

Oxford Textbook of Old Age Psychiatry (3 edn)

Edited by Tom Denning, Alan Thomas, Robert Stewart, and John-Paul Taylor

[Previous Edition \(2 ed.\)](#)

Abstract

The Oxford Textbook of Old Age Psychiatry, Third Edition, has been thoroughly updated to keep pace with the developments that have taken place in old age psychiatry since publication of the Second Edition in 2013, including the publication of the DSM-5/ICD-11 classification criteria. The Third Edition also includes new chapters on the ageing brain; the experience of dementia; carers' issues; biomarkers; and old age psychiatry in low- and middle-income countries. This is an essential reference for old age psychiatrists, geriatricians, and other clinicians who are interested in the mental health care of older people.

Preface

Author(s): Tom Denning

Welcome to the third edition of the *Oxford Textbook of Old Age Psychiatry* !

Although it is the third edition of this title, the book has a longer ancestry. In 1965, the late Felix Post published *Clinical Psychiatry of Late Life*, undoubtedly one of the earliest texts in our field. The gap left when this book went out of print was filled by Robin Jacoby and Catherine Oppenheimer's *Psychiatry in the Elderly*, which appeared in 1991. This book was revolutionary in its inclusion of highly practical chapters dedicated to topics such as driving and mental capacity that were not available elsewhere. The fourth edition of *Psychiatry in the Elderly* became the first edition of this Oxford Textbook.

Over the period covered by these successive publications, the numbers of older people have grown worldwide and continue to do so. Changing birth rates, work patterns, trends in migration, and diverse economic forces are transforming our societies. