younger ones (Klaus, 2005). The victims more frequently know the perpetrators, who often are their spouse or a family member (Bachman and Meloy, 2008). Therefore, compared to assault against younger victims, elder assault is more likely to occur at home than in public places (Bachman and Meloy, 2008).

The physical consequences of falling victim of violent crime can be particularly serious for older individuals, especially if they are frail. Several studies on older female victims have reported that they more frequently require medical attention for physical injuries, in comparison with younger female victims (Bachman et al., 1998; Bachman et al., 2004). Research also confirms that the risk of death following assault is higher among older victims than among younger ones (Chu and Kraus, 2004).

The evidence relating to violent crime in care homes and institutional settings is very limited, particularly around resident-to-resident violence, which remains the most common type of violence in these settings (Lachs et al., 2007). In terms of staff-to-resident violence, research studies tend to include violent acts within the overall category of elder abuse, which also includes emotional and psychological abuse, making it difficult to derive specific data for violence (Bachman and Meloy, 2008). Moreover, the few studies available are based on reports of members of staff, which limits the accuracy of reporting, given their conflict of interest in reporting malpractice. In one US study (Pillemer and Hudson, 1993), 17% of the nursing staff admitted to having used excessive physical restraint against residents and 10% to having pushed, grabbed, or shoved a resident in the last month. However, in another US sample of nurses working in home facilities, only 3% admitted to having used any type of violence in the last year (Pillemer and Bachman, 1991).

Several risk factors for staff-to-resident violence have been identified. They include: residents' characteristics (dementia and high-dependency needs) (Talerico et al., 2002; National Center on Elder Abuse, 2000, 2005); staff characteristics (young age, poor education, little experience of work with older residents) (Pillemer and Bachman, 1991; Pillemer and Moore, 1990); staffing issues (inadequate training, low staffing, high turnover, work-related stress, and 'burn-out' (National Center on Elder Abuse, 2000), (Pillemer and Bachman, 1991; Pillemer and Moore, 1990; Shaw, 1998); and infrastructural issues (i.e. accessibility issues) (National Center of Elder Abuse, 2000).

Sexual violence

There is no consensus across different jurisdictions on what constitutes sexual violence, and in some instances the term sexual abuse is used interchangeably. Sexual violence can encompass actions perpetrated by individuals known or unknown to the victim (Johannesen and LoGiudice, 2013). The matter is further complicated by the fact that for sexual

Older people as victims and perpetrators of crime

offences, unlike for other offences, the issue of consent is central to determining whether an offence has been committed or not. Therefore, the same action could either be consensual sex or rape. In the case of older people, their ability to consent may be affected by mental disorders and cognitive decline to a larger extent than in younger individuals. Therefore, it may well be that what was previously consensual sex with a long-term partner is later technically a crime, as one of the two partners has lost their capacity to consent. Such issues pose significant challenges to providers of services for older people, who have to strike a balance between protecting individuals from unwanted sexual activities while not depriving them of pleasurable activities in the context of a loving relationship. Here, we only present data around sexual violence.

Contrary common assumptions, research evidence suggests that the risk of sexual victimization does not decrease with age, particularly among women (European Union Agency for Fundamental Rights, 2014; Mann et al., 2014; Stockl et al., 2012). The prevalence of self-reported elder sexual violence ranges between 0.2% (O’Keeffe et al., 2007) and 17% (Lisboa et al., 2009). Risk factors include being a woman of white ethnicity (though this perhaps reflects the likelihood of reporting rather than a true increase in prevalence), being aged between 60 and 70 years old (Baker et al., 2009; Ball and Fowler, 2008; Bows and Westmarland, 2017; Jeary, 2005; Lea et al., 2011; Naughton et al., 2010; O’Keeffe et al., 2007), having poor physical and psychological health, cognitive impairment (i.e. intellectual disability, dementia), and poor communication skills (Pinto et al., 2014). As with homicide, elder sexual assault most often occurs in the victim’s home and in care homes/institutional settings, rather than in public places (Ball and Fowler, 2008; Jeary, 2005; Teaster et al., 2001).

Perpetrators tend to be male, often much younger than the victim, and with previous convictions (Bows, 2017). Research has also evidenced that, in contrast with younger victims, sexual violence committed by strangers is more common (Bows, 2017). In care homes and institutional settings, while some studies have found that members of staff are the most likely perpetrators (Baker et al., 2009), others have reported that peer-to-peer sexual violence is more common (Roberto and Teaster, 2005).

The impact of sexual assaults on older victims can be both physical and emotional. While the risk of HIV and other sexually transmitted diseases is in line with younger female victims of sexual assault (Sormanti and Shibusawa, 2008; Sormanti et al., 2004), older victims are more likely to experience genital trauma (Jones et al., 2009; Morgan et al., 2011; Muram et al., 1992; Ramin, 1997; Templeton, 2005). High mortality rates have also been reported, with over half of the sexually assaulted older women dying within one year (Burgess et al., 2000). As in younger victims, emotional consequences of sexual violence include low self-esteem, hopelessness, numbness, social withdrawal, sleeping problems,

Older people as victims and perpetrators of crime

flashbacks, and nightmares, though these effects might be more severe in older people (Burgess, 2006; Jeary, 2005).

Financial fraud

A necessary distinction is to be made between financial abuse and financial fraud, the first being perpetrated by people known to the victim, the latter not necessarily occurring in the context of victim-perpetrator acquaintance. Financial fraud includes doorstep crime (selling goods or services at extortionate prices), bank account theft, mass marketing fraud (e.g. asking for upfront payment for goods or services), pension fraud, investment fraud, and cybercrime (Age UK, 2015). These crimes may be perpetrated through the web, mail, phone, and texts (Age UK, 2015), through various expedients, such as befriending or coercing the victim, using false credentials or credible documentation (Button, Lewis, and Tapley, 2009), selling dreams at a low price, and taking relatively small amounts of money (Age UK, 2015). The victims are often included in 'sucker lists', making them susceptible to further victimization (Age UK, 2015).

Prevalence studies report high prevalences of financial fraud of older people: 53% of people over 65 years old believe they have been the victim of this crime and 70% of those responding to the financial requests of scammers have lost money. This percentage amounts to 500,000 people in the UK alone (Age UK, 2015). Older people are much more likely to be targeted than younger people, as more than half the cases of financial fraud are perpetrated against people over 55 years old, who also experience twofold financial losses, the mean loss per scam being £684 for victims below 55 years old, and £1,261 for those aged above 55 (Age UK, 2015).

The most common type of financial fraud among older people is doorstep crime, with 85% of the victims above 65 years old being a victim of this type of crime (Andrews, 2014). The victims are more likely to live alone (62%) and have a physical impairment (63%) (Andrews, 2014). Social isolation (40%), depression in the last six months (36%), and bereavement in the past two years (33%) are also common, and cognitive impairment is present in 14% of the older victims (Andrews, 2014).

As for other types of crimes, prevalence estimates of elder financial fraud may be conservative, as the phenomenon may be largely underreported due to several factors, including a sense of shame on the part of the victims (Age UK, 2015). Risk factors include social isolation and cognitive impairment, as well as victims' overconfidence in their capability to make financial investments (Lea et al., 2009).

The impact of financial fraud is both practical and psychological. Financial losses can take a higher toll on older people, who may have to live on limited fixed income. Research has identified that 46% of older victims experience financial difficulties (Andrews, 2014). Deteriorating

Older people as victims and perpetrators of crime

psychological health is also common among the victims of financial fraud, who may be exposed to stress, anger, and loss of self-esteem (Age UK, 2015). 40% of victims report a sense of shame and 28% symptoms of depression (Andrews, 2014).

Older people as victims of abuse

Abuse or acquaintance violence is defined as 'a single or repeated act, or lack of appropriate action, occurring within any relationship, where there is an expectation of trust which causes harm or distress to an older person' (Wood et al., 2010). Abuse can be intentional, but sometimes the perpetrator may be unaware of the harm being caused to the older person (Wood et al., 2010). Either way, the concept of abuse implies an existing relationship between the perpetrator and the victim.

While abuse against children and women has been the focus of research, policy, and prevention/intervention strategies since the 1960s (Kleinschmidt, 1997), elder abuse was neglected until the mid-1970s, when the phenomenon was first identified as 'granny battering' (Baker, 1975; Burston, 1975). Since then, the understanding of elder abuse, how it is perpetrated, experienced, prevented, and dealt with has grown. This development notwithstanding, abuse of older people has not yet been comprehensively addressed in international health policy documents (Yon et al., 2017). The recently established 17 Sustainable Development Goals of the United Nations mention abuse against women (target 5.2) and children (target 16.2), but there is no reference to abuse against older people (United Nations, 2017). In addition, progress has been hindered by governmental underfunding of campaigns, programmes, and interventions. In 2009, in the US, the annual spending for all activities related to elder abuse was \$11.9 million, compared with \$649 million for women and \$7 billion for children (Dong, 2015). To raise awareness among policy makers, professionals, and the public, the International Network for the Prevention of Elder Abuse (INPEA) designated 15 June as World Elder Abuse Awareness day for the first time in 2006, ratified by the United Nations in 2010 (United Nations, 2013).

Elder abuse includes:

- Physical abuse, causing physical harm, pain or injury, through restraining, hitting, grabbing, pushing, slapping, and bruising the older person (Wyandt, 2004).
- Psychological or verbal abuse, which may cause emotional harm or pain to the older person through humiliation, insults, infantilization, yelling, and threats (Wyandt, 2004; Kleinschmidt, 1997).
- Sexual abuse, engaging in any non-consensual sexual act with an older person.
- Financial abuse, the illegal or improper exploitation or use of funds or other resources of the older person (WHO, 2002), which may include misappropriation or mismanagement of financial assets,

Older people as victims and perpetrators of crime

account takeover, investment fraud, pension fraud, and inheritance fraud (Age UK, 2015).

- Neglect, failing to fulfil the care needs of the older person or provide assistance in activities of daily living (Kleinschmidt, 1997).

A culture-sensitive approach to considering these five categories is crucial, as marked variations exist across cultures as to what constitutes elder abuse (Pillemer et al., 2016). Caution is required when comparing prevalence data across different countries too. Sooryanarayana and colleagues (2013) found that prevalence rates in high-income countries are higher than those reported in low-income countries, due to the cultural variations on how the phenomenon is perceived and reported (Kleinschmidt, 1997). As an example, in parts of India and Africa it is customary that widows are forced into finding a new husband, they may be banished and their financial assets (e.g. property) may be seized by family members (Kumari, 2014; McFerson, 2013). While this would be classed as abuse in other countries, it is unlikely to be reported as such in countries where such behaviour is the cultural norm.

How elder abuse is defined also depends on different concepts of who is regarded an 'older person'. Some countries, such as Ireland, consider a retired individual over the age of 65 to be 'older', while others use 60 years old as criterion for inclusion in the older age category (Ryan, 2009). In Australia, Aborigines are considered older at age 50 (Wainer et al., 2010) and the cut-off is as low as 45 years old for indigenous women, given their lower life expectancy (McFerran, 2008).

The perception of elder abuse also varies with age and gender. Young people tend to identify abuse only in more serious cases, while older people are more likely to acknowledge the subtleties of emotional abuse (Daskalopoulos et al., 2007; Childs et al., 2000). In addition, a UK study found that women are more knowledgeable of elder abuse and aware of its extent, compared to men (Hussein et al., 2007).

How serious the abusive behaviour is perceived to be also depends on the victim's characteristics. In those not considered of 'sound mind', such as in dementia or in the presence of other mental health issues, the abuse may be less likely to be acknowledged by others (Werner et al., 2006; Mills et al., 1998).

Prevalence of elder abuse

A recent review by Yon and colleagues (2017), based on 52 studies in 28 countries, presents the most up to date pooled prevalence data on elder abuse. The authors report a 15.7% prevalence for 'any form of abuse', equal to one in six (141 million) older adults worldwide.

In relation to single countries, in the UK, 2.6% of older people aged 66 and above residing in private accommodation report any type of abuse on the part of family, friends, or caregivers each year (Biggs et al., 2009). In

Older people as victims and perpetrators of crime

the US, 10% of respondents to a phone survey reported being abused (Peterson et al., 2014; Burnes et al., 2015). A similar prevalence (9%) was found in a population-based nationally representative study in the US involving 3,000 community-residing participants aged 57–85 (Laumann et al., 2008). Prevalence data range from 1% to 4% in Australia; in Norway, Finland, and the Netherlands the estimate is around 5%, in Sweden and France 17% and 20% respectively (Fallon, 2006), and in Spain over 40% (Sooryanarayana et al., 2013).

High prevalence is also found in some Asian countries, where a review synthesizing results from 18 studies, using one-year prevalence rates, found that India had a higher aggregate rate for all types of abuse (14%), compared to Europe (6%) and Canada (4%) (Pillemer et al., 2016). The marked differences across countries can be explained by the lack of standardized tests to detect abuse, with a range of assessments and methods employed in the existing literature, paired with different age cut-offs for inclusion in the older age category (Sooryanarayana et al., 2013).

In relation to specific types of abuse, Cooper and colleagues (2008) found that one in four older people experienced significant levels of psychological abuse, which was identified as the most prevalent type of abuse. This was followed by neglect, financial abuse, and physical abuse. The least reported form of abuse was sexual abuse, with prevalence varying from 0.04% in Nigeria (Pillemer et al., 2016) to 1.3% in Spain (Sooryanarayana et al., 2013). It is relevant to note, however, that these data probably underestimate the problem, as identification and reporting of elder abuse is affected by several factors, including how visible the signs of abuse are, the victims' expectation of outcome following disclosure (e.g. will they be believed or stigmatized), and being able to report the abuse (e.g. if there are physical and other restrictions preventing access to the police) (Fealy et al., 2012).

Abuse against older people occurs most frequently within the person's home (67%), followed by nursing homes (12%), residential care facilities (10%), hospitals (5%), and sheltered accommodation (4%) (Ogg and Bennett, 1992). The presence of abuse within care homes was confirmed in a study based on self-reports by nurses, 88% of whom had witnessed elder abuse in the workplace at least once and 12% on a frequent basis (House of Commons, 2004). Cooper and colleagues (2008) reported that 16% of members of staff in residential care facilities admitted to having engaged in some form of psychological abuse.

All these figures are likely to be underestimates given the low reporting rates by the victims. For instance, in a US study, Pillemer and Finkelhor (1988) found that only one in 14 cases of abuse was reported, while a UK study found that one among seven victims of physical abuse and half of the victims of verbal abuse disclosed their experiences (Homer and Gilleard, 1990). In a Canadian study, just one in 20 older people who had been financially abused reported it (Podnieks, 1993). While, therefore, prevalence rates vary, partly due to methodological challenges and

Older people as victims and perpetrators of crime

differences, it is clear that elder abuse constitutes a significant problem worldwide.

Risk factors for elder abuse

A number of victim characteristics have been associated with elder abuse. These can be divided into six broad categories: i) mental health; ii) physical health; iii) ethnicity; iv) gender; v) age; and vi) living arrangements.

Mental health

Both psychological distress and the presence of a mental disorder increase the risk of victimization (Dong et al., 2008; Dong and Simon, 2008). For example, clinical symptoms of depression have been found to increase the risk of becoming the victim of abuse (Lachs et al., 1997).

Those with dementia are at particular risk of abuse with prevalence rates ranging from 28% to 52%. Severity of symptoms of psychosis, aggression, depression and anxiety (Cooper and Livingston, 2014; Conner et al., 2011), and higher care and dependency needs appear to be correlated to higher risk of victimization (Pillemer et al., 2016; Lachs and Pillemer, 2015; Dong, 2015; Murphy et al., 2013). There are some distinctive characteristics of abuse of people with dementia. More than one-third of victims were found to be the victims of multiple forms of abuse simultaneously (Wigglesworth et al., 2010). In addition to being victims, older people with dementia may also be perpetrators of abuse, either against their carers (Cooney et al., 2006) or against peers in residential care settings (Shinoda-Tagawa et al., 2004).

Following abuse, victims with dementia present with more frequent behavioural symptoms of distress, compared to older people without dementia (Burgess, 2006). In addition, mortality is higher (Dong et al., 2009) and may be partly accounted for by the overprescribing of antipsychotic drugs to contain behavioural symptoms (House of Commons, 2004).

The identification of abuse can be extremely challenging. Many behavioural symptoms and physical signs (e.g. social withdrawal, communication difficulties) can be misinterpreted as caused by the underlying disorder (Dong et al., 2014). Interview screening protocols may not be easily administered to people with deteriorating cognition, and, in fact, most existing screening tools have not been validated with this population (Wigglesworth et al., 2010). Even when identified, the perpetrators of abuse against older people with dementia are less likely to be prosecuted than those of victims who do not have dementia (Burgess, 2006).

Given the challenges of dealing with abuse against older people with dementia, efforts have focused on prevention strategies. The STRAteies for RelaTives (START), for example, is a psychological intervention to help

Older people as victims and perpetrators of crime

with the stress and emotional burden experienced by family carers, and has proven effective in reducing abusive behaviours (Cooper et al., 2016; Livingston et al., 2013).

Physical health

Declining physical health is also associated with elder abuse (Biggs et al., 2009). Kamavarapu and colleagues (2017) reported that 49%–70% of older individuals who were the victims of abuse had physical impairments such as mobility issues, sensory impairment (loss of sight), and incontinence. Physical ill health was associated with increased financial abuse in the US, UK, and Canada (Laumann et al., 2008; O’Keeffe et al., 2007; Podnieks, 1993), with physical, sexual, and emotional abuse in Israel (Lowenstein et al., Enosh, 2009), and with neglect in the US, Canada, and Israel (Acierno et al., 2010; Amstadter et al., 2011; Burnes et al., 2015; Lowenstein et al., 2009; Pillemer and Finkelhor, 1988; Podnieks, 1993).

Ethnicity

Studies investigating ethnicity and elder abuse suggest that prevalence differences between groups relate more to help-seeking attitudes (i.e. how acceptable it is within the culture to seek help following abuse), rather than ethnicity per se. Proneness to help-seeking was found to be less common among Korean-Americans, compared to black people and white people, and this was explained in terms of the value attributed to behaviours that preserve family unity ahead of personal independence, typical of Korean culture (Moon and Williams, 1993).

Gender

As with women of all age groups, older women are exposed to a high risk of abuse. Although some researchers, including from Australia, Canada, Norway, Sweden, and the US, have carried out pioneering work in the field, gender-related issues in elder abuse have been often neglected (Penhale, 2003). In relation to older women with refugee status living in conflict zones, research and practice is even less advanced (United Nations, 2013).

The largest prevalence study around abuse of older women is the European Union prevalence study of Abuse and Violence against Older Women (AVOW) (Luoma et al., 2011), which found that 28.1% of women had suffered from any type of abuse, 23.6% from emotional abuse, 8.8% from financial abuse, 5.4% from neglect, 3.1% from sexual abuse, and 2.5% from physical abuse. Results from a study in China on older community dwellers found higher rates for physical abuse (6.3%), emotional abuse (28.4%) and neglect (13.8%), but a lower prevalence for financial abuse (1.9%) (Wu et al., 2012). A high prevalence of emotional abuse (33.7%) was confirmed in a Hong Kong study on intimate partner abuse (Yan and Chan, 2012). Women were also found to be more exposed than men to any type of elder abuse in studies carried out in the US

Older people as victims and perpetrators of crime

(Laumann et al., 2008), the UK (Wood et al., 2010), Portugal (Gil et al., 2015), India (Chokkanathan and Lee, 2006), Ireland (Naughton et al., 2010), Israel (Lowenstein et al., 2009), and Mexico (Giraldo-Rodríguez and Rosas-Carrasco, 2013).

Being lonely and retired were the most relevant predictors of the victimization of older women (United Nations, 2013), and the most frequent perpetrators were their spouses and partners (Luoma et al., 2011). The most commonly reported consequences of abuse were found to be low quality of life, increased anxiety symptoms, and feelings of hopelessness, anger, and low self-esteem (Luoma et al., 2011).

Significant challenges in identifying abuse against older women are related to poor reporting rates. Barriers to disclosing abuse have been divided into internal (i.e. inherent to the individual) and external (i.e. inherent to the environment). Internal factors which can override the victim's need for safety and disclosure include self-blame, the need to protect the family unit and the children, feelings of powerlessness, and the fear of not being believed (United Nations, 2013). External variables comprise threatening attitudes and behaviour from the perpetrator, rejection from the family, and a lack of trust that law enforcement agencies can end the abuse (United Nations, 2013).

It has long been acknowledged that the impact of internal and external barriers, and indeed the abuse of older women as a phenomenon, can be better understood within a feminist framework. This perspective asserts that abuse is mediated by the inequity and power imbalance that sees women in a disadvantaged position compared to men in all societies and cultures (Nerenberg, 2006). Therefore, any prevention and intervention campaign, as well as legislative change, should promote equal rights in society for older women (Nerenberg, 2006).

Age

A lack of consistency is found in relation to victims' age. Several international studies reported a higher risk of abuse for the older age category (85 years old and above) compared to the younger group (65–85 years old) (Biggs et al., 2009; Giraldo-Rodríguez and Rosas-Carrasco, 2013; Gil et al., 2015; Naughton et al., 2010). However, research in the US found an association between younger age and increased risk for physical, emotional, and financial abuse and neglect (Acierno et al., 2010; Burnes et al., 2015; Laumann et al., 2008). Once again, these apparently conflicting findings are likely to be influenced by reporting and ascertainment issues in the various studies.

Living arrangements

Findings from the literature around living arrangements as a risk factor are also discordant. Some studies indicate that being married is a precursor for abuse in general (Pillemer and Finkelhor, 1988), and for emotional and physical abuse in particular (Podnieks, 1993; Soares et al.,

Older people as victims and perpetrators of crime

2010). This can be explained by the shared living environment with the potential perpetrator (Wood et al., 2010). In line with this, Lachs and Pillemer (2015) reported that a higher number of household members increased the risk for elder abuse, in particular in the presence of poor income or financial difficulties, and when the family members were depending on the older person for housing and finance (Wood et al., 2010).

Other studies, however, found a correlation between not being married and being the victim of abuse, both for aggregated abuse (Giraldo-Rodríguez and Rosas-Carrasco, 2013; Naughton et al., 2010; O’Keeffe et al., 2007) and for any single type of abuse (Burnes et al., 2015; Laumann et al., 2008; O’Keeffe et al., 2007; Podnieks, 1993; Wu et al., 2012). Higher risk for victimization was also reported among older people who are lonely (Dong et al., 2007) and who lack social support (Amstadter et al., 2010).

Even less is known in relation to institutional settings (Lachs and Pillemer, 2015). In these settings, abuse may be perpetrated by a range of people, including members of staff and visitors (e.g. family, friends). Increasing interest has also been given to the phenomenon of elder abuse perpetrated by fellow residents, which seems to be more prevalent than abuse from staff (Pillemer et al., 2011).

Although for various reasons, including fear of retribution, abuse in institutional settings may pass unreported and unidentified (Kleinschmidt, 1997), the evidence suggests that abuse may be more prevalent than in the community (Pillemer et al., 2016) and increased by: i) organizational issues, including understaffing, inadequate training, and stress; ii) problems in staff-resident relationships, such as poor communication; iii) environmental factors, including poor health and safety; and iv) policy and regulations, such as an overly strict regime (Bennett et al., 1997). Therefore, adequate strategies (regulation, policies, management of the workforce) are crucial to ensure good practice in the workplace.

Several specific tools have been developed to investigate abuse in institutional settings. The Elders’ Psychological Abuse Scale (EPAS) (Wang et al., 2007) detects psychological abuse in long-term facilities, the Caregiver Psychological Elder Abuse Behavior Scale (CPEAB) (Hsieh et al., 2009) investigates violent behaviour as reported by staff of nursing homes, while the 24-item list of maltreatment/abuse acts (Cohen et al., 2010) is administered to the older residents. These context-specific tools may contribute to service improvement, as they represent an invaluable support for providers to identify when abuse is occurring.

Perpetrators of elder abuse

The explanatory model for elder abuse contends that risk is mainly affected by the perpetrator’s rather than the victim’s characteristics

Older people as victims and perpetrators of crime

(Anetzberger, 2000). Ramsey-Klawnsnick (2000) divided perpetrators of elder abuse into five typologies:

1. The 'Overwhelmed', who may experience such high levels of emotional burden and stress in providing care to the older person (the caregiver stress hypothesis) that it can result in abusive behaviour.
2. The 'Impaired', who present with health issues that make them more prone to abusive behaviour. These include individuals with a history of mental or physical health problems, substance dependence, a history of serious psychiatric conditions such as personality disorder, or a history of offending (Laumann et al., 2008; Amstadter et al., 2011; Chokkanathan and Lee, 2006; Oh et al., 2006; Soares et al., 2010; O'Keeffe et al., 2007).
3. The 'Narcissistic', who are driven by personal gains to be derived from the abuse. The classic example is individuals who are unemployed and/or in financial difficulties and who depend financially on the victim (Wood et al., 2010).
4. The 'Bullying', who justify their abusive behaviour in terms of the victim not fulfilling their expectations. For example, health care staff may become perpetrators of violent behaviour against older residents who repeatedly fail to abide by the rules and regime of the residential home.
5. The 'Sadistic', who are prone to criminal behaviour and may have a history of serious offending (Lachs and Pillemer, 2015).

Overall, the perpetrators are more likely to be family members of the victims than not (Lachs and Pillemer, 2015). In institutional settings, however, Benbow and Haddad (1993) found that a large proportion of the perpetrators of sexual abuse were fellow residents. Differences in terms of gender are minimal. Ryan (2009) reported that 56% of perpetrators of abuse are male and 44% females. Wood and colleagues (2010) found no difference in the proportion of male and female financial abusers.

The impact of elder abuse

Although very limited research has looked into the consequences of elder abuse, its negative impact in several spheres of the victim's life is undisputed.

In relation to physical health, the consequences of abuse can be very serious for older people, given their frailty. A systematic review synthesizing data around the types of injuries following elder abuse reported injuries to the arms and shoulders (44%), face, teeth, and neck (23%), head (12%), legs and hips (11%), and torso (10%) (Murphy et al., 2013). There is also evidence of higher emergency department use (Dong et al., 2011) and hospitalization (Dong and Simon, 2013), and an increased mortality risk associated with elder abuse (Dong et al., 2013).

Older people as victims and perpetrators of crime

Serious consequences are also reported for mental health with increased symptoms of depression, anxiety, and post-traumatic stress (Dong et al., 2013; Mouton et al., 2010; Gibbs and Mosqueda, 2010). These are often triggered by overall psychological distress, which is accompanied by feelings of shame, fear, guilt, denial, helplessness, and alienation (Booth et al., 1996; Goldstein, 1996). The severity of symptoms is associated with the type of abuse. Emotional and verbal abuse are more positively correlated with increased psychological distress, compared with physical abuse (Begle et al., 2011; Coker et al., 2002; Pico-Alfonso et al., 2006).

A negative impact on financial stability and quality of life can be the result of financial abuse among those who have limited income and for whom the loss of any amount of money leads to a failure to fulfil their basic needs (WHO/IPNEA, 2002; Alves and Wilson, 2008; Al-Baho, 2004).

Identifying elder victimization

Given their frequent contact with older people in a variety of settings, including general practices, emergency departments, hospitals, and surgeries, health care professionals play a central role in identifying elder abuse and violence (Wood et al., 2010). It is therefore crucial for these professionals to receive adequate training to raise their awareness of the issue, be educated on the identification of signs of violence, become aware of the resources available to intervene, and manage suspected cases effectively by liaising with the relevant agencies (Lachs and Pillemer, 2015; Shefet et al., 2007). Training should also be focused on encouraging sympathetic views and attitudes toward older people and on sensitizing staff to age-related issues (Pillemer et al., 2016).

The two main strategies for improved identification of elder abuse, which ideally should be combined for increased accuracy, are a clinical interview and a physical examination (Cohen et al., 2007). Before any of these assessments are undertaken, however, the health professional should assess the mental capacity of the older person. Where the person is deemed to be fully capable, the investigation can proceed, the older person becoming directly responsible for any choice made during and following the investigation (Wang et al., 2015). Where the person lacks capacity, a suitable person should be identified to help them—for instance, there may be a person, often a relative, with an enduring power of attorney. If it is suspected that the identified person is the perpetrator of the violence, the case should be referred to social services (Wang et al., 2015; see also Chapter 55 for further information about safeguarding).

The interview should ideally be undertaken with the older person separate from any potential perpetrator (Lachs and Pillemer, 2015) and should include an investigation of their personal context (e.g. culture, living arrangements, family characteristics) (Dong, 2015). The health professional undertaking the interview should adopt a sympathetic attitude and avoid being confrontational or drawing any conclusions

Older people as victims and perpetrators of crime

before the facts have been ascertained (Lachs and Pillemer, 2015; Kleinschmidt, 1997).

A physical inspection of the older person can detect evidence of possible violence. There are typical signs that can indicate some form of violence, including scars, lacerations, bruising, burns, fractures, injuries, sexually transmitted diseases, decubitus ulcers, poor hygiene, dehydration, and malnutrition (Wyandt, 2004). Although none of these signs is unequivocally associated with violence, as they may be symptoms of a range of age-related conditions, they nonetheless provide visible evidence which may be relevant in future proceedings and should therefore be adequately recorded (Lachs and Pillemer, 2015). Where abuse occurs, physical signs are often accompanied by frequent medical appointments or visits to emergency departments and by some behavioural symptoms, which may include but are not limited to appearing fearful, withdrawn, nervous, and helpless (Wyandt, 2004).

In addition to clinical experience, health professionals can rely on several screening tools for violence. These include the self-report Vulnerability to Abuse Screening Scale (VASS) (Schofield et al., 2002), the ten-item tool for disclosure of abuse by Cohen and colleagues (2007), the Elder Abuse Suspicion Index (EASI) (Yaffe et al., 2008), the Elder Assessment Instrument (EAI) (Fulmer et al., 2004; Fulmer and Wetle, 1986; Fulmer et al., 1984) and the evident signs of abuse inventory (Cohen et al., 2006; Fulmer et al., 2004; Cohen et al., 2007; Cohen et al., 2010).

Reporting elder victimization

Several barriers may hinder the process of reporting violence towards older people. The older person may be reluctant to disclose violence or even to collaborate in an investigation, because they may feel guilty, embarrassed, ashamed, fearful of reprisal, afraid they may be relocated or institutionalized, or that they may not be believed (Burgess, 2006; Kleinschmidt, 1997). Language and cultural barriers may also play a part (Lachs and Pillemer, 2015). In addition, the criminal justice system might be unwilling to get involved due to uncertainties regarding the reliability of the older person as witness. It is therefore essential that support is available to the potential victim in this process.

Secondly, the consequences of violence, physical or emotional, can be easily misinterpreted as linked to normal age-related maladies, but false positives can also occur (Wyandt, 2004; Lachs and Pillemer, 2015). Some types of violence, namely sexual abuse, may pass undiagnosed, as they are not typically expected to occur in old age and might therefore be overlooked (Falk et al., 1997; Gray and Acierno, 2002).

Thirdly, health professionals might conceal abuse because of the sensitivity of the topic, an unawareness of the resources available to help, or simply to avoid detection of their own wrongdoing (Lachs and Pillemer, 2015). Even when reported, an investigation can take several weeks or

Older people as victims and perpetrators of crime

even months, during which the health professional is required to make decisions in the face of ongoing uncertainties (Lachs and Pillemer, 2015).

Preventing elder victimization

As elder abuse and violence have become a global health concern, the World Health Assembly recently published a strategy aimed to reduce elder violence worldwide, through a collaborative action plan and joint initiatives (WHO, 2017). These include: i) increasing the evidence base and understanding of elder abuse, its types and its extent, particularly in low and middle-income countries; ii) developing guidance on how to respond to elder abuse; iii) sharing good practice across countries on how to prevent elder abuse; and iv) implementing collaborating networks worldwide to fight elder abuse.

Several strategies have the potential to prevent elder violence and abuse, although consistent evidence of their effectiveness is still limited (Ploeg et al., 2009; Sethi et al., 2011; Stolee et al., 2012). These strategies can be divided into interventions focused on single individuals (i.e. at-risk individuals or any potential perpetrator), and interventions focused on the community/society and in the workplace, especially care home settings.

Among the most common strategies in the first group are caregiver interventions, which aim to reduce carer burden, manage stress and increase social connection (Wood et al., 2010; Pillemer et al., 2016). Such interventions include peer and professionally-led support groups, psychological treatment (e.g. anger management), training on providing care (e.g. preparing meals), education on age-related issues, and respite care (finding temporary alternative care arrangements so that the primary caregivers can take time off their caring duties) (Wood et al., 2010; Pillemer et al., 2016).

Prevention strategies for potential victims can be non-specific (i.e. targeted to all types of violence or abuse) or specific (i.e. depending on the type of violence or abuse they aim to tackle). In the first group, telephone helplines represent a valuable resource to provide emotional and practical advice to potential victims. Phone helplines can also function as intervention (i.e. post-violence) strategies. They are staffed by volunteers or professionals and often work around the clock (Pillemer et al., 2016). In contrast with web-based chats, which require IT literacy, telephones are widely accessible, even in low-income countries. In relation to specific prevention strategies, money management training catering to older individuals who may be at risk of financial abuse provides older people with external support and assistance in carrying out financial routines, such as paying bills, manage shopping money, and banking (Pillemer et al., 2016).

Prevention strategies in the community and in society, such as mass media (television, radio, printed materials, and the web) campaigns, aim to promote a more positive image of older people as valuable members of

Older people as victims and perpetrators of crime

the community, in order to stigmatize elder abuse. These initiatives include educating the younger generations (in schools, universities, and community settings) about the value of older people in society (Baker et al., 2016).

Prevention strategies in care homes include:

1. Identifying especially vulnerable individuals and implementing strategies to reduce their risk of victimization (e.g. offering low-stimulation environments to decrease challenging behaviours and aggression).
2. Increasing the knowledge and skills of members of staff to identify and deal with challenging behaviours (e.g. de-escalation training) to prevent violent responses against older individuals;
3. Creating a safe environment and culture of openness/support (e.g. through regular community meetings) to increase the confidence of staff and service users to discuss issues of violence and abuse;
4. Carrying out pre-employment background checks and closely monitoring members of staff, perhaps especially those at higher risk of becoming perpetrators (i.e. male, non-trained, front-line care staff) (Kamavarapu et al., 2017).

Intervening in cases of elder victimization

In order to tackle elder abuse, appropriate policies and laws are required, including local, national and international strategies to report and deal with violence affecting older people (Baker et al., 2016). The US has the most comprehensive advanced national system for the reporting and management of elder violence, which operates at the single-state level, and is supported by the National Centre on Elder Abuse at the federal level (Krug et al., 2002). Specific legislation to protect older victims is also in place in Canada, Japan, South Korea, Israel, and Slovenia.

In the UK, notification of suspected abuse to the relevant local authority, which is legally bound to make an enquiry, theoretically requires the consent of the victim. In most circumstances, however, this is bypassed (e.g. because of lack of mental capacity, ongoing risk to the victim, potential risk of the perpetrator to other members of the public, suspected violence within the NHS or professional care contexts) (Age UK, 2017), thus raising ethical dilemmas around the rights and autonomy of the individual. In Japan, Israel, and some states and provinces in the US, Canada, and Australia, the law mandates the reporting of elder abuse without the victim's consent (Wood et al., 2010).

Following the identification of violence, the primary goal of an intervention strategy is to ensure the victim's safety. This can be obtained through hospitalization (if the victim is in immediate need of health assistance), emergency shelters (when the victim needs immediate transfer to a temporary safe setting; Pillemer et al., 2016), and support groups. The secondary goal is to arrange support according to the

Older people as victims and perpetrators of crime

person's needs, which usually is by means of multidisciplinary teams, given the multidimensional needs of older victims (Lachs and Pillemer, 2015). Multidisciplinary teams comprise a range of professionals with different fields of expertise, including the criminal justice system, primary physical, mental, and social health care, the legal system, financial services, and social and adult protective services. Such teams have been found to improve outcomes in addressing issues related to elder violence in a number of studies (Blowers et al., 2012; Navarro et al., 2013; Rizzo et al., 2015; Teaster et al., 2003; Ulrey and Brandl, 2012).

Conclusion

The existing knowledge gap around elder crime requires further research at various levels. Given the increasing diversity of the ageing population, this includes considering how cultural factors have an impact on elder violence. Community-based participatory research and research partnerships with stakeholders would enable researchers to better capture the cultural dimensions of the phenomenon (Dong, 2015). Collaboration between academic researchers and members of the public would also deepen the understanding of the impact that societal ageism has on the perpetration of violence and abuse against older people.

Another area requiring further research is that of effective interventions to prevent violence and abuse. A recent review of the evidence around prevention strategies found that only ten intervention studies had been carried out to assess the effectiveness of interventions for elder abuse, with all obtaining equivocal results (Pillemer et al., 2016). In addition, there is virtually no comparative international literature or cost-effectiveness analysis looking at the sustainability of existing interventions (Pillemer et al., 2016). In order to fill this gap and to determine which interventions (or elements of them) are really effective and financially sustainable, there is a need for high-quality randomized controlled trials carried out in both high-, middle-, and low-income countries (Baker et al., 2016).

Older people as perpetrators of crime

This section focuses on the existing evidence around older people as perpetrators of crime. The section opens with overall data around prevalence and types of crime, clinical characteristics of older offenders, and how elder crime is dealt with within different legal systems. It differentiates between older prisoners and older patients in forensic psychiatric settings. It presents and compares epidemiological data about each population against those of younger offenders. Finally, it discusses relevant issues around ageing in forensic settings.

Operational definition: Who is an ageing offender?

Before delving into what is known about ageing offenders and about their experience of the justice system, an operational definition of 'ageing offender' is necessary.

Older people as victims and perpetrators of crime

Despite an ongoing debate around an appropriate age cut-off, given the highly subjective experience of the ageing process, old age forensic psychiatric and social health care researchers and practitioners generally set age 50 as criterion for inclusion in the older offender age group. This is based on evidence that ageing offenders experience poorer health and a quicker ageing process compared to people living in the community, for whom the United Nations set 60 years as criterion for older age (Natarajan and Mulvana, 2017; Cooney and Braggins, 2010). This is therefore also the cut-off we use in this chapter.

Prevalence of crime and type of offending in older people

It is generally accepted that offending peaks in younger age, adolescence, and early adulthood, though the gap between convictions in younger and older people might decrease over time. While most authors (e.g. Yorston, 2013; Natarajan and Mulvana, 2017) report that crime rates in older people appear to be stable over time with people over the age of 60 contributing approximately 1% to overall crime statistics, several countries have reported an increase in both newly convicted older people and older prisoners. For example, the number of prisoners over 60 years old in the Netherlands increased from 60 to 234 in the period 1994–2006 (van Alphen and Oei, 2010).

In England and Wales in 2003, sexual offences, theft and handling stolen goods, and violence (including homicide) were the three largest categories of indictable offences in those aged 60 and over, while among prisoners over 60 years of age nearly 60% were serving their sentence for a sexual offence (Fazel, 2014).

Rates of homicide committed by older people vary and should be interpreted with caution, given that they might be under-reported in certain settings (e.g. assaults between residents in care homes that result in death) (Yorston, 2013). In the UK, where homicide rates are among the lowest worldwide, the Office for National Statistics (ONS) (2018a) reported that in 2006, people over 55 years old were responsible for 26 homicides, accounting for 4% of the total number of homicides in the UK; in 2016, they were responsible for 11 homicides, accounting for 5% of the total. In contrast, in 2016, adults aged 45–54 were responsible for 23 homicides (10% of total); the percentage was even higher in the group 35–44 (50 homicides; 22% of total) (ONS, 2018a).

Compared to younger perpetrators, older individuals more frequently commit homicide against family members, particularly female spouses (Fazel et al., 2007). They are more likely to kill their victims through strangulation/suffocation (Hunt et al., 2010), and they have a higher prevalence of active psychiatric conditions affecting judgment and impulse control, including dementia and affective psychosis (Fazel and Grann, 2002). However, older perpetrators are less likely to be acting under the influence of substances (Hunt et al., 2010). The phenomenon of 'dyadic death' (i.e. suicide occurring after the homicide of the spouse) is

Older people as victims and perpetrators of crime

more common among older than younger offenders (Fazel et al., 2007; Cohen et al., 1998). Motivations often include a fear of not being able to care for the other person any more in the face of illness and frailty, or the view that a disabled spouse may be better off dead.

Within forensic psychiatric settings, homicide is the commonest offence leading to admission (Yorston and Taylor, 2009; Shah, 2006; Lightbody et al., 2010; Coid et al., 2002). In fact, older patients in secure settings (60 years old and above) have an index offence of murder significantly more frequently than younger patients (16–59 years old), the ratio between the two groups being 5.71 (Coid et al., 2002). This might be explained by the fact that those with such offences stay longer and therefore they will eventually be part of the older group.

The ONS reported that in 2017, in 14% of the cases of rape or assault by penetration (including attempts), the offender was 40 years old and above; in 1% of the cases, the offender was 60 years old and over (ONS, 2018b). This figure is aligned with those of other countries. Despite the prosecution and convictions of older sex offenders having increased over time, such crimes might be underreported, because sexuality in old age is still a sensitive topic among many professionals working in hospitals and care homes (Yorston, 2013). Nonetheless, some studies in old age forensic psychiatry reported that sexual offences surpassed homicide as the primary offence leading to admission (Curtice et al., 2003).

The perpetrators of sexual offences are more likely to be male and the victims female (Curtice et al., 2003; Tomar et al., 2005). Compared to younger sex offenders, child sexual abuse was found to be much more prevalent in the older group (Yorston, 2013), but recidivism rates were lower (Fazel et al., 2006b; Barbaree et al., 2003). The sexual offence most likely occurs at home (72%) and in the presence of a psychiatric condition (33%) (Curtice et al., 2003). Hypersexuality and sexual disinhibition, which have a 17% prevalence in neurodegenerative condition such as dementia (Series and Degano, 2005), are also linked to an increased risk for sexual offences.

Acquisitive offences have been reported as among the commonest in older individuals and the most frequent reason for arrest in older people (Yorston, 2013). In a large study on ageing offenders, Needham-Bennett and colleagues (1996) found that theft accounted for 63% of all offences among people aged 60 years old and above, compared to 22% for all types of assaults, 10% for firearm, drug, and public order offences, and 4% for criminal damage. Shoplifting is the most prevalent among the acquisitive offences (58%) (Needham-Bennett et al., 1996). Offenders are as likely to be men as women, most likely to be single, poor, and unemployed, though perhaps surprisingly, people with higher levels of education are also over-represented (Lamontagne et al., 2000).

Older people as victims and perpetrators of crime

Despite the high prevalence, most cases of acquisitive offences are not considered serious enough to be prosecuted and most older offenders (58%) are only cautioned (Needham-Bennett et al., 1996). As a result, less than one in three offenders (28%) were referred to welfare agencies (e.g. for psychiatric evaluation) in one study (Needham-Bennett et al., 1996). Given that engaging in shoplifting has been found to be associated with depression and fulfilment of psychological needs (Lamontagne et al., 2000), failure to offer offenders mental health treatment may result in an exacerbation of their symptoms (Yorston, 2013).

Clinical characteristics of older offenders

Older offenders can be divided into three distinct types (Natarajan and Mulvana, 2017): Those who start offending early and continue into old age, those who committed an offence earlier in their life and remain incarcerated into older age as a result, and those who commit their first offence at an older age. Only limited data is available about the number of offenders in each of these groups, though one US study (Steffensmeier and Motivans, 2000) suggested that, in prison, the second group was the smallest, with each of the other two groups accounting for over two-fifths of prisoners over 55 years.

We report on the prevalence of disorders in prison and secure forensic settings later in this chapter. Here, we briefly outline psychopathological characteristics of particular relevance to older offenders. Psychotic and mood disorders most frequently lead to the involvement of psychiatric services and, depending on the seriousness of the illness, to a transfer from prison to a hospital setting in all age groups.

Cognitive decline is a particularly important issue for older offenders, whether or not it occurs in the context of a formally diagnosed dementia. In addition to impairments in memory, typical of dementia, other symptoms may make the individual more prone to behavioural difficulties, including offending, such as disinhibited behaviour, lack of judgment, and impairment in executive function (e.g. a lack of planning and impulse control). These symptoms may result in reactive (as opposed to planned) aggression (Yorston, 2013). On the other hand, personality disorder symptoms, which may also include impulsivity, are generally regarded to decrease in severity with age, though changes in life circumstances as may occur in older people might lead to an exacerbation of symptoms. While of importance in all ages, an interview with an older person's relative or carer to identify any changes in behaviour is especially crucial.

When assessing and managing risk in the context of these disorders, practitioners need to consider the potential limitations of risk assessment tools, which have been standardized with younger populations. This is particularly so with actuarial risk assessment tools, which predict risk according to percentages of those who go on to reoffend or allocate offenders to high, medium or low risk bands. The presence of cognitive impairment/dementia could both increase (e.g. through an increase in

Older people as victims and perpetrators of crime

impulsivity) and decrease (e.g. through apathy, lack of opportunity) risk (Natarajan and Mulvana, 2017). A detailed, individualized assessment using a structured professional judgment approach, including a formulation of the risks (type and severity of risk, triggers, motivators, inhibitors, protective factors) and their management, is required in each case.

The route to prison and forensic psychiatric services

Although different countries adopt different legal systems and procedures, the general principles around the detention and care of offenders are similar (Edworthy et al., 2016; Salize et al., 2005). Once an individual is charged with an offence, three options are available: acquittal, punishment, or diversion into a treatment setting, including hospital admission (Völlm et al., 2017a). A prerequisite for punishment is criminal responsibility for the offence, the criteria for which may vary across jurisdictions (Völlm et al., 2017a). If criminal responsibility is present, the offender can be sentenced, including to imprisonment.

If not deemed fully responsible for the criminal act, the offender is either acquitted or required to undergo some type of forensic psychiatric treatment (Völlm et al., 2017a). In order for the offender to have access to treatment, in most European countries a degree of reduced responsibility is a prerequisite (Völlm et al., 2017a). There are some exceptions, however, for example, in the UK, where admission to forensic psychiatric care can occur regardless of criminal responsibility and can be ordered based solely on the person's mental condition at the time of assessment (Konrad and Völlm, 2010). In addition, some countries allow transfer from prison to forensic psychiatric settings, if the detainee develops a psychiatric illness which requires specialist care. The mentally disordered offender (MDO) may then later move back to prison, though more frequently, they remain in the treatment setting.

Psychiatric treatment for MDOs can be offered as in-patient services, out-patient (i.e. community) services, or within the prison system. In most jurisdictions, excluding countries such as Italy, Croatia, and Portugal, offenders in in-patient forensic psychiatric units can be detained beyond the length of the prison sentence they would have been given for the same crime, had they not been mentally disordered (Völlm et al., 2016).

However, the majority of mentally disordered offenders are found within the prison system, even in jurisdictions where specialist services exist (Völlm et al., 2017a). Provision equivalent to care in the community is the guiding principle of prison care, as per the United Nations Standard Minimum Rules for the Treatment of Prisoners and the UN Convention on the Rights of Persons with Disabilities. It is questionable, however, to what extent different countries operate in full compliance with the standards prescribed (Gee and Bertrand-Godfrey, 2014).

Older people as victims and perpetrators of crime

In-patient forensic psychiatric services are offered in most countries at different levels of security, based on the risk that the patient poses to themselves or others (Salize et al., 2005), but there are notable exceptions. In Italy, in-patient forensic psychiatric services are offered in residential units at one single (low) level of security (Di Lorito et al., 2017a,c). In addition to a degree of security, other common elements of in-patient forensic psychiatric services are medical, psychological, and social interventions offered by multidisciplinary teams (Tapp et al., 2016).

Out-patient services offered in the community are available in a limited number of countries, including Austria, Belgium, Germany, the Netherlands, the UK, and Poland (Heitzman and Markiewicz, 2017; Sugarman and Oakley, 2012; Salize et al., 2005). These provide treatment to offenders equivalent to that offered to non-offending community citizens, one important difference being that it can have elements which are mandated by the courts (Völlm et al., 2017a).

Issues relating to arrest, interviewing, and trial in older offenders

Several authors have suggested that older offenders were previously dealt with differently by the criminal justice system, in particular that they were less likely to be arrested and charged due to issues around fitness to plead and an assumption that older people pose less of a risk to society compared to younger offenders (Yorston, 2013). However, given the increase in older offenders (as outlined in this chapter), this seems to have changed in recent years. Older people who appear to have a mental health problem affecting their ability to participate in proceedings, like vulnerable younger offenders, should have the right to be accompanied by an 'appropriate adult' when interviewed by the police, to ensure that they understand what is happening to them and why (e.g. Police and Criminal Evidence Act, 1984 for England and Wales).

When standing trial, the first, requirement before criminal responsibility can be considered, is to determine whether the defendant is fit to plead and stand trial (i.e. 'fitness to plead' in the context of UK law or 'competence to stand trial' in US law). This is to ensure that the defendant has a fair trial (i.e. he/she is able to participate effectively in the proceedings). In UK law, as an example, criteria for fitness to plead are (Rogers et al., 2008):

- ability to plead
- ability to understand the evidence
- ability to understand the court proceedings
- ability to instruct a lawyer
- knowing that a juror can be challenged.

Fitness to plead can be affected by both mental and physical abilities. Examples of the former include cognitive functioning or delusional thinking, while sensory impairment can also affect someone's capacity to

Older people as victims and perpetrators of crime

follow proceedings. It is important that arrangements are made to achieve fitness to plead where possible, for example, through adjustments of the proceedings (e.g. shorter sessions) or visual/hearing aids. When fitness to plead is in question, the defendant is likely to be assessed by a psychiatrist, who will be able to comment on possible adjustments. The assessment is the same for older and younger individuals, but issues like cognitive functioning, including memory and executive function, as well as physical impairments, are likely to play a more important role in older defendants.

Ageing Prisoners

Prevalence

Since 2000, the general prison population worldwide has grown by about 6% (Walmsley, 2016). In some countries, such as Spain, offenders are released from prison at age 80 and in Azerbaijan and Russia life sentences cannot be given to people over 65 years old (Penal Reform International, 2015). However, in most countries worldwide the number of ageing prisoners has markedly increased, representing the fastest growing group (Joyce and Maschi, 2015; Davoren et al., 2015; Cornish et al., 2016).

In the period 2000–2010, for instance, the number of ageing inmates in Australia increased by 36% (Baidawi, 2015) and in Canada by 50% (Penal Reform International, 2015). In the period 2002–2011, Japan experienced an increase of around 100%, while in the US, the number of ageing prisoners increased by a record 300% (Williams et al., 2012). In the UK, a 169% increase in the population of prisoners over 50 years old was reported in the period 2002–2016, while the percentage of prisoners below 20 years old decreased from 13% to 6% between 2005 and 2016 (Allen and Watson, 2017).

Ageing prisoners now constitute 10% of the total prison population in Ireland (Joyce and Maschi, 2015), 15% in the UK (Allen and Watson, 2017), 19% in the US (Carson, 2015), and 25% in Italy (ISTAT, 2015). At the end of 2016, the UK prison system even had one prisoner aged over 100 years (Allen and Watson, 2017).

The phenomenon of an increasingly older prison population is caused by several factors (Frazer, 2003). Longer life expectancy and fewer releases by parole boards have reduced the turnover and led to an accumulation of ageing detainees (Senior et al., 2013). Societal attitudes toward ageing offenders have become less lenient. Crimes that were seldom reported to the authorities in the past, such as sexual offences, are now more frequently prosecuted (Frazer, 2003, Yorston, 2015b). Advances in forensic evidence caused a 95% increase between 1995 and 2005 in the charge and incarceration in old age of people who have committed historical offences (RECOOP, 2017). At the same time, in some countries, tougher sentencing policies have been adopted to discourage crime, and

Older people as victims and perpetrators of crime

ageing offenders are receiving life sentences more often than in the past (Frazer, 2003; Moll, 2013).

Psychiatric morbidity

While prisoners of all age groups experience poor mental health (Baldwin and Leete, 2012; Cooney and Braggins, 2010; Moll, 2013), the added challenges of ageing in restrictive settings and the poor physical, mental, and social health care provision may further expose ageing prisoners to deteriorating mental health. Although limited epidemiological research exists, a recent systematic review and meta-analysis synthesizing the existing international evidence found that almost 40% of ageing prisoners experience at least one psychiatric disorder, including depression (28.3%), alcohol abuse (15.9%), and psychoses (5.5%) (Di Lorito et al., 2018b). The prevalence reported in the overall prison population (i.e. all ages), based on 109 studies including 33,588 prisoners in 24 countries, was 11.4% for depression and 3.7% for psychosis (Fazel and Seewald, 2012). In relation to alcohol abuse, an international systematic review based on 13 studies on the overall prison population reported an 18–30% prevalence for male prisoners and a 10–24% prevalence for female prisoners (Fazel et al., 2006a). We can therefore conclude that, compared to prisoners of all ages, in the older prisoners' group depression and psychoses are more prevalent and alcohol abuse is less prevalent.

When comparing data from the older prison population against the prevalence found among ageing people in the community, a greater Relative Risk (RR) was found for most psychiatric disorders, including depression, schizophrenia/psychoses, bipolar disorder, cognitive impairment, personality disorder, anxiety disorders and PTSD (Di Lorito et al., 2018c). The RR was highest for schizophrenia/psychoses, evidencing that ageing prisoners may potentially experience more severe psychiatric conditions (Di Lorito et al., 2018b).

Conversely, the RR was not statistically significantly higher for dementia (Di Lorito et al., 2018b). This may be due to several factors: i) lack of systematic cognitive assessment within the prison system (Moll, 2013); ii) a prison culture oriented towards principles of punishment rather than care, which, in the absence of geriatric training among prison staff, may hinder the identification and diagnosis of the condition (Moll, 2013); and iii) lower incarceration rates or diversion from prison for offenders with dementia (Natarajan and Mulvana, 2017).

Suicide rates are also markedly high among ageing prisoners. Handtke and Wangmo (2014) found that 50% of ageing prisoners engage in suicidal thinking, as they may come to such a level of despair and alienation from life that they view death as the only possible escape from their misery. Although younger age has been identified as a risk factor for self-harm in the general population (Hawton et al., 2014), a large UK

Older people as victims and perpetrators of crime

study reported that 'only' 30% of male prisoners aged 16–20 years old had engaged in suicidal thoughts in the previous year (Lader et al., 2000).

The challenges of ageing in prison

A recent systematic review of 25 international studies around the individual experience of ageing prisoners (Di Lorito et al., 2018c) reported that despite emerging examples of good practice, the inadequacy of the prison system to respond to the unique physical and social health care needs of ageing prisoners has a detrimental impact on their overall experience of imprisonment (Aday, 1994; Lemieux et al., 2002; Smyer et al., 1997). In the UK context, these findings confirmed previous evidence gathered by the prison inspectorate (HM Inspectorate of Prisons, 2013). This report commented that, although prison services are becoming a key accommodation and care provider for ageing offenders, little emphasis is placed on the rehabilitation and needs of this population (HM Inspectorate of Prisons, 2013).

Currently, most prison institutions across the world are affected by common barriers that hinder care provision. Among these is what has been defined by Crawley (2005) 'institutional thoughtlessness', the widespread neglect of mental and social care health needs of ageing prisoners. Institutional thoughtlessness is partly explained in terms of untrained prison staff. Although some initiatives, such as the Community Ageing Health Project in the US, have delivered geriatric training to all professionals working in the justice system (Ahalt and Williams, 2015), most prison staff are unable to appreciate the difficulties that the prison regime presents to ageing prisoners or, if they do acknowledge the problems, they may feel powerless to act.

The neglect of ageing prisoners' needs is further caused by a macho prison culture, which views care duties as feminine and makes staff reluctant to undertake them (Moll, 2013). In addition, compared to the younger inmates, who are often more assertive self-advocates, ageing prisoners appear more reserved and often reluctant to disclose their needs, which may therefore pass unnoticed (Doron, 2007).

Further challenges are presented by declining physical health. Ageing prisoners have been evidenced to present with greater mobility needs compared to both younger prisoners and ageing individuals in the community, and more than 80% suffer from chronic conditions or disability (Natarajan and Mulvana, 2017). Prison institutions do not seem able to respond adequately to the ageing prisoners' accessibility needs, often providing inaccessible prison cells and bathrooms, narrow doors, and key facilities (i.e. healthcare offices) located on the upper floors of century-old buildings (Senior et al., 2013; Crawley, 2005; Joyce and Maschi, 2015). This is in contravention of the UK Disability Discrimination Act 2005.

Older people as victims and perpetrators of crime

Some examples of good practice, however, are emerging. For example, Her Majesty's Prison (HMP) in Norwich in the UK offers an in-patient healthcare facility for ageing prisoners, and HMPs Frankland, Kingston, and Whymott have dedicated wings for ageing prisoners (Natarajan and Mulvana, 2017). In the US, specialist services for ageing prisoners are common, including the creation of specialized units or wards for people living with dementia or the implementation of peer-support programmes to promote the inclusion and independence of prisoners in need (Moll, 2013). However, much remains to be done for current prison services to be considered dementia-friendly (Joyce and Maschi, 2015).

In relation to the activities offered in the prison system, Senior and colleagues (2013) reported that, in England and Wales, only half of the recreational programmes were suitable for ageing prisoners, while 67% were not accessible for anyone with mobility issues. Because of these barriers to taking part in activities, ageing prisoners may become reluctant to venture out of their cells and in turn develop feelings of social isolation and disengagement, which may have a negative impact on their process of rehabilitation (Crawley, 2005). The frequent loss of family contact experienced by ageing prisoners, and the death of partners or spouses, only add to the risk of alienation from life (Moll, 2013; Crawley, 2005).

The process of release into the community may also be more problematic for older prisoners. One study found that 50% of ageing ex-prisoners ended up homeless and destitute (Senior et al., 2013; Joyce and Maschi, 2015), compared to 30% for the overall (i.e. all ages) prisoner population (Niven and Stewart, 2005). The lack of systematic pre-release courses tailored to the unique needs of ageing prisoners and the poor liaison between prisons, probation services and offender managers often leave them unprepared to face the challenges of life in the community (Senior et al., 2013).

Ageing forensic psychiatric patients

Ageing forensic psychiatric patients represent a minority of the patients living in secure institutions. Nonetheless, as for ageing prisoners, given the recent changes in cultural attitudes toward ageing offenders (Yorston, 2015b; Frazer, 2003), the ageing trends in the population (Senior et al., 2013) and a tougher approach to crime (HM Inspectorate of Prisons, 2008), their number is on the rise.

In a UK study carried out over 20 years ago at Broadmoor Hospital (one of the three UK high-security services), 8% of patients were aged 60 years old and above (Wong et al., 1995). At the present time, in Rampton Hospital (another UK high-security service), one patient in five falls within this age category (Di Lorito, et al., 2019b). This trend, however, is not specific to the UK context, as similar prevalence rates have been reported elsewhere. In Italy, for example, in a single-site case study on ageing forensic psychiatric patients, Di Lorito and colleagues (2017b)

Older people as victims and perpetrators of crime

reported that 20% of the patients were over the age of 50. In Germany, 20% of all patients in forensic-psychiatric hospitals and substance misuse units (in Germany different sections apply to those with offending related to substance misuse) are over 50 years old (Dönisch-Seidel, personal communication).

Despite this increasing prevalence, research around older forensic psychiatric patients remains scant.

Demographic data

Available data suggest that in terms of gender composition, the overwhelming majority of older patients in secure care—at least 85%—are males. In our study at Rampton Hospital, one of the three high security units in the UK, 89% of the patients were male, a male to female ratio of over 8:1 (Di Lorito et al., 2019b). This is not greatly different from younger patients: Coid and colleagues (2002) found that around 85% of patients aged below 60 years old in secure settings were male.

In relation to marital status, a significantly smaller percentage of patients over 60 years old were single (31%), compared to patients under 60 years old (73%) (Coid et al., 2002). In relation to ethnic composition, white patients were found to be most prevalent, making up to 100% of the sample in the UK studies (Curtice et al., 2003; Lightbody et al., 2010; Yorston and Taylor, 2009). The proportion of white ethnicity was higher among older patients (88%) than younger patients (75%) (Coid et al., 2002).

Contact with services

Older patients typically have long admissions, ranging from an average of 14 years (Lightbody et al., 2010) to 26 years (Shah, 2006). This is longer than for either prisoners sentenced for the same offence or for patients in general psychiatric services with a similar mental disorder (Völlm et al., 2016). A recent study on long-term patients in medium and high-security hospitals found a positive correlation between age and length of stay (Völlm et al., 2017b).

Coid and colleagues (2002) reported that 11% of 61 patients over 60 years old in medium and high secure forensic psychiatry services in the UK over a seven-year period were admitted following non-criminalized behavioural disorder, compared to 28% of younger patients. The same authors found a statistically significant lower percentage of older patients admitted to high security (3%), compared with the younger patients (15%) (Coid et al., 2002).

The majority of older patients (65%) had previous psychiatric admission (Paradis et al., 2000; Lightbody et al., 2010), whose number averaged two (range 0–10) (Yorston and Taylor, 2009). However, previous psychiatric admission of older offenders was significantly lower than younger offenders according to Coid and colleagues (2002), who also found that

Older people as victims and perpetrators of crime

23% of older patients had been in prison, a lower percentage than among the younger offenders. Prison transfers amounted to up to 60% in a UK study on long-stay patients (Völlm et al., 2016).

Mental health

Yorston and Taylor (2009) found that 36% of patients over 60 years old in a UK high-secure service had schizophrenia, 27% delusional disorder, and 9% schizoaffective disorder. High prevalence of psychotic illness was also found in a retrospective study of older patients residing in secure psychiatric settings in Scotland between 1998 and 2007, with an aggregated prevalence of 64% for schizophrenia, schizotypal and delusional disorders (Lightbody et al., 2010). However, Coid and colleagues (2002) found that the prevalence of schizophrenia was significantly lower in older patients (33%), compared to younger patients (58%). Conversely, the older patients had a significantly higher prevalence of delusional disorder.

Personality disorder was found to be the most prevalent psychiatric disorder among older patients in a cross sectional study carried out in three secure settings in the UK (61%) (Di Lorito et al., 2019b). The older patients had significantly higher prevalence of schizoid personality disorder, as opposed to the younger patients, who were more frequently diagnosed with antisocial and borderline personality disorder (Coid et al., 2002). Lifetime prevalence of depression was 42% for older patients, compared to 18% for younger patients, the difference being statistically significant (Coid et al., 2002). The difference may indicate that the added challenges of ageing in secure settings may expose the older patients to being vulnerable to psychiatric disorder.

Paradis and colleagues (2000) found that 33% of the older patients were affected by some type of dementia (2% with Alzheimer's disease). Similar findings were reported by Shah (2006), who found a dementia prevalence of 27%. One study reported a prevalence of below 10% (Tomar et al., 2005). Organic brain syndrome was statistically significantly more prevalent in the older patients (33%) compared to the younger ones (12%) (Coid et al., 2002). However, only a small percentage (less than 20%) of older patients had undergone any formal cognitive testing (Curtice et al., 2003; Lightbody et al., 2010). Thus, the rates reported could underestimate the extent of the problem. Regardless, the higher rates of dementia in forensic secure settings compared to the prison system might indicate that diversion into psychiatric care might be more appropriate for this patient group.

A formal diagnosis of alcohol abuse appears to be relatively uncommon, around 3% to 6% of older patients (Curtice et al., 2003; Paradis et al., 2000). However, the rates were much higher if regular consumption was considered (41%) (Curtice et al., 2003). Coid and colleagues (2002) found no significant differences compared to the younger patients, and the prevalence of drug abuse and dependence among older patients was

Older people as victims and perpetrators of crime

much lower than among younger patients (0% and 52%, respectively, though these figures are likely to have changed since the time of that study).

Physical health

Forensic psychiatric patients of all ages experience poorer physical health and have a shorter life expectancy (10–20 years less) compared to people living in the community (Davies, 2013). In addition, older patients may be affected by age-related conditions, which exacerbate their overall physical wellbeing.

Curtice and colleagues (2003) found that 44% of older patients had one health problem and 16% had two or more. On average, each patient had one to two diagnoses of physical illness upon admission, which increased to more than two upon discharge (Shah, 2006; Lightbody et al., 2010). Mobility problems were prevalent, affecting up to 61% of the ageing patients in one study (Lightbody et al., 2010). One-fifth of the sample suffered from sensory impairment, including hearing (16%) and eyesight problems (6%) (Curtice et al., 2003). Cardiac disease, hypertension, and diabetes were also widespread, with a prevalence of 23%, 15%, and 13%, respectively (Paradis et al., 2000).

Qualitative studies

Very limited data exist around the individual experience of ageing patients in forensic settings at the international level. One common theme emerging from studies carried out in the UK and Italy (Yorston and Taylor, 2009; Di Lorito et al., 2017b, 2018a) is the challenges of life in confinement and how the limitations to freedom have a negative impact on the experience of ageing patients. For example, patients complain about the rigidity of policies around gender separation, which do not reflect the reality of life in the community and are therefore believed to hinder successful reintegration into life outside the institution (Yorston and Taylor, 2009; Di Lorito et al., 2017 b, 2018a).

Given the challenges of life in secure settings, ageing patients adopt a variety of coping mechanisms, the most reported of which is relying on strong support networks (Yorston and Taylor, 2009; Di Lorito et al., 2018a). In this sense, the clinical team on the ward plays a central role in promoting the emotional wellbeing of the patients, given the extended time they spend with them on a daily basis (Dutta et al., 2016). In fact, several patients reported how, in times of difficulty, they preferred to talk to the staff on the ward (e.g. nurses), rather than wait for psychology consultation (Yorston and Taylor, 2009). Older patients generally appreciated the effort of the members of staff on the ward to go beyond traditional work duties and develop genuine relationships with them, which enhances both clinical rapport and the therapeutic journey of the patients (Di Lorito et al., 2018a, 2019a).

Older people as victims and perpetrators of crime

Peers may also represent a source of support. Although most patients reported having a special friend or a small group of friends to confide in, they acknowledged that the common mental health symptoms may hinder good rapport at times (Di Lorito et al., 2017b). Similar mixed feelings apply to their relationships with younger patients. While several older patients appreciated the balance and diversity of mixed (i.e. younger and ageing) wards, others reported irreconcilable differences and called for the creation of separate wards for ageing patients (Di Lorito et al., 2017b). Another argument in support of the creation of aging patients' wards is related to the unique care needs of this population, treatment and security, and the barriers to addressing these in mixed ward environments. For example, some occupational therapists raised concerns about fitting handrails to aid ageing patients' mobility, as they thought these would present security issues for the younger patients (Yorston and Taylor, 2009).

In relation to personal resources to deal with the difficulties of life in confinement, older patients frequently reported a strong sense of spirituality, which provides them with inner peace and comfort (Di Lorito et al., 2017b). This was in contrast to younger patients, who may be reluctant to voice a religious dimension to their life. In order to find the emotional strength to deal with their present difficulties, older patients also resort to positive thinking, by recalling happy memories or imagining a future life outside the institution (Di Lorito et al., 2017b, 2018a).

Ageing patients also emphasized the importance of getting off the ward to boost their recovery. Although the existing programmes of vocational, educational, and cultural activities were generally found to be satisfactory, some patients wished to be more involved in the development and design of age-friendly activities (Di Lorito et al., 2017b, 2018a; Yorston and Taylor, 2009). Pressures on budgets and staffing levels, experienced by most forensic psychiatric systems worldwide, are therefore likely to be a significant barrier to improved services for older patients. Issues of security may also represent a challenge to implementing recovery-oriented activities in more restrictive settings.

Discharge from the service is also a challenge for the mental wellbeing of older patients, many of whom have spent a long time in the service. Several patients reported developing emotional attachment to the institution, and anxiety at the uncertainty of future prospects (Yorston and Taylor, 2009). This may be particularly so in legal systems, such as the UK, where some patients may be transferred back to prison after their discharge from the mental health service. These challenges may be difficult to overcome and require extra effort on the part of the multidisciplinary team to encourage the patients to move along their pathway (Yorston and Taylor, 2009). Therefore, older patients who have been in the service for a long time need careful attention and tailored individual discharge plans (Yorston and Taylor, 2009).

Older people as victims and perpetrators of crime

Conclusion

The United Nations has identified ageing offenders as a special need population, owing to their unique physical, mental health and social care needs (Atabay, 2009). This requires the development of adequate strategies to ensure improvement of forensic service provision for this population.

One option that could address the unique needs of older offenders is the development or further implementation of services specifically catering for older offenders, both within the prison system and in the forensic psychiatric sector (Tomar et al., 2005; Nnatu et al., 2005). Some argue that separate services for older offenders are not ethically acceptable, as these may cause segregation and have unsustainable costs; they advocate in favour of mixed-age services, which may have added benefits (e.g. a calming effect of older individuals on younger ones, locality rather than distance of services from home area) (Di Lorito, et al., 2019a). Others instead emphasize the benefits of specialist care provided by adequately trained professionals and view dedicated services as safer environments, with reduced risk for bullying and victimization (Natarajan and Mulvana, 2017). Super-specialization of forensic services with minority populations, such as women, people with learning disabilities, and deaf people, has so far proved effective in boosting service users' experience, and represents a further argument in favour of dedicated services for older offenders (Natarajan and Mulvana, 2017). Furthermore, these services might offer end-of-life and palliative care to address the intensive care needs of offenders with progressive conditions, who cannot be released in the community on compassionate grounds, given their risk.

In the ongoing debate around specialist care provision, some implications for service improvement in the current mixed-age units can be derived. In order to boost opportunities for recovery of older offenders, services should further develop: i) specialist expertise through staff training; ii) age-relevant treatment and activities; and iii) age-friendly environments. Expertise in forensic mental health and in geriatric issues are a key requirement for staff dealing with older offenders (Natarajan and Mulvana, 2017). Sensitizing all members of the multidisciplinary team to age-related needs requires a change of culture, with a greater balance between duties of restrictiveness and care. The emphasis on rehabilitation through care is typical of strength-based frameworks such as the Good Lives Model (Chu and Ward, 2015; Robertson et al., 2011) and the Recovery model (Drennan et al., 2014), which are recommended across all forensic settings. Forensic services need to offer treatment and activities which better respond to the unique rehabilitation/recovery needs of older offenders, such as Cognitive Stimulation Therapy (CST), reminiscing, speech and language therapy, physiotherapy, and mobility work (Di Lorito, et al., 2019a; Natarajan and Mulvana, 2017). Finally, to promote independence in the presence of deteriorating physical and mental abilities, modifications to the environment and the daily routine may be necessary. These include orientation aids/cues to facilitate

Older people as victims and perpetrators of crime

navigation within the premises, more frequent daily planning meetings, and special furniture (e.g. shower chairs, handrails) (Natarajan and Mulvana, 2017).

Service improvement should be supported/informed by dedicated policy on older offenders, which has only been developed in few countries thus far. In Ireland, for example, the Prison Service Strategic Plan 2016–2018 includes the development and implementation of the first national strategy on older prisoners (Joyce and Maschi, 2015). In other countries, standards of health care provision for ageing offenders are aligned to principles and guidelines established in international human rights documents, such as Article 3 of the European Convention of Human Rights (ECHR), or based on general national policies. In the UK, equality in the treatment and care of ageing offenders is granted through the National Institute for Health and Care Excellence (NICE) guidelines on mental wellbeing and independence in ageing people (NICE, 2015) and the Care Act 2015. The latter document, for example, establishes the responsibility for local authorities to provide equal social health care to all older individuals.

In the absence of dedicated strategies, however, these general policies do not seem sufficient to ensure consistent levels of quality in service provision across different institutions. At present, the existing examples of good practice are largely dependent on the commitment of individual institutions and the enthusiasm of staff (Yorston, 2015a). In order to ensure uniformity in quality standards and promote good practice, accumulating evidence suggests that policy makers should take initiative at the governmental level and develop specific national strategies to address the unique needs of older offenders.

Driving and psychiatric illness in later life

Chapter: Driving and psychiatric illness in later life

Author(s): Desmond O'Neill and Mark J. Rapoport

DOI: 10.1093/med/9780198807292.003.0057

Overview of mobility and health

Mobility and driving evoke a curious response in health care personnel. With most areas of function, we assess and treat people so as to maximize that function. The literature on driving and disease, however, has until recently been biased in favour of the identification of those who should not drive, rather than maximizing health and function so that older people can participate and integrate maximally with society (O'Neill et al., 2011). This matter assumes great importance in view of the dramatic rise in the proportion of older people in our society. It is further emphasized by the enormous increase in the numbers of older people who wish to continue driving, given the changing age demographic and increased access to the motor vehicle. In the United States (US), at successive White House Conferences on Aging, transportation has been rated as enormously important in older people's lives, even prioritized over Medicare and Medicaid (Carp et al., 1980; White House Conference on Aging, 2005).

Driving and psychiatric illness in later life

This is backed up by the finding that problems with transportation form a major barrier to healthcare access (Okoro et al., 2005; Syed et al., 2013).

Some of the negative attitude to older drivers stems from a more widespread failure to appreciate the idiosyncratic and often paradoxical approach of our society to mobility and safety. Despite high-profile campaigns to promote safety on our roads by way of exhortations to reduce speed and avoid alcohol, at virtually every level of transport policy, mobility takes priority over safety. If safety were paramount, the speed limit would be 20 miles per hour and governors would be fitted to car engines prevent this speed limit from being breached. It is also likely that we would have a more graduated entry to driving while in the late teens or early twenties (Masten et al., 2011). This is because youth and inexperience breed risky driving behaviours that cause crashes. In contrast to the emphasis on mobility over safety for youth, there is an unfortunate emphasis of many governments on stigmatizing older drivers, emphasizing safety over mobility, in the absence of evidence (White and O'Neill, 2000; Mitchell, 2008). Older drivers are forced to undergo regular medical checks in most countries of the European Union, despite evidence that this practice is harmful (Hakamies-Blomqvist et al., 1996; Langford et al., 2004) or ineffective (Rock 1998). This ageist legislation is not based on any factual evidence and reflects the weakness of organized advocacy for older people. This is despite the fact that older drivers have one of the best safety records of any group of drivers in society (Evans, 1988).

Sometimes a U-shaped curve is displayed showing that older drivers have a higher crash risk per mile than younger drivers do (Broughton, 1988). This is spurious for several reasons. Not only do older drivers drive considerably fewer miles than their younger peers, but several studies have shown that this finding is an artefact of low mileage, possibly as a result of higher proportion of trips on non-freeway (or non-divided-lane) roads—if low mileage is controlled for in comparisons with younger drivers, the difference in crash rate disappears (Hakamies-Blomqvist et al., 2002; Langford et al., 2006, 2013). In addition, the crash risk in all other actuarial settings is per year, rather than on distance travelled. Finally, old people are more fragile and are more likely to suffer death or serious injury for a given severity of crash than young people are (Brorsson, 1989; Lyman et al., 2002).

Health and driving

There is a famous illustration in Goodman and Gilman's pharmacology textbook that illustrates the process of absorbing a new medication into medical practice. This oscillates from an initial enthusiastic acceptance to a sceptical rejection, and then finally there is a reasoned assessment of the positive and negative aspects of the drug (Fig. 57.1). This is a similar process to that which occurs when healthcare professionals encounter the concept of driving and illness for the first time. At the outset, working in an environment where a highly selected population are much more

Driving and psychiatric illness in later life

likely to have a high burden of disease, it is inevitable that the potential risks should be perceived first rather than the impact on mobility of driving cessation (O'Neill et al., 1992). As the researchers in the area gain perspective, a totally different concept comes to the fore—that of the major threat posed to the mobility of older people by age-related disease (Metz, 2000). Finally, the fusion of both points of view is achieved, whereby an enabling process is developed which encompasses the mechanisms for helping those who can no longer drive to seek alternative methods of transport, secure in the knowledge that they had due process in a thorough evaluation and remediation (O'Neill, 2000). In a welcome development for the new millennium, this more balanced approach has been adopted by the Organization for Economic Cooperation and Development (OECD, 2001), the European Conference of Ministers of Transport (CEMT, 2001), the US Transportation Research Board (2004), and Transport Canada (Road Safety Canada Consulting, 2011).

Fig. 57.1
Oscillations in the development of a drug.

Driving is a health-related issue: there is a consistent pattern in many countries around the world of driving cessation relating to illness and loss of function (Campbell et al., 1993; Forrest et al., 1997; Kostyniuk et al., 1998), although driving may persist after other socially useful patterns of mobility have been affected (Hjorthol, 2001). This pattern is reflected in several studies of dementia and driving (Foley et al., 2000). Older people tend not to discuss concerns about driving with healthcare providers (Johnson, 1998): this is a cause of concern as it is possible that remediable medical causes of driving cessation may not be addressed. Lack of access to transportation, and in particular, to driving, is associated with reduced social integration (Mezuk and Rebok, 2008), reduced access to health care (Wallace et al., 2006) as well as earlier

Driving and psychiatric illness in later life

admission to nursing home care, mortality, and a doubling of depressive symptoms (Marottoli et al., 1997; Chihuri et al., 2016).

Skills and resources needed for assessment of driving

Many professionals working in the psychiatry of old age feel at a loss when confronted with older people who both have psychiatric illness and drive a car. They often do not realize that their many skills used in clinical decision-making also form the basis of making decisions on driving and mobility. These skills are founded in multidisciplinary assessment, and an enabling philosophy and advocacy for older people in the face of nihilism and ageism. In practice, the same skills are seen in the integration of clinical assessment and input from the multidisciplinary team in the calculation of risk in other areas of clinical practice such as deciding on discharge to home from hospital. Elements of the decision-making process for hospital discharge include careful multidisciplinary evaluation, discussion with carers, and perhaps a trial visit home. The elements of that process are very similar to the assessment of fitness to drive. Not only may relatives place security before independence, but as with hospital discharge planning, an approach based on psychometric/cognitive testing is not likely to be helpful. This often surprises clinicians; while psychometric support is important in backing up our diagnostic abilities, it is rarely of help when making decisions about function. For example, the decision that the patient is no longer fit to remain at home and requires placement in a nursing home is much more likely to be taken on the basis of measures of function and behaviour than on psychometric measures.

The premise that the expertise of those who practice psychiatry with older people already contains some of the elements necessary for mobility assessments is not a charter for dilettantism. Rather, it is a challenge to us to develop the extra resources required to ensure that we have adequate support when making decisions about enhancing the safe mobility of older people. This has many parallels with the task of assessing safety at home or capacity to manage financial affairs: in these cases, it is good practice to liaise with an occupational therapist or a neuropsychologist. There has also been a failure to capitalize on the rich level of knowledge of psychiatrists: many of the studies of their practice have been more concerned to highlight their lack of knowledge of the driving regulations rather than to draw on their collected wisdom (Elwood, 1998; Menard et al., 2006; Orr and Elworthy, 2008; Curwen and Jebreel, 2012). It is likely that their estimates of the parameters of safe mobility in their patient groups would have equal, if not greater, validity than current driving regulations restricting driving in psychiatric populations—regulations which are often arbitrary and sometimes counterintuitive and unfair. A helpful addition to this knowledge base is provided by a paper examining the perceptions of psychiatrists and occupational physicians on the minimum period of driving cessation for drivers with psychiatric illness and alcohol dependence (Ryan et al., 2017). That manuscript indicated not only variability in the time

Driving and psychiatric illness in later life

considered appropriate, but also a tendency to shorter periods off the road than specified in the national guidelines.

At a minimum, the assessment of the impact of psychiatric illness on mobility in later life requires a careful medical and psychiatric assessment, and an informant history (Briggs and O'Neill, 2016). Access to occupational therapy and/or neuropsychology as well as access to a specialist driver assessment is often critical to these assessments, although there are challenges with access and cost (Rapoport et al., 2007; Vrkljan et al., 2013). Given that patients may have medical and psychiatric morbidity, guides for assessing older drivers and those with medical illness have been produced in various countries (Carr et al., 2010; Austroads and National Transport Commission, 2017; Drivers Medical Group/Driver and Vehicle Licensing Agency 2012; Canadian Medical Association, 2017).

There may be a case for developing driver assessment services at a regional level, particularly for those cases where decision-making is not clear after the first assessment. A specific concern relates to the funding of such services. For example, although the mobility/risk problem is clearly health-related in origin, Medicare in the US and Canada will not refund specialist driving assessment and the attendant cost may deter older drivers from seeking help. Similar self-funding challenges exist in other countries with greater or lesser degree of governmental subsidy. The psychiatrist will also need to know the local regulations on fitness to drive and older driver screening, on the obligations of the patient to disclose relevant illnesses to the driver licencing authority and insurance company, and an awareness of the local requirements for physician disclosure, if any.

Assessment of driving behaviour

A model of driving behaviour

Driving is an over-learned skill with a significant behavioural component (Ranney, 1994). The most major advance in this area has been the understanding that a purely cognitive model of driving ability does not adequately reflect the complexity and hierarchical nature of the driving task. We also know that clinicians working with a range of diseases, including dementia, may not accurately predict test road testing ability of drivers (Heikkila et al., 1998; Brown, et al., 2005a; Ranchet et al., 2016a,b). Driver behaviour is complex and one of the simplest and most easily applicable models has been the hierarchy of Michon, which uses strategic, tactical, and operational factors (Michon, 1985). Examples of these levels include: at the strategic level, the choice of whether or not to travel; the tactical decision, e.g. whether or not to overtake; and the operational level, e.g. deciding what to do when overtaking and faced with an oncoming car. Factors at all three of these levels can pose hazards to road safety when impairment exists.

Advice to patient/carer ± driver licensing authority

If driving too hazardous, consider alternative mobility strategies

Not all levels of assessment will be required by all patients: a patient with a homonymous hemianopia is barred from driving throughout the European Union and in most of North America (Carr et al., 2010; Canadian Council of Motor Transport Administrators, 2013), and active planning of alternative transportation is appropriate, including referral to

Driving and psychiatric illness in later life

a social worker, if available. Equally, a mild cognitive deficit may only require a review by the physician and occupational therapist. The overall interdisciplinary assessment should attempt to provide solutions to both maintaining activities and exploring transport needs. An on-road test may be helpful in more than just the obvious ways: for example, it may demonstrate deficits to a patient or a carer who is ambivalent about the patient stopping driving. At a therapeutic level, members of the team may be able to help the patient come to terms with the losses associated with stopping driving. The occupational therapist may be able to maximize the patient's activities and function and help focus on preserved areas of achievement, while the social worker can advise on alternative methods of transport. This team approach to assessment should save time and offer efficiencies in the assessment process and associated costs for occupational therapy, neuropsychology, and road driver assessors.

Informant history

In addition to the usual work-up, the medical assessment should include a driving history from patient and carer (Iverson et al., 2010). Such informant history may be useful (Brown et al., 2005), especially given clear evidence of the collaborative nature of the driving task among those older people who drive with a regular partner (Vrkljan and Polgar, 2007). Asking about recent crashes is useful, as this can also be supportive information in terms of increased risk, whether through pre-morbid 'risky' behaviour (Fuller, 1992) or the effects of age-related disease (Daigneault et al., 2002). Caregiver concern about driving ability, in particular, is a challenging area for clinicians. A history of recent crashes has been recommended as an important consideration and marker for the need for driving, but the absence of any recent collisions is considered less predictive or helpful (Iverson et al., 2010). Caregiver concerns were associated with road-test outcomes in two recent studies of cognitively impaired drivers (Bixby et al., 2015; Hemmy et al., 2016). However, in one of those studies the caregiver concerns were only correlated with on-road and naturalistic driving outcomes when the caregiver was an adult child (mostly female in that study), but when the caregiver was a spouse (mostly male), better ratings of driving ability were counter-intuitively associated with worse driving performance (Bixby et al., 2015).

Cognitive screening tests

The relatively poor clinical utility of cognitive scales in determining fitness to drive (Molnar et al., 2006a) relates to their lack of congruity to current models of driving behaviour and capabilities (Fuller, 2005). This does not mean that cognition should not be assessed, but rather that such measures should be integrated with other factors in the comprehensive assessment, including an assessment of insight/anosognosia, judgment skills, and strategic thinking. The Mini-Mental State Examination (MMSE) (Folstein et al., 1975) was one of the first simple screening measures of cognitive impairment reviewed in terms of driving and dementia and illustrates the challenge of over-reliance on such instruments. A

Driving and psychiatric illness in later life

attempted consensus exercise suggested that those who score 17 or less on MMSE require further assessment in a formal way (Lundberg et al., 1997). The choice of cut-off at a relatively low score reflected unease among the participants that reliance on a simple test such as the MMSE would over-simplify the complex task of appropriate assessment of older people with dementia.

The next stage of testing described in the literature has been performed mainly by occupational therapists and neuropsychologists. None of the studies has been sufficiently large to have a reasonable predictive value or to determine cut-off points on neuropsychological test batteries. This situation is parallel to that in memory clinics where there is a wide variation in the test batteries used. It is likely that the important elements of successful assessment that assist in discriminating safe from unsafe drivers are the choice of key domains, familiarity with a test battery, and the development of an understanding and close liaison between the physician and the occupational therapist and/or neuropsychologist.

Specific tests which show some degree of correlation with driving ability in more than one study (Mathias and Lucas, 2009) include the MMSE, the Trail Making Test (Maag, 1984; Janke and Eberhard, 1998; Mazer et al., 1998; Stutts, 1998); and a range of tests of visual attention (Klavora et al., 1995; Duchek et al., 1998; Marottoli et al., 1998; Owsley et al., 1998; Trobe, 1998), including the Useful Field of View®, (a composite measure of pre-attentive processing, incorporating speed of visual information processing, ability to ignore distractors (selective attention) and ability to divide attention; Ball et al., 1991), and the Driving Scenes Test of the Neuropsychological Assessment Battery (Brown et al., 2005b). Several other tests have been assessed in single studies, including traffic sign recognition (Carr et al., 1991).

Overall, numerous detailed neuropsychological tests have been correlated with driving behaviour but few are sufficiently robust to calculate cut-off points for risky driving (Molnar et al., 2006a; Hird et al., 2016). More recent studies of other frequently used cognitive screening instruments, the Montreal Cognitive Assessment (MoCA) and the Clock Drawing Test to be only modestly predictive of on-road performance in samples of older adults (Manning et al., 2014; Hollis et al., 2015). All of these tests can be criticized for taking an overcognitive view of the driving task, an excessively circumscribed concept of the breadth of cognitive function and a failure to incorporate the cognitive gains of later life in tandem with the losses (O'Neill, 2012). Reviews of this topic are available from the US National Highway Transportation Safety Administration (Staplin et al., 1999) and elsewhere (Reger et al., 2004; Molnar et al., 2006a; Bennett et al., 2016; Hird et al., 2016).

In conjunction with the clinical assessment and collateral history, these tests will help to decide which patients require on-road testing, as well as those who are likely to be too dangerous to test on-road.

Driving and psychiatric illness in later life

Role of on-road testing

On-road driver testing is generally considered the gold standard and should be offered to all patients in whom there is uncertainty about driving skills, as long as they are not clearly dangerous when driving and not disqualified from driving for other reasons, e.g. homonymous hemianopia or convulsions. At least three different road tests have been tested empirically, but the sample sizes of the studies have been relatively small (Fitten et al., 1995; Hunt et al., 1997; Dobbs et al., 1998). Furthermore, although one study reported a fairly acceptable one-month test-retest reliability of 0.76 for one of these road tests (Hunt et al., 1997), other data on reliability of these tests are lacking for this supposedly gold-standard. From the point of view of external and predictive validity, many driving errors on these tests may represent normative changes with age (Selander et al., 2011), and data is lacking correlating on-road test with actual driving, because of ethical limitations of allowing those who fail to continue driving.

Dementia

Our recent systematic review of studies published from 2005 to 2015 found only two studies comparing motor vehicle crashes (MVCs) in patients with dementia to a healthy comparison group without dementia (Chee et al., 2017). One study showed that drivers with a diagnosis of dementia had more than a fourfold increase in risk of collisions per 1,000 miles driven in their retrospective analysis at baseline, but during the three-year prospective study period 11% of normal controls had a collision compared to only 1% of drivers with dementia—a difference that was not, however, statistically significant when corrected for the number of miles actually driven (Ott et al., 2008). The other study identified showed no statistically significant increase in MVCs over the same time span (Davis et al., 2012). A prior systematic review incorporating studies published from 1996 to 2006 found that all three identified retrospective studies using informant-reported collision risk consistently found greater collision risks among patients with dementia than controls, but studies were much more variable when considering only official state-recorded collisions—only one of three of these studies was positive (Man-Son-Hing et al., 2007).

In contrast, our more recent systematic review (Chee et al., 2017) found robust medium to large effects of dementia on driving abilities in six of the seven identified studies that examined driving impairment comparing with healthy controls. Furthermore, in that review, a meta-analysis of four identified studies, those with dementia were much more likely to fail a road test than healthy controls (RR 10.77, 95% CI 3.00–38.62, $z = 3.65$, $p < 0.001$). Thus, determining the risk of collisions in people with cognitive impairment or dementia remains elusive, largely because of challenges in recruiting patients for such studies and of measuring exposure to driving. The very limited body of literature, mostly based on proxy reporting,

Driving and psychiatric illness in later life

shows conflicting results, in contrast to compelling and consistent evidence of deterioration in driving skills.

Even though there are difficulties establishing an increased risk of collision specifically associated with dementia relative to controls without dementia, at a population level such events are not rare in the community. In a cohort of 210,550 patients with dementia observed from 1997 to 2005 in Ontario, Canada, 40,508 (19.2%) had active driver's licenses (Rapoport et al., 2008). Of those with active licenses, almost one-quarter (24.1%) were involved in a collision, and in the vast majority (77.9%) of these, the crashes occurred before the diagnosis of dementia (defined in that particular study by a prescription for a cholinesterase inhibitor). In that sample, the patients had been deemed at fault for more than half of the collisions, and personal injury occurred in almost a quarter of cases. When patients with dementia drive, they continue to do so for a long time (Herrmann et al., 2006), even while their driving deteriorates (Duchek et al., 2003), potentially posing concerns for safety over time. However, drivers in Quebec who were registered as affected by dementia had a lower crash rate than the population average (Dow et al., 2013).

The Canadian Medical Association Driver's Guide suggest a trichotomized approach, based on opinion and heuristics, rather than evidence (Canadian Medical Association, 2017). The physician is asked to consider the answer to four questions based on the results of their assessment:

1. Would I get into a car with the patient driving?
2. Would I let a loved one get into a car with the patient driving?
3. Would I want to be crossing the street in front of a car with the patient driving?
4. Would I want to have a loved one cross the street in front of a car with the patient driving?

For each question, three answers are possible: 'yes' (meaning there are no concerns that would trigger further testing), 'uncertain' (meaning that more tests are required), and 'no' (meaning that the risk is clear and too high). This approach can be critiqued for potential bias relating to negative misperceptions about older drivers and ideally should be assessed as to its utility in further studies.

Although most people with progressive illnesses such as the dementias will eventually undergo decline function and behaviour, it is not clear to what extent this poses a public health risk from a driving perspective (Carr and Ott, 2010). It is more likely that the process of reducing mileage and eventual withdrawal from driving protects the general public from the harmful effects of the illness on driving safety (Trope et al., 1996; Carr et al., 2000). Reassuringly, the process of self-regulation in terms of reduced mileage is also apparent with mild cognitive impairment (O'Connor et al., 2010). Indeed, focus groups of those with Alzheimer's disease, their caregivers and professionals were almost unanimous in saying that, with self-regulation, those with mild AD should continue to

Driving and psychiatric illness in later life

drive (Perkinson et al., 2005). Nonetheless, clinicians and patients should agree on a follow-up schedule for review of deterioration of their clinical status to the point that driving skills may become unsafe which is congruent with practice in their jurisdiction.

Other psychiatric illnesses

The role and impact of illnesses in older age on driving other than dementia has been even less widely studied, apart from alcohol dependency. The overall impression from the literature is that the added risk from schizophrenia and affective disorders is small (Marshall, 2008), although the issue is complicated by the use of psychoactive medications (Soyka et al., 2005). The emphasis on risk rather than on mobility is similar to the rest of the field, and it is likely that those with psychiatric illness have less mobility than the population as a whole. In an early study, Buttigliere and Guenette (1967) found that subjects with psychiatric illness had accident and violation records similar to the general population. Patients with schizophrenia and depot neuroleptics show a worse driving performance on a driving test than unmedicated healthy controls (Wylie et al., 1993), but concrete evidence of increased crash risk is not available. A Swiss study (Sacher, 1978) of mostly young and middle-aged people with schizophrenia showed more violations and accidents in those with delusions of a religious type, but fewer accidents or violations among those with a 'cautious, anxious character'.

Even more recent studies of driving in patients with psychiatric illness, although mostly not older adults, have been limited by the use of psychomotor and cognitive tests as proxies for driving, in the absence of tests of actual driving (De Las Cuevas and Sanz, 2008; Segmiller et al., 2013). An observational study in Australia (Berecki-Gisolf et al., 2015) found that of 743 drivers who were injured in a non-fatal motor vehicle collision, 12% had used antidepressants in the year prior to the injury, and the authors concluded that less than half of antidepressant use after injury could be attributable to the injury itself. However, it should be noted that only one quarter of their sample was aged 65 years and over, and no conclusions could be made about the risk of collision associated with these antidepressants. In a study of older adults in Ontario (Rapoport et al., 2011), 5% of 159,678 individuals who had a motor vehicle collision between 2000 and 2007 had received an antidepressant in the month prior to the collision. Although the risk of collision associated with a second-generation antidepressant (SSRIs and newer agents) was modestly increased (HR 1.10, 95% confidence interval 1.07–1.13, $p < 0.0001$), this association was restricted to those who were prescribed a benzodiazepine or strong anticholinergic medication concurrently with the antidepressant, and was restricted to the first three to four months after the antidepressant was prescribed.

The use of car crashes as a means of suicide is considered to occur in a very small proportion of crashes, despite a suggestion from early studies that this might be a more marked problem. Subsequent studies have

Driving and psychiatric illness in later life

shown the risk to be quite small (Tabachnik et al., 1966; Schmidt et al., 1977; Isherwood et al., 1982), including a recent survey reported in abstract form of 16 US states from 2005 to 2011 in which only 1% of violent suicides were categorized as suicides by motor vehicle. The authors note that those who completed suicide by motor vehicle were younger than those who died by other methods of suicide, and were predominantly white, male, and under the age of 55. About one-third of the suicide-by-car sample tested positive for alcohol, and one-third had a current mental health problem at the time of their death, although only a quarter were receiving treatment for this (Sung, 2017).

So where does this leave the clinician in this area? Key considerations are likely to be the severity and stability of the patient's condition, their insight, impulsiveness, and their ability to appropriately engage with the strategic, tactical, and operational elements of driving to prevent and avoid road hazards, as well as clarifying that there are no suicidal plans which, in this context, might involve a vehicle (Canadian Medical Association, 2017). Ideally, adverse effects of medications will be minimized, with due caution with the use of sedating antipsychotics or long-acting benzodiazepines.

Medications

An area of increasing debate over the last 25 years has been the potential impact of psychoactive medications on driver safety. This interest has paralleled studies showing an impact of these medications on increasing the risk of other injuries (Ray et al., 1992), notably falls. A number of studies have suggested that physicians should be concerned about diminished driving skills and increased crash risk with psychoactive medications (Ray et al., 1993; Hemmelgarn et al., 1997). In terms of numbers of prescriptions, the main groups implicated are the benzodiazepines (Hemmelgarn et al., 1997) and antidepressants (Ray et al., 1992). If a true increased risk can be established and quantified, by medication type and dosage, restrictions either in prescribing or on driving (or both) may be an achievable component of a crash-prevention strategy.

Demonstrating cause and effect has been problematic. Separating the effects of the disease from those of the medications is not easy: depression, anxiety, and insomnia may have an impact on driving behaviour that might be ameliorated by pharmacological treatment. Studies on volunteers do not replicate clinical experience. There is significant research that has examined reaction time, braking time, and deviation of lateral position in relation to psychoactive medications using simulators or on the road testing (Rapoport and Banina, 2007; Verster and Roth, 2011, 2012) but there is a relative absence of research into the impact of medications on the strategic and tactical elements of driving.

Driving and psychiatric illness in later life

A parallel here is to consider the theoretical differences between tricyclic anti-depressants (TCAs) and selective serotoninergic reuptake inhibitors (SSRIs) in relation to the risk of falls. Although SSRIs would seem to have theoretical advantages, clinical studies have not been able to show any difference in fall rates between older people on TCAs or SSRIs (Thapa et al., 1998). In the study described previously of antidepressants and crashes in older adults in Ontario, the observed modest risk of crash associated with second-generation antidepressants was not at all observed with first generation antidepressants such as tricyclics and monoamine oxidase inhibitors (Rapoport et al., 2011). Epidemiological studies of car crashes often have shortcomings, such as how they match controls with cases, in the exclusion of fatalities (which are more likely to involve alcohol and possibly psychoactive drugs), unreliability in medication recall at interview, lack of valid diagnostic categorization prior to the crash, and failure to control for the many variables that affect crash risk.

We conducted a systematic review of the literature from 1946 to 2013 pertaining to antidepressants and driving in older adults (Cameron and Rapoport, 2016). We found only one experimental study on this topic, which found imipramine to have detrimental effects on highway driving, whereas nefazodone (an antidepressant that has largely been discontinued) did not, although this was not a study of depressed older adults. Seven of eight identified population-based studies reported a significant increased risk of involvement in a collision associated with antidepressant use. However, these studies had significant limitations, including lack of reporting on dose and duration of the drug, lack of information of driving exposure, lack of adjustment for confounders such as other medication use, lack of ascertainment of at-fault status, and generally a lack of distinction between classes of antidepressants, let alone individual agents.

A meta-analysis of 11 epidemiologic and 16 experimental studies showed an association between benzodiazepines and MVCs in six case-control studies (OR 1.61, 95% CI 1.21–2.13), and in three cohort studies (OR 1.60, 95% CI 1.29–1.97) (Rapoport et al., 2009). The heterogeneity in the analysis was reduced when restricting to the three case-control studies and two cohort studies involving older adults, although the magnitude of the association was somewhat attenuated. The newer class of sedatives, Z-drugs, such as zopiclone and zolpidem, may be no safer (although there have been no head-to-head comparisons to date with respect to driving safety); there was generally an increased risk of collision associated with these drugs in recent studies, mostly case-crossover design in which patients serve as their own controls. Such a design eliminates the problem of comparing patients with dissimilar controls. Zolpidem was associated with an increased collision risk in four recent studies (Gustavsen et al., 2008; Gibson et al., 2009; Yang et al., 2011; Orriols et al., 2011), of which only two included older adults (Orriols et al., 2011; Yang et al., 2011). Zopiclone was associated with collision in three recent

Driving and psychiatric illness in later life

studies (Barbone et al., 1998; Gustavsen et al., 2008; Gibson et al., 2009), but not in two others (Orriols et al., 2011; Yang et al., 2011). Only one of the three positive studies of zopiclone included older adults (Barbone et al., 1998), and both of the negative studies included older adults. The magnitude of effects of these studies was variable.

Universal advice against driving while taking benzodiazepines and Z-drugs is not yet supported by these studies, but it should accelerate both epidemiological and policy interest in the subject, as well as clinical caution. Those who prescribe benzodiazepines and Z-drugs need to recognize that most adult patients are drivers or potential drivers. Active consideration should be given as to whether the illness is likely to affect driving skills and whether the patient has a past crash history. The patient should be advised not to drive if they cannot abstain from alcohol while on treatment with benzodiazepines. Most importantly, the prescriber should query whether the patient really needs a benzodiazepine, and if they do, whether it needs to be long acting, as the longer-acting benzodiazepines are more closely associated with collisions (Hemmelgarn et al., 1997; Rapoport et al., 2009).

Practical guidelines

In advising a patient who is also a driver, the psychiatrist must first ask how the patient's illness affects their mobility. A secondary goal is to assess the potential safety risk. The considerations outlined in Box 57.1 should be assessed, and ideally any longer-term decisions on driving should be made when the patient's condition is stabilized and optimized. An interim decision will have to be made until the assessment is completed, and this may involve asking the patient to desist from driving temporarily. Some countries have reasonably well-developed schemata for helping clinicians and, increasingly, they have recognized the value of specialist opinion. For example, the 'At-a-Glance' leaflets from the UK driver licencing authorities (<http://www.dvla.gov.uk/media/pdf/medical/aagv1.pdf>) have moved on from an assumption that hospitalization is the norm for significant psychiatric illness, to a model based more on ambulatory care, with reference made to specialist opinion. Some of the driver licensing authorities' criteria also seem unnecessarily strict and, as the field of driver assessment matures, it will be important that professional organizations make representations to driver licensing authorities to ensure that the regulations are fair. Guidelines from the Association for the Advancement of Automotive Medicine stress the importance of leaving many of the decisions to the specialist, assuming appropriate assessment back-up (Dobbs, 2002). The quality of clinical practice guidelines on assessing drivers with medical illness has been recently criticized for limitations in rigour, stakeholder involvement, and applicability (Rapoport et al., 2015), and efforts to improve these are being made. In the interim, physicians who feel that the regulations hinder the health, wellbeing, and mobility of their patient unnecessarily may need to consult their medical defence organization about the clash of

Driving and psychiatric illness in later life

ethical responsibilities that they may feel toward to both their patient and others.

In some cases, it may be apparent that there are no concerns about driving safety or, conversely, that the patient is too unstable or compromised to drive safely. In cases where the judgment lies in between, a full assessment including an on-road driving test may be required. Once a decision has been made, the psychiatrist needs to inform the patient of their responsibility to report to the local driver licensing authorities and/or their insurance company: this discussion should be documented in the clinical notes. We tend to phrase this by suggesting to the patient that they review their insurance policy documentation. Patients' responsibilities vary enormously from jurisdiction to jurisdiction. Failure to inform the patient of the relevant requirement may expose the doctor to criticism or even litigation. The psychiatrist also needs to be aware of any statutory requirements for physicians to report illnesses such as dementia to driver licensing authorities, as is the case in California and most Canadian provinces. Reporting a driver when one lacks confidence that there will be a fair and sensitive assessment by the driver licensing authority can pose an ethical dilemma. It is also notable that living in a jurisdiction with mandatory reporting does not appear to have an impact on driving cessation in Alzheimer's disease (Herrmann et al., 2006), raising a question over the usefulness of mandatory reporting, which may have the unintended effect of deterring patients with dementia from seeking care from their physician. In a jurisdiction with mandatory reporting legislation, there was considerable variability between physicians (mostly geriatric psychiatrists and geriatricians) in the frequency with which hypothetical cases with mild dementia and mild cognitive were reported to the transportation authorities (Rapoport et al., 2014b). Although clinical variables such as caregiver concern and cognitive performance were predictors of whether reports were submitted, physician-related factors, such as male gender and a tendency to experience stress from having to deal with areas of medical uncertainty, also increased physician reporting (Rapoport et al., 2014a).

If the assessment points to safe driving practice, the decision to allow continued driving entails several further judgments on the part of the doctor. These are:

1. Interval before review
2. Possible restriction
3. Driving accompanied
4. Licencing authority reporting relationship in the jurisdiction
5. Insurance reporting responsibility i.e. doctor or patient.

Since dementia is a progressive illness and affective disorders and alcohol dependency are recurrent or relapsing diseases, it is prudent to make any declaration of fitness to drive subject to regular review. For dementia, our own practice is to review again in six months, or sooner if

Driving and psychiatric illness in later life

any deterioration is reported by the carer (Breen et al., 2007). Some support is given for this approach in one of the longitudinal studies of driving and dementia (Duchek et al., 2003) and in a systematic review (Molnar et al., 2006b). Following evidence that the crash rate is reduced if the driver is accompanied (Bédard et al., 1996), it could be sensible to advise the patient to driving only when there is someone else in the car, using the accompanied driver paradigm (Shua-Haim and Gross, 1996). Although the phrase 'co-pilot' has been used in the literature for accompanied driving, this might imply participation in the driving process, as opposed to presence and observation, and thus 'accompanied driving' represents a better description. There is also preliminary evidence from the state of Utah that those drivers with restricted driving licences have lower crash rates (Vernon et al., 2002), and this is almost certainly an under-utilized strategy (Langford and Koppel, 2011), although the use of this strategy among patients with psychiatric illness has not been evaluated. Patients should be advised to avoid traffic congestion as well as driving at night and in bad weather. Nonetheless, empirical evidence supporting accompanied driving and driving restrictions among patients with psychiatric conditions including dementia are lacking. The patient and carers should be advised to acquaint themselves with local driver licensing authority requirements as well as the policy of their motor insurance company. All of these should be clearly recorded in the medical notes.

Supporting cessation

How do older drivers with dementia deal with driving cessation when driving is no longer possible?

There is strong evidence that most drivers with dementia not only limit their own driving and cease driving voluntarily (Foley et al., 2000) but also are amenable to pressure from family and physicians. In one of the largest studies 18% stopped driving of their own accord, 23% because of physician advice, 42% because of family members, and the rest by a combination of interventions (Trope et al., 1996). In a recent study, factors predictive of driving cessation included global deterioration, lower level of cognition (Talbot et al., 2005), and some interesting trends on neuropsychiatric behaviour; agitation made it less likely that a patient would cease driving, whereas apathy and hallucinations made it more likely (Herrmann et al., 2006). Living in rural areas is associated with later cessation of driving (Talbot et al., 2005). There are no studies of how patients with dementia compensate for the loss of independent transport mobility afforded by driving that is needed to fulfil their social, occupational, and health needs, and considerable concern exists that these needs are not met adequately (Taylor and Tripodes, 2001). However, psychological adaptation to driving cessation may be helped by diagnosis and psychotherapeutic input (Bahro et al., 1995).

Driving and psychiatric illness in later life

There have, however, been very few controlled studies assessing the impact of interventions aimed at supporting driving cessation among older adults. In a recent systematic review (Rapoport et al., 2017), we identified three such studies—one was described an intervention for retired drivers with dementia, another was aimed at caregivers of drivers with dementia, and the third included retired and retiring drivers without dementia. The study of retired drivers incorporated a 16-week group based programme with problem- and emotion-focused coping strategies, and reported a significant effect on depressive symptoms compared with a traditional support group (Dobbs et al., 2009). The study of caregivers involved a four-week programme of two-hour group educational sessions and reported significant effects on self-efficacy, acceptance, and preparedness for change compared with two control groups—a waiting list and those given written materials only (Stern et al., 2008). In the study of older adults without dementia, six weekly group sessions of education and support increased their reported episodes of getting out of the home relative to a waiting list control (Liddle et al., 2014). These studies provide promising approaches toward supporting older drivers through the cessation process, although they are limited by their use of subjective ratings.

In the meantime, what should doctors advise for those patients they assess as unfit to drive? If the assessment supports driving cessation, patients and carers should be advised of this, and a social worker consulted to help maximize transportation alternatives (Windsor and Anstey, 2006). Giving up driving can have a considerable effect on lifestyle. Healthy older drivers accept that their physician's advice can be very influential in helping them decide to give up driving (Rabbitt et al., 1996).

The way we deal with driving reflects how we help the patient to deal with the reality of the deficits caused by dementia or other psychiatric illnesses. If the positive and collaborative approach described is not successful, confidentiality may have to be broken for a small minority of cases. Most professional associations for physicians accept that the principle of confidentiality is covered to a degree by a 'common good' principle of protecting third parties when direct advice to the patient is ignored (American Medical Association, 1999). Removal of the driving licence is not likely to have much effect on these patients, and the vehicle may need to be disabled (Donnelly and Karlinsky, 1990) and all local repair services warned not to respond to calls from the patient. In such cases, medicolegal advice should be sought from the malpractice organization before breaching confidentiality, and such actions should be in alignment with local healthcare policies.

In the event of a decision to advise cessation of driving, advice from a medical social worker may be helpful in planning strategies for using alternative modes of travel. This may be particularly difficult in rural settings: the political system has not woken up to the need for adequate paratransit, i.e. tailored, affordable, and reliable assisted transport that is

Driving and psychiatric illness in later life

acceptable to older adults with physical and/or mental disability (Freund, 2000). Tailored transport (paratransit) is expensive, but there are imaginative social economy models (such as ITNAmerica.org) that have shown promise (Freund, 2007), and may ultimately be found to have benefits in reducing institutionalization and in improving quality of life.

Screening for dementia among older drivers

Despite the lack of convincing evidence for an older driver 'problem', ageist policies in many jurisdictions have led to screening programmes for older drivers. In the absence of reliable and sensitive assessment tools and this approach is flawed, as illustrated by data from Scandinavia (Hakamies-Blomqvist et al., 1996). Finland had regular age-related medical certification of fitness to drive, whereas Sweden had no routine medical involvement in licence renewal. The number of older people dying in car crashes in Finland was no less than in Sweden but the number of those dying as pedestrians and cyclists was higher, possibly, in part due to the fact that drivers were unnecessarily removed from their cars. Equally, in Australia, the state with the lowest number of crashes among older drivers was the one that did not undertake age-based medical screening of older drivers (Langford et al., 2004). Adding a cognitive screening test to a population medical screening programme in Denmark was shown also to have no effect upon in-car mortality, but instead appears to increase the deaths among older road users, suggesting that screening shifted older persons from driving to less safe modes of transportation (Siren and Meng, 2012).

A more minimalist and less medical approach using very simple measures, such as a vision test and a written skill examination may be more helpful (Levy et al., 1995): unfortunately this approach is also associated with a reduction in the number of older drivers, and thus has a possible negative health impact, given the extensive literature of the negative impacts of driving cessation (Levy, 1995). Another approach is opportunistic health screening, for example, those older drivers with traffic violations (Johansson et al., 1996). It remains to be seen whether these and other screening policies reduce mobility among older people, which is a practical and civil rights issue of great importance.

Conclusions

There are numerous challenges for the psychiatrist assessing older adults who drive. All psychiatric conditions have the potential to impair driving, but, conversely, there are other older adults with the same conditions whose driving does not seem to be impaired. Predicting who is and who is not impaired is quite difficult, as physicians simply do not have the capacity for direct observation of their patients' driving. Most older adults who drive rely on their vehicle for autonomy and social engagement, and withdrawal of driving privileges can lead to adverse psychosocial consequences and worsening of their psychiatric condition, even when cessation is necessary for public and patient safety. The

Driving and psychiatric illness in later life

situation is further frustrated by a lack of empirical evidence of the magnitude of the true risks of the psychiatric conditions and their treatments, evidence for interventions to support community mobility and life-space of older adults planning driving cessation and beyond cessation, and rigorous clinical practice guidelines. We have advocated in this chapter for a practical approach that makes use of a multidisciplinary team and a destigmatizing of the older driver and the driver with psychiatric illness. We have emphasized the precarious balance of safety and autonomy, a considered consultation with collateral informants, a judicious understanding of local legislation, and red flags that may highlight a problem with driving ability. This should be coupled with an emphasis on providing psychosocial and psychiatric support for older adults in planning for driving cessation, and for maintaining community mobility after they have stopped driving.

The law relating to mental capacity and mental health

Chapter: The law relating to mental capacity and mental health

Author(s): Kay Wheat

DOI: 10.1093/med/9780198807292.003.0058

Introduction

The law discussed in this chapter is primarily the law of England and Wales, but there are many parallels between the law discussed here and other jurisdictions. By way of illustration, the jurisdictions of the US, Canada, Australia, New Zealand, South Africa, and the countries of South Asia are all based upon the English common law. For example, the concept of 'necessity' is a common law concept that was used prior to the Mental Capacity Act to justify non-consensual treatment in certain circumstances, and this will be available in those common law jurisdictions lacking specific legislation relating to capacity.

Prior to the passing of the Mental Capacity Act 2005, there were no statutory provisions relating specifically to decision-making capacity. Persons who did not have capacity were treated in their best interests based upon the common law doctrine of necessity. It is this doctrine that had enabled doctors to lawfully treat unconscious patients, i.e. those with

The law relating to mental capacity and mental health

temporary lack of capacity, and it was further developed so that it could be used to treat persons permanently lacking in capacity, such as people with dementia. Furthermore, the power of the original Court of Protection had only been statutorily defined in relation to dealing with the property of the person lacking capacity. This lacuna and other concerns gave rise to a Law Commission Consultation Paper and Report, and a number of government papers. The Mental Capacity Act was passed in 2005. Significantly, the original proposal was for a Mental Incapacity Act, but this was changed to emphasize what has become a presumption in favour of a person having capacity.

However, before we move on to the Mental Capacity Act, it is appropriate to consider a particular aspect of capacity law that has been considered by the courts since the nineteenth century.

Testamentary capacity

This is something that is particularly relevant to older people. If a will is not valid, due to a number of reasons, one of which is testamentary incapacity, then either the law of intestacy will apply, or an earlier valid will remains the applicable instrument. In the case of *Burns v Burns* [2016] EWCA Civ, 37, the Court of Appeal had to consider an appeal from a decision of the High Court that a will made in 2005 was valid. As is usually the case in this type of litigation, the matter had come before the court because of a dispute between the beneficiaries following the death in 2010 of the testator at age 89. In 2004 she had undergone a number of assessments, and was diagnosed as suffering from moderate to severe depression. The issue before the Court of Appeal was whether the judge was entitled to form his conclusion on the medical and other evidence before him. The first of the medical evidence was a Mini-Mental State Examination (MMSE) carried out in 2003 by a community psychiatric nurse where the testator scored 19 out of 30, with her main shortcomings being in memory assessment and orientation/awareness of the current circumstances such as date, season, etc., and failing to recall objects mentioned to her earlier by the nurse. The second evidence was given by the manager of her care home; this evidence was found to be inconclusive on the basis that her mental state may well have been different in 2004 from 2010 when she died (the manager had known her during this period, but conceded this point). A subsequent occupational therapy assessment, carried out in 2005, had concluded that the testator had moderate impairment and a medium level of dependency. The Court of Appeal held that the judge in the High Court had been entitled to find that she had capacity and knew and approved the contents of her will, despite the evidence that there was some mental impairment at the time.

The judge referred to the 'golden rule', which essentially is not a rule of law but guidance to a lawyer dealing with a testator whose capacity may be in doubt, and which, as confirmed in the case of *Buckenham v Dickenson* [2000] WTLR, states that the lawyer should have prior knowledge of the testator, should consider whether the will should be

The law relating to mental capacity and mental health

witnessed by an approved medical practitioner, and that the proposed will should be considered in the context of any earlier will, and making sure that the reading through of the will is not 'an idle ceremony'. Despite impairment, the judge decided, on the basis of the case of *Parker v Felgate* [1883] 8PD 171, that she knew she was signing a will and that she was aware of her assets. It was described as a 'simple will'. There was much discussion about the judge's conclusions, but the Court of Appeal found that the judgment was not unsound, given that the judge had heard all the evidence and had taken into consideration the applicable law.

Looking back at the assessments in *Burns*, and, for example, the poor scores on orientation, it is interesting to consider the case of *Simon v Byford* [2014 EWCA Civ 280, another Court of Appeal case, where it had been held that capacity was about understanding and not a test of memory.

It is worth noting here that statutory wills can be authorized by the Court of Protection. An example is the case of *Re J (A Protected Party)* [2016] EWCOP 52, where it was held that it was in the best interests of an elderly woman suffering from dementia for a statutory will to be executed on her behalf, whereby her estate was to be left in unequal shares to her two sons. This was based upon her past and present wishes and matters that she would have taken into account if she had capacity.

The Mental Capacity Act 2005 (MCA)

The MCA applies to everyone over the age of 16, but, of course, has a particular application to older people because of the potential for them losing capacity being greater than that of the general population. Prior to the enactment of the MCA, there were powers vested in the Court of Protection that enabled the property of those without capacity to be managed, but there were no provisions to cover personal welfare matters. These were dealt with by the inherent jurisdiction of the courts under the common law. The key change made by the MCA is that it remedies this gap and the Court of Protection now has power to make welfare decisions, as well as property, etc.

Having said that, the provisions of the MCA do not add a great deal to the common law, but for non-lawyers it is more accessible, and there are useful additions, embellishments, and clarifications. For example, there are five principles contained within section 1 of the MCA: a presumption of capacity until established otherwise; all practical steps must have been taken to help a person make a decision before concluding that he lacks capacity; unwise decisions are not to be taken as evidence of lack of capacity; any act done or decision made in respect of someone without capacity must be in his best interests; and an act or decision must be arrived at after due consideration has been given to achieving least restrictive and the person's rights and freedom of action.

The law relating to mental capacity and mental health

People lacking capacity

The law takes a functional approach, i.e. it depends upon the nature of the decision to be made as to whether a person has capacity. There is a tendency to think in terms of life and death decisions, partly because these are the most serious, and partly because it is in that area that most of the court applications lie. However, the same principles apply to decisions of everyday life (e.g. what does this person want to wear, to eat) and clearly the capacity to make such decisions is present in all but the most seriously disabled people. There is also a tendency to think in terms of medical care and treatment because of their almost unique quality of invading bodily integrity. However, many other personal welfare decisions can be equally serious, in particular, the decisions as to where and with whom one lives.

The functional approach is illustrated well by the case of *London Borough of Southwark v (1)KA (2)MA (3)RN* [2016] EWCOP 20. K, aged 29, had learning disabilities. He lived with his family and could not manage without that support and the support of a day centre. His family were hoping to find a wife for him. The local authority obtained forced marriage protection orders and applied to the Court of Protection for a declaration that he did not have the capacity to litigate, make personal welfare decisions, and decisions about sexual relations and marriage. The court found that he lacked capacity only in respect of litigation. He understood about marriage, sex, and pregnancy, and he understood his basic care and health needs, the role of a doctor, and the need to take medical advice. He did not understand the law or why his circumstances should come before the court and therefore he could not litigate unaided.

Section 2 of the MCA states that, in order to come within the ambit of the legislation, a person will only lack capacity if it is because of 'an impairment of, or a disturbance in the functioning of, the mind or brain'. It can be permanent or temporary and incapacity cannot be established merely by reference to age or appearance or behavioural traits, something particularly to be kept in mind when dealing with older people. In section 3, it states that a person lacks capacity if he is unable to: understand the information relevant to the decision; retain that information; use or weigh up the information to make the decision; or communicate the decision. This is almost the test used in the case of *Re C (Adult: Refusal of Treatment)* (1994) 1 WLR 290, where there was no reference to communication, but an additional requirement was imposed by the court: the patient must believe the information. The problem with this requirement is that a patient's beliefs can be irrelevant. This is illustrated by the facts of that case. The patient was told that without the treatment he did not want he had an 85% chance of dying. In such circumstances, a patient might not believe what he was being told, despite factual evidence to the contrary, and this might be because he believes the doctors are lying to him. In such a case, this might mean that he does not have capacity. On the other hand, he could genuinely believe that he fell into the 15% of people who would not die. In other words, the

The law relating to mental capacity and mental health

question of belief is not helpful in deciding on capacity. In any event, this aspect of the judgment was not imported into the MCA.

Information relevant to the decision includes information about the consequences of deciding in one way or another, or of failing to make a decision at all, and the information has to be communicated to the person in the most appropriate way, e.g. by the use of simple language or visual aids. Retention of the information only has to be for a short period of time. The language is certainly very open-textured, although assistance may be obtained from the MCA Code of Practice (Department of Constitutional Affairs, 2007).

The MCA is more likely to be applicable in the case of older people than the Mental Health Act 1983 (MHA), as their mental disorder is more likely to be some form of dementia leading to lack of capacity, whereas many disorders, such as bipolar disorder, often affecting a much younger population, do not necessarily affect capacity.

Best interests

Again, the language of section 4 that deals with best interests is very general, as it has to be, but the devil is in the detail of the application of the section to a particular case. The MCA Code of Practice provides guidance on this, stressing the importance of the caveat that age, appearance, and behaviour are not relevant factors in capacity law, and they should not be used in deciding what is in a person's best interests. There is also a requirement to consider whether the person concerned will regain capacity. This could be important in cases where an older patient is, for example, confused as the result of an acute infection. Insofar as is reasonably practicable, the person must be permitted, and indeed encouraged, to participate in any act done for him and any decision affecting him, and the person's past and present wishes, feelings, beliefs, and values must be taken into account and, in particular, any relevant written statement made when the person had capacity. Where appropriate, the views of others must be taken into account. Curiously, section 4(5) states that '[w]here the determination relates to life-sustaining treatment he must not, in considering whether the treatment is in the best interests of the person concerned, be motivated by a desire to bring about his death', and one is tempted to say that we are all highly relieved to know this. The provision was inserted as a result of concerns expressed by the anti-euthanasia lobby. Interestingly, it has been held by the House of Lords that it is possible to sanction a procedure on the basis that it is not against the interests of the person concerned. This was in the case of *S v S* (1972) AC 24 and is prior to the enactment of the Mental Capacity Act. It concerned an application to the court for an order that a blood sample be taken from a child in order to establish paternity, and it was said that this would not be against the interests of the child and the appropriate order was made.

The law relating to mental capacity and mental health

By way of a comparative illustration, in the US the concept of 'substituted judgment' is favoured as a test for the validity of decisions made in incapacity cases. This means that the decision is based upon what the person would have wanted if he had capacity (Weber, 1985). This was canvassed in the House of Lords case of *Airedale National Health Service Trust v Bland* (1993) AC 789, and rejected by the court, and arguably the court was right, on the basis that it was too narrow a test. After all, a person's views might not have been known, or he may never have had capacity, in which case the test is meaningless. However, the court recognized that substituted judgment could be a legitimate factor in deciding what is in best interests, and that has been incorporated into the MCA.

There are many cases on best interests, and most of them simply turn on their own facts. A recent case, *Re IH (Observance of Muslim Practice)* [2017] EWCOP 9, concerned a 39-year-old man suffering from a profound learning disability. Due to this impairment he had no understanding of religion and religious observations. The Court of Protection had to decide whether it was in his best interests, firstly, on the application of the Official Solicitor, to be required to fast during the daylight hours of Ramadan, and secondly, on the application of his father, to be required to have his axillary and pubic hair trimmed in accordance with Islamic culture and religious practice. The judge held that it was not in his best interests in both cases. In the case of fasting, the judge held that the man had no understanding of the religious significance of the withholding of food and water, and this would cause him distress and he might become distressed and/or aggressive. There was also concern that it might increase the side effects of his medication. In the case of the trimming of hair, again he would not understand why this was being done, and again it was likely to cause him distress and/or anger. The trimming of hair is part of the Islamic tradition of 'ritual cleanliness', but the judge held that he would derive no spiritual benefit from this, as he already had an elevated status because of his incapacity. The latter aspect is interesting in that it requires a view to be taken that without capacity, observance of religious practices is not required because of something akin to the absence of free will.

In *Cheshire & Wirral Partnership NHS Foundation Trust v Z* [2016] EWCOP 56, the case before the Court of Protection concerned a patient detained under section 3 of the MHA. We consider the MHA later in the chapter and although there is no reference to 'best interests' under the Act, this case effectively decided what was in the best interests of this patient without consideration of her capacity, because as she was detained under the Act she could be treated without consent even if she had capacity. She had suffered from a very extreme form of anorexia nervosa since the age of 15. Now aged 46, apart from her eating disorder and the underlying psychological problems, she was developing physical ill health, in particular severe osteoporosis. Her dangerously low weight was such that she was detained under section 3 of the MHA, not, of

The law relating to mental capacity and mental health

course, because of her physical condition, but because of her mental disorder and the fact that she posed a danger to herself. Her medical team had three options for treatment. The first was to continue to detain, and feed her under restraint. The second was to detain and feed her under sedation. The third was that she should be discharged from the section 3 detention and treated voluntarily. The evidence was that the first option posed a serious risk to her musculoskeletal integrity because of her osteoporosis, and the second option posed a similarly serious risk of her undergoing respiratory or cardiac arrest because of her overall physical fragility. The third option was held to be the best one for her, as the team had stressed that she could return to hospital at any time, and there was evidence that her mental state improved when not being subjected to enforced treatment. Even though she had a 30-year history of not cooperating with treatment regimes, the third option, it was held, would at least preserve her dignity and autonomy. The use of the last word is interesting as it could imply that she did have capacity.

It is worth pointing out that, just because the courts are considering *best interests* (emphasis added), it does not mean that the best possible course of action must be on offer. In (1) *ACCG* (2) *ACC v (1)MN (2) MR N (3)MRS N* [2017 UKSC 22], the UK Supreme Court stated that when the Court of Protection was making decisions on behalf of incapacitated adults, the court was limited to what the public authority (in this case, the appropriate Clinical Commissioning Group) would agree to implement, i.e. there could be no hypothetical proposals advanced as being in the best interests of the incapacitated person that a public authority would then be bound to implement.

The additional factor in best interests is that an act or decision must be arrived at after due consideration has been given to achieving the least restrictive effect on the person's rights and freedom of action. This leads us to consider the Deprivation of Liberty Safeguards.

Deprivation of liberty safeguards (DOLS)

The history of these safeguards goes back to the use of section 131 of the MHA 1983, which permits patients to enter psychiatric hospitals as informal patients, who in theory are free to leave at any time. In *R v Bournewood Community and Mental Health NHS Trust ex p L* (1998) 3 All ER 289, an autistic man had been admitted informally to a mental health unit. He normally lived with carers who understood him very well, but on this occasion at the day centre he visited he became very distressed, and it was felt appropriate to take him to the unit. When he arrived at the unit, he was described as being 'compliant' and he remained there for several months. The treating psychiatrist stated that if he had resisted treatment and confinement then they would have gone through the process of formal detention. The House of Lords was divided on the approach to this but decided that he was being treated under the common law doctrine of necessity, i.e. in his best interests. This doctrine had always been applied to emergency medical treatment, where patients

The law relating to mental capacity and mental health

are often treated without consent as they are unconscious or unable to give consent for other reasons. The common law had elaborated on this to justify treatment of incapable patients 'in their best interests' in non-emergency situations. In most circumstances this is sensible and uncontroversial, but in a few key areas, e.g. mental health, it is fraught with difficulty. There was a subsequent application to the European Court of Human Rights (*HL v United Kingdom* (2005) 40 EHRR 32). Under Article 5 of the European Convention on Human Rights, there is a right not to be deprived of liberty save in specific circumstances, and, in any event, there must be adequate safeguards to protect a person who is deprived of their liberty unlawfully. Not surprisingly, the Court found that there had been a violation of Article 5. This was because the deprivation was based entirely on the clinical assessments at the hospital and there was not an appropriate vehicle for the patient to use to obtain a speedy resolution to the situation, as informal patients are not subject to the Mental Health Review Tribunal process that applies to patients who are compulsorily detained. The other point in relation to this case and the European Convention is that the Convention only can only be invoked against actions that are attributable to the state. This is because if there is scope for private bodies to breach Convention Rights, then legal and regulatory regimes should be imposed by the state to prevent this happening.

As a result of this case, the government amended the MCA to include the Deprivation of Liberty Safeguards (DOLS) contained in sections 4A and 4B of the Act. They apply to anyone aged 18 or over, and cover patients in hospitals and people in care homes registered under the Care Standards Act 2000, whether private or publicly owned, but note later on, where we consider subsequent case law that suggests a wider ambit. If there is a person or a patient, the hospital or home must apply to the supervisory body (the local authority) for authorization of deprivation of liberty if it is believed that the person lacks capacity and has been deprived, or risks being deprived, of his liberty. Being deprived of liberty is not just being in a locked ward or care home; it can consist of treatment within the unit, such as confining people to chairs or similar restrictions. Deprivation of liberty can also be authorized by the Court of Protection. It will immediately be seen that there is much scope for avoidance of the authorization process in that this will depend upon the subjective assessments of whether someone is being deprived of his liberty (apart from undertaking the normal difficulties of assessment of capacity) and how far people running care homes, for example, are aware of precisely what deprivation of liberties may consist of. The DOLS are frequently criticized as being fundamentally flawed. Jones (2008) suggests that a '... procedure has been created that is hugely complex, voluminous, badly drafted, overly bureaucratic and difficult to understand, and yet provides mentally incapacitated people with minimum safeguards'.

The European Court of Human Rights has held that there are two elements of a confinement that must be satisfied in order for there to be a

The law relating to mental capacity and mental health

deprivation of liberty. First, there has to be established an objective element of confinement to a certain limited place for a not-negligible length of time, and second, there is the subjective element, which means that there has been no consent to the confinement (*Storck v Germany* (2005) 43 EHRR 96). A recent Court of Appeal decision, applying these criteria, while concerned with young women, is nevertheless applicable to the situation of many older people. *P and Q and Surrey County Council v CA and LA and Equality and Human Rights Commission* (2011) EWCA Civ 190, concerned two girls, described as having middle to severe learning difficulties, one of whom lived in a foster home and the other in a small specialist unit. The Court of Appeal held that there was no deprivation of liberty. The judge at first instance had held that, since they were happy in their care environments, there was no deprivation as this contentment was relevant to the objective element of confinement. The Court of Appeal rejected this as being relevant to this aspect, but stated that it was relevant to whether any deprivation was in their best interests. Lord Justice Wilson stated that persons living at home will not normally be deprived of their liberty, and a foster home or a carer's home was not much less 'normal', and 'even when the person lives in an institution rather than in a family home, there is a wide spectrum between the small children's home or nursing home, on the one hand, and a hospital designed for compulsory detentions like Bournewood; and it is in my view necessary to place each case along it' [para. 28]. This case was appealed to the Supreme Court where it was conjoined with another case which concerned an adult with cerebral palsy who lived in local authority accommodation with two other residents. He needed help with all the activities of daily living, but saw his mother regularly, went to a day centre, and participated in various social activities. The Court of Appeal went on to develop the concept of 'relative normality', stating that it was wrong to compare someone whose capacity was impaired with someone who was unimpaired, where control and supervision would be a deprivation of liberty.

In the UK Supreme Court (*Cheshire West and Chester Council v P and Surrey County Council v P* [2014] UKSC 19), the appeals were allowed. In *Cheshire West*, the life of P was completely controlled and therefore it amounted to a deprivation of liberty, and in *Surrey County Council*, it was held that the fact that people were happy and supported in their environment was not a factor when deciding deprivation of liberty because, as we have seen in the *HL* case, compliance has no effect upon whether there has been such a deprivation. The Supreme Court set down what Lady Hale referred to as the acid test. This is simply that when someone is under the complete control and supervision of those caring for them and are not free to leave the place where they live, they are deprived of their liberty. Lady Hale went on to say that: 'Furthermore, that deprivation is the responsibility of the state. Similar constraints would not necessarily amount to a deprivation of liberty for the purpose of article 5 if imposed by parents in the exercise of their ordinary parental responsibilities and outside the legal framework governing state

The law relating to mental capacity and mental health

intervention in the lives of children or people who lack the capacity to make their own decisions.’ [para. 54]. In a phrase that is frequently quoted she also stated that ‘a gilded cage is still a cage’ [para. 46].

This point was considered by the Court of Appeal in *Secretary of State for Justice v (1) Staffordshire County Council (2) SRK (by his Litigation Friend, SK) (3) RK (4) Irwin Mitchell Trust Corp* [2016] EWCA Civ 1317. As a result of receiving damages for personal injury, K received 24-hour care that was managed by the Irwin Mitchell Trust Corporation, which had been appointed by the Court of Protection to act as K’s representative (‘deputy’ in the language of the MCA; see ‘Procedural matters’). The deputy informed the local authority that, due to the accommodation arrangements, there may be a deprivation of liberty and a welfare order was applied for, and granted by the Court of Protection as, although these were private care arrangements, there were insufficient procedural safeguards to satisfy the state’s positive obligations under Article 5. The Secretary of State appealed on the basis that the criminal and civil law, and enforceable obligations on public bodies in respect of vulnerable people were sufficient to satisfy this. The Court of Appeal dismissed the appeal on the basis that the operation of the law relied upon by the Secretary of State, was dependent upon wrong-doing being brought to the attention of the state; there was no process of assessment and review of such private care to provide the necessary safeguards.

In 2014, via the process of post-legislative scrutiny, the House of Lords Select Committee made a number of recommendations as to the operation of the MCA. One was that there be an independent body to oversee the functioning of the MCA (<https://publications.parliament.uk/pa/ld201314/ldselect/ldmentalcap/139/139.pdf> Recommendation 4, para. 14) and the other key finding expressed concerns about the DOLS. The view was that the safeguards do not provide sufficient protection, and that the legislative provisions should be re-drafted (<https://publications.parliament.uk/pa/ld201314/ldselect/ldmentalcap/139/139.pdf> Recommendation 14, para. 34). In addition, it was clear that *Cheshire West* would significantly increase the number of DOLS. This, plus the Select Committee Report, resulted in the Law Commission undertaking consultation on the operation of the Act. The Commission reported in March 2017, making a number of recommendations. In the context of DOLS, it recommend that there should be increased rights to instruct an independent advocate (at the moment under the MCA there is provision for the independent advocates to be available in certain circumstances); a system of inspection and review of the circumstances in which people are deprived of their liberty; the extension of the powers to authorize a deprivation of liberty; extending DOLS to those aged 16 and 17; a simplified version of the best interests assessment which emphasizes that, in all cases, arrangements must be necessary and proportionate before they can be authorized. There was also some rather vague reference to human rights, and the fact that protection should be

The law relating to mental capacity and mental health

extended to all care settings, including domestic settings, on the basis that this would avoid applications to the Court of Protection.

The government eventually responded by passing the Mental Capacity (Amendment) Act 2019, which replaces DOLS with new measures known as Liberty Protection Safeguards, intended for introduction in 2020. These are intended to be simpler to operate, but much will depend on the content of the accompanying Code of Practice, which is still being developed.

Advance decisions and lasting powers of attorney

First of all, these should properly be described as advance 'refusals' in that no patient, whatever the treatment concerned relates to, can make an advance request for a specific treatment, or, at least, he could make a request, but no clinician would be bound by it. The law therefore permits people only to say what treatment they do *not* want in the event of them losing their capacity. Sections 24–26 of the MCA effectively codify the previous common law position, where advance decisions were recognized. In order to make an advance decision, one has to have capacity and be aged 18 or over. The decision will bind treating physicians if the patient loses capacity. However, the sticky points are contained within section 25, which states that the decision must be both 'valid' and 'applicable'. The decision must not have been withdrawn by the patient, but also must not be inconsistent with subsequent behaviour of the patient. The Explanatory Notes to the MCA give the example of a patient who was formerly a Jehovah's Witness who made an advance decision of refusal of blood transfusions and who later married into the Muslim faith, but has forgotten to destroy the advance decision. It will also only be valid if the patient has lost capacity; one would hope this would be self-evident, but it is correct to make this beyond doubt. The circumstances in which the decision, while valid, might not be applicable are those where the decision is not clear as to the circumstances in which it would apply, or that new treatments have become available for conditions when there were no treatments, or much less onerous treatments are now available. Section 25(5)–(6) contains a number of additional formalities that have to be complied with if the refusal is of life-sustaining treatment. An advance decision will not be valid if, subsequent to it, the patient gives another person a Lasting Power of Attorney under section 9. These cover personal care and treatment, whereas the 'Enduring Powers of Attorney' that preceded the MCA had a much more restricted remit.

Procedural matters

It is outside the scope of this chapter to examine the detail, but it is worth pointing out that most decisions on behalf of incapacitated patients will be made by relatives, carers, social workers, and healthcare professionals, without any reference to the courts. However, there is provision within the MCA of new powers for the Court of Protection; prior to the MCA, this court only dealt with the property affairs of incapable

The law relating to mental capacity and mental health

people, but these powers have been extended to include all personal welfare decisions. The court is mostly populated by judges from the Family Division of the High Court. The court can make declarations as to whether someone has capacity to make particular decisions, or whether a course of action is in his best interests, or whether a valid advance decision exists and whether it is applicable; deal with financial matters, e.g. authorizing the sale of property; resolve issues relating to lasting powers of attorney; and appoint deputies to make decisions for incapable people for whom less formal processes are not available. The MCA does also provide for Independent Mental Capacity Advocates to be appointed in cases where the person has no one else who can be consulted on best interests.

Finally, it has been held that the MCA has not ousted the High Court's inherent jurisdiction to deal with cases that fall outside the Act, and to protect vulnerable adults who were under constraint, subject to coercion or undue influence, or deprived of capacity for some other reason (*DL v A Local Authority and Others* (2012) EWCA Civ 253).

Adults with Incapacity (Scotland) Act 2000

The MCA only applies in England and Wales. The Scottish Act is somewhat different from the MCA in that it does not use the concept of best interests in decision-making, rather referring to whether any act done in connection with the incapacitated adult is for his 'benefit' (section (1)(2)). The reasoning behind this is that the notion of best interests is more paternalistic as it was developed in the context of the law relating to children, and the concept of benefit is more respectful of the individual's own wishes. Arguably, it is a question of semantics, because under the MCA (section 4(6)) there is a requirement that, in deciding what is in the best interests of the patient, the past and present wishes, feelings, beliefs, and values of the patient must all be taken into account.

The Mental Health Act 1983 (MHA)

Given that a significant number of older people who come within the ambit of psychiatric services will be living with dementia or related mental disabilities, the Mental Capacity Act 2005 will almost certainly be the most commonly used legislation. However, there can be circumstances in which it may be more appropriate to use the mental health legislation that provides for compulsory detention of patients. Although the MHA does provide for detention of people who have come through the criminal justice system and for whom it is more appropriate to receive treatment rather than mere custody, it is outside the scope of this chapter, which is concerned with civil admissions only.

There was a move in the late 1990s to reform the MHA of 1983, and in 1998 the government set up a scoping study review committee to report. The report ('Richardson Report') focused upon patient-centred reform, but the recommendations were not followed. In addition, because of

The law relating to mental capacity and mental health

concern about dangerous patients not being compulsorily detainable, the Home Office issued a consultation document on Managing Dangerous People with Severe Personality Disorder (DPSD) that put forward draconian proposals. The principal impetus for this was the case of Michael Stone, who committed homicide following release from a psychiatric hospital, on the basis that he suffered from a psychopathic disorder and the Act provided that such patients could not be detained for long-term treatment if they were deemed to be 'untreatable' (for an appraisal of DPSD and its limited clinical utility, see Duggan, 2011). Again, this initiative gathered dust, as did a number of other attempts to make changes to the 1983 Act. Finally, the MHA 2007 made a relatively modest number of changes to the 1983 Act. It is important to remember that the 2007 was an amending Act and the 1983 is still the current Act in force.

The main provisions of the Act remain the same. The power to compulsorily detain for both short and long term remains and the criteria to be satisfied are the same: basically, the patient has to be suffering from some form of mental disorder and he has to be a danger to himself or to others. These requirements are fairly standard in the legislation in other jurisdictions, too. There are four main changes. First, the Act provides for an independent advocacy scheme for those patients who have been detained but have no other form of representation. Second, where it is considered necessary to detain patients for longer than 28 days, the requirement that they be suffering from conditions such as 'mental illness', 'mental impairment', and 'psychopathic disorder' has gone (the last condition no doubt having bemused clinicians for some time). For any form of detention, the patient just has to be suffering from 'mental disorder'. Third, as an adjunct to this, the 'treatability' requirement has been removed. Under the original 1983 Act, for long-term detention the patient had to be suffering from mental illness, mental impairment, severe mental impairment, or psychopathic disorder and, in the case of non-severe mental impairment and psychopathic disorder, the patient had to be 'treatable'. Part of the definitions of non-severe mental impairment and psychopathic disorder was that they both be associated with 'abnormally aggressive or seriously irresponsible conduct on the part of the person concerned'. The requirement that these patients be treatable was based upon the Percy Commission's recommendations, upon which the 1959 MHA was based, and the requirement was re-enacted in the 1983 Act. Commendably, these recommendations sought to preserve civil liberties and protect citizens from detention before they had committed a criminal act: 'If one is to apply preventive control to psychopathic patients under wider conditions than these, one is in effect applying to them preventive detention in hospital in circumstances which would not justify preventive detention in prison under the criminal law' (Percy Commission, 1957).

Unfortunately, laudable as these sentiments were, the consequences were not always good. Some such patients can be extremely difficult to manage

The law relating to mental capacity and mental health

and the treatability condition meant that a decision to discharge them could be exercised on this basis. Of course, as far as older people are concerned, while they may well have fitted into this category because of 'irresponsible conduct', they would be easier to manage because they would often be more physically frail. The fourth major change to the Act has been the introduction of compulsory treatment in the community, which is an attempt to deal with the well-known 'revolving door' syndrome, i.e. certain patients, such as those suffering from psychosis, would be compulsorily admitted to hospital, stabilized, and discharged, only to neglect to take medication and find themselves back in hospital.

The basis of civil detention under the MHA is roughly the same as in many other jurisdictions, i.e. in addition to being mentally disordered the patient must pose a risk to himself or to others. It is beyond the scope of this chapter to debate the libertarian issues at the heart of this, but suffice it to say that there are two key issues here. First, some would argue that, although it is understandable that society wants to do something about those who pose a risk to others, apart from those with mental health problems, we wait for people to commit criminal offences before any action is taken against them; and second, if we can justify detention because of the threat to others, why should people, who merely pose a risk to themselves, be detained?

Informal admission

As discussed earlier, a misuse of section 131 of the MHA led to considerable litigation and an eventual visit to the European Court of Human Rights. The Act continues to provide for informal admission under section 131. It was originally part of the legislation for the avoidance of any doubt that statutory provisions that provide for compulsory admission for psychiatric patients do not imply that patients who are admitted for inpatient psychiatric treatment have to be admitted via the use of compulsory measures. Such patients are described as 'informal' patients, because to call them 'voluntary patients' suggests that they have capacity, and, as has been shown, section 131 can be used for 'compliant' patients lacking in capacity and they are protected by the DOLS. Informal patients are free to leave hospital at any time and cannot be treated without their consent.

Compulsory detention under the Act—the key players

The approved mental health professional (AMHP)

This is the new title for the professional formerly called the 'approved social worker'. The role is the same in that the AMHPs have, under section 13 of the Act, a duty (note that a duty is more than a power) to make an application for admission to hospital or an application for guardianship if they are satisfied that an application should be made. They are required to have regard to any wishes expressed by relatives or the patient and any other relevant circumstances. It should be noted that

The law relating to mental capacity and mental health

this is a *personal* duty and not a duty as a functionary of the local authority that has appointed them.

The nearest relative

A nearest relative (defined under section 26 in descending order of proximity of relationship) can also apply for the patient to be admitted under the Act. There was an earlier proposal in the debate about reform of the MHA to abolish and/or change the role of the nearest relative. However, it has remained with a small but significant change in that the patient can apply to the court under section 29(3) of the MHA for his nearest relative to be displaced on the ground that he is unsuitable to act. Although the nearest relative is defined under section 26, under the displacement provisions of section 29(3), anyone who is suitable can be appointed as the patient's nearest relative.

The doctors

The application for detention must be supported by medical recommendations, and normally this will be two recommendations. However, in emergencies (see Admission for assessment in emergencies—section 4), one recommendation will suffice.

Compulsory detention under the Act—the criteria

The requirement that patients be suffering from mental disorder

Patients cannot be detained unless they are suffering from mental disorder, and the definition of mental disorder (section 1(2)) is exactly the same as the definition in the Mental Capacity Act 2005, i.e. any disorder or disability of mind, which, pursuant to section 1(3), does not include addiction to alcohol or drugs, although 'dual diagnosis' is possible. That is, people who have a mental disorder and an addiction can be detained under the MHA as it was recognized that there was a risk of patients being denied help by both the mental health services and those dealing with substance misuse. For further information interested readers are referred to the Department of Health guidance.

People living with a learning disability shall not be considered to be suffering from mental disorder unless the disability is associated with abnormally aggressive or seriously irresponsible conduct. It was held in *Re F (Mental Health Act: Guardianship)* (2000) 1 FLR 192 that 'seriously irresponsible' has to be linked to a significant risk of harm to self or others, so a 17-year-old who wanted to go home, where she had been severely neglected, was not being seriously irresponsible.

It should also be noted that if the patient is subsequently found not to have been suffering from mental disorder at all, there will be no illegality in the detention (*R v Kirklees Metropolitan BC ex p C* (1993) 2 FLR 187).

The law relating to mental capacity and mental health

Admission for assessment—section 2

Although the section refers to assessment, quite rightly, treatment can be given to the patient under section 2 detention, but the primary purpose is to provide for a short-term admission to decide what might be needed in the long term. The patient must be suffering from mental disorder 'of a nature or degree which warrants the detention of the patient *in hospital*' (emphasis added) and he 'ought to be so detained in the interests of his own health or safety or with a view to the protection of other persons'. For section 2 applications made by an AMHP, there is no requirement that the nearest relative be consulted, but that person should be informed that an application is to be made, and if the nearest relative expresses any wishes, then these should be taken into account by the AMHP (section 13(1)).

Admission under this section is for a maximum of 28 days and is not renewable, but it has been held that the discretion to make an application should not be fettered in any way (*R v South Western Hospital Managers ex p M* (1994) 1 All ER 161). Thus, a second section 2 application made immediately after the expiry of the first one might be justifiable, although it would certainly be open to an application for judicial review.

Admission for treatment—section 3

If further detention after a section 2 admission is required, then normally this would be made under section 3, where the conditions are that it has to be 'necessary' for the patient's health and safety or for the protection of others, and that it is appropriate for him to receive treatment in hospital and this cannot be provided unless he is detained. It may be a matter of semantics, but the difference in the wording means that 'ought to be detained' under section 2 is not as stringent as it being necessary, which implies that there is a bigger threat to health and safety in the case of a section 3 admission. Admission under section 3 is for six months and is renewable.

Admission for assessment in emergencies—section 4

If there is an 'urgent necessity', then an application can be made under section 4 which requires only one medical recommendation. The wording of the section should be heeded and this power should not be used in cases where it is simply more convenient to admit in this way; it is there to apply to genuine emergencies only. The admission only lasts for 72 hours, so that a second recommendation should be obtained before the expiration of that period.

Admission for inpatients—section 5

In the case of an informal patient, he may decide to discharge himself from hospital. Similar provisions as section 4 apply in such a case and the

The law relating to mental capacity and mental health

admission lasts for 72 hours. Suitably qualified nurses also have a similar holding power in such cases, which lasts for six hours.

Leave of absence

Under section 17 of the MHA, the responsible clinician has the power to grant a leave of absence to a patient detained under section 3. The court has been reluctant to distinguish between in-patient and outpatient treatment, so that it has rejected a judicial review claim from a patient detained under section 3, and where an application was made for a renewal of her detention where her treatment plan consisted entirely of treatment within the community (*R (On the Application of DR) v Mersey Care NHS Trust* (2002) All ER(d) 28). The purpose of it was originally to permit treatment in the community, so it is questionable whether section 17 would be used in such cases, given that it is now possible to make community treatment orders. Certainly, judicial review should be successful if section 17 was now used for this purpose.

Guardianship—section 7

This is a little-used power. It is not about detention of a patient, nor is it about medical treatment. It is about general personal care. The requirement, in addition to suffering from mental disorder (which in the case of someone with a learning disability has to be coupled with abnormally aggressive or seriously irresponsible conduct), is that the mental disorder warrants reception into guardianship. Normally the guardian will be the local authority, but that is not a condition under the MHA. The powers of the guardian are to require specified residence, to require attendance for medical treatment, education, and training, and to require access to the person concerned. There can be no insistence on any form of treatment. It might be appropriate to use this in the case of an older person with or without capacity if he is neglectful of his personal needs and there is no better way to manage it, but, as we have seen, much can be done under the MCA in the best interests of the person concerned.

Treatment of those who are compulsorily detained

Section 63—treatment where no consent required

This does not apply to those detained under sections 4 and 5 and does not apply to guardianship. It states that consent is not necessary for treatment to be given to patients if it is treatment for the mental disorder. 'Mental disorder' has been given a very wide interpretation by the courts because it is defined under the MHA as including 'nursing, and also includes care, habilitation, and rehabilitation under medical supervision' (section 145(1)). It has included force-feeding for a patient classified as being psychopathic who was refusing to eat as a form of self-harm (*B v Croydon Health Authority* (1994) 2WLR 294), but it was held by the Court of Appeal in *St George's Healthcare NHS Trust v S* (1998) 3 All ER 673 that it has to be treatment for a condition that is integral to the

The law relating to mental capacity and mental health

mental disorder, which perhaps does not take us a great deal further forward.

The relationship between section 63 and advance decisions under the MCA was considered in the case of *Nottinghamshire Healthcare NHS Trust v RC* [2014] EWHC 1317 (COP). This concerned a man with a serious personality disorder who was detained under the MHA. Being a Jehovah's Witness, he had made an advance decision to refuse blood products. He self-harmed and the question arose as to whether he could be given blood products as he was on anticoagulants due to a history of thrombosis. The advance decision was not relevant as this would only be had regard to, if, and when, he lost capacity. The decision to be made by the court was whether he could still be given blood products under the provisions of section 63. It was held that to allow this would be an abuse of power and would be a denial of a most basic freedom.

Sections 57, 58, and 58A

These are treatments to which section 63 does not apply. As consent is necessary, these treatments cannot be given to anyone who lacks capacity. Section 57 requires the consent of the patient *and* a second opinion and is about the most controversial treatments. It covers psychosurgery and any other form of treatment specified by the Secretary of State (at present the only specified treatment is surgical implantation of hormones to reduce the male sex drive).

Section 58 and 58A treatments require consent *or* a second opinion. Section 58 treatment is the administration of medication in excess of a period of three months. Section 58A treatment is electroconvulsive therapy or any other treatment specified by regulations made by the 'appropriate national authority'.

Section 62—urgent treatment

Despite needing consent, this part of the MHA provides for the requirements of sections 57 and 58 to be dispensed if urgent treatment is necessary. The treatment must either i) be immediately necessary to save the patient's life; ii), being irreversible, be immediately necessary to prevent a serious deterioration of his condition; iii) not being irreversible or hazardous, be immediately necessary to alleviate serious suffering by the patient; or iv) represent the minimum interference necessary to prevent the patient from behaving violently or being a danger to himself or to others. Where the treatment is under section 58A, then the treatment has to be necessary under scenarios i) or ii). Section 57 treatments would be unlikely to satisfy the condition section in terms of hazard/irreversibility. The circumstances in which section 62 would apply therefore are most likely to be in relation to section 58 in a case where the three-month period for the administration of medication was about to elapse and it was not possible to obtain a second opinion in time.

The law relating to mental capacity and mental health

Community treatment orders (CTOs)

Introduced into the MHA by the MHA 2007, CTOs (section 17A) can only be made in respect of patients who have been discharged from hospital having been detained under section 3. In a case where a CTO was thought desirable for a section 2 patient, therefore, it would be necessary to detain under section 3 and then discharge the patient. An AMHP and the responsible clinician have to be satisfied that the patient is suffering from a mental disorder of a nature or to a degree that makes it appropriate for him to receive medical treatment and that it is necessary for the patient's health or safety, or for the protection of others, that the patient should receive treatment, and that it can be provided in the community. The last condition is subject to the power to recall the patient to hospital and it must be necessary for this power to be applied. The patient does not have to consent, but it is unlikely that a CTO would be made if the patient objected.

Looking back to the DOLS, the case of *PJ (A Patient) v Local Health Board* [2015] UKUT 480 (AAC) examined the question as to whether the conditions of a CTO would result in an unlawful deprivation of liberty. In PJ's case, he was discharged to a care home, would be subject to the regime of that home, and if allowed leave in the community he would be subject to provisions for revocation of that leave and the triggering of absconding protocols. The Mental Health Review Tribunal had held that that there was no deprivation of liberty as there was no continuous control and supervision, and that the CTO took precedence over human rights issues. The Upper Tribunal allowed the appeal on the basis that the granting of a freedom to 'take leave' that could be revoked, constituted a deprivation of liberty. It stated that Tribunals should address the following questions: would the conditions, on an objective assessment, result in a deprivation of liberty; if so, had the patient the capacity to consent to this; would this consent avoid a breach of Article 5; if the patient lacked capacity could the deprivation be authorized under the MCA; whether section 64D of the MHA (the provision that provides that patients lacking capacity can be given treatment in the community) can be relied upon to avoid a breach of Article 5, and how the aforementioned matters should be taken into account by a tribunal in deciding whether to uphold a CTO or discharge it.

Leaving hospital

First, it must be noted that the patient can be discharged under section 23, although it is lawful to delay discharge, even if there is no longer a justification for detention, if there is good reason to do so, e.g. putting into place aftercare facilities under section 117.

Second, detention can be challenged in one of three ways. Under section 66, patients have a right to apply to a Mental Health Review Tribunal for a review of their case. The nearest relative also has a right to apply, and there is an automatic review process under section 68, whereby hospital

The law relating to mental capacity and mental health

managers must refer to a Tribunal any patient admitted for treatment who has not exercised his right to apply within the first six months. The remit of the Tribunal is to decide whether the conditions for detention under the MHA still apply. However, there may be irregularities that cannot be remedied by use of the statutory review system, and in those circumstances the common law remedies of habeas corpus and judicial review may be used. For example, any allegation that there is a breach of the Human Rights Act 1998 would be made via judicial review.

Finally, it should be noted that although the Care Quality Commission cannot act to remove patients from detention under the Act, it does hear complaints and its members make hospital visits.

Relationship between the Mental Health Act 1983 and the Mental Capacity Act 2005

As demonstrated, there are two quite separate regimes at play in this area. The MCA is primarily about treatment in best interests and about using the least restrictive treatment of patients where possible. It is about taking into account the beliefs and wishes and feelings of the patient when deciding on the best course of action. The MHA is partly about protecting the patient from self-harm, but is also about protecting the public and doing this via a system of restraint and compulsory treatment.

There could be a great deal of temptation for treating clinicians in a formal MHA situation to state that it is in the patient's best interests to be detained. However, if the formal detention provisions of the MHA apply, then the MCA has no part to play, even if the patient lacks capacity. Paragraph 5 of Schedule 1 of the MCA states that:

2. P is ineligible [to be deprived of his liberty] if the following conditions are met.
3. The first condition is that the relevant instrument authorises P to be a mental health patient.
4. The second condition is that P objects—
 - (a) to being a mental health patient, or
 - (b) to being given some or all of the mental health treatment.

It was confirmed in the case of *W Primary Care Trust v TB* (2009) EWHC 1737 that this means that if the patient objects to confinement and the admission criteria under the MHA are met, then the MCA should not be used. Schedule 1A of the MCA lists a number of factors that should be taken into account in deciding whether the patient 'objects', including behaviour, wishes, feelings, views, beliefs, and values. However, as Richardson (2010) points out: 'provided these statutory factors are *taken into account*, clinicians are free to use their own judgment in determining the presence or absence of objection. This may present clinicians with welcome discretion when dealing with individual cases, but it provides little certainty for those directly affected by the eventual decision'.

The law relating to mental capacity and mental health

It is only when patients are informally admitted for treatment for mental disorder that the DOLS apply, and in all other respects, such as the applicability of the MCA principles or the requirement of best interests, the MCA applies. In making psychiatric treatment decisions, therefore, the key considerations are whether the provisions of the MHA are satisfied and whether there is any objection on the part of the patient. However, if we look back to best interests, and the case of *Cheshire & Wirral Partnership NHS Foundation Trust v Z* [2016] EWCOP 56, we can see that, out of the treatment options available to a patient who clearly could be detained under the MHA, what was 'best for her' was the basis for deciding whether the section 3 detention should be discharged.

The relationship between the two pieces of legislation was considered in the case of *J v Foundation Trust* (2009) EWHC 2972 Fam, which concerned a 65-year-old man who suffered from vascular dementia and Korsakoff's syndrome. He also suffered from diabetes but because of his mental disorder he was unable to manage his diabetes appropriately, running the risk of death or serious injury. He was detained under section 2 of the MHA for assessment, but later treated under the MCA, by way of a standard authorization for deprivation of his liberty, initially at a clinic and later in a care home. He objected to being detained insofar as his detention was for treatment of his mental disorder. The judge held that J was receiving treatment in hospital to make sure he took medication for his diabetes, and not to ensure treatment for mental disorder, and that he was only given medication for his mental disorder if he did not object to taking it. Consequently, if the need for physical treatment had not existed, J should not have been detained in hospital to receive his mental treatment, and so the only effective reason for his detention was his need for physical treatment. The DOLS authorization therefore did not authorize J to be a mental health patient. The same approach resulted in the conclusion that J was not within the scope of the 1983 Act, and J's objections to treatment for mental disorder were of academic interest only.
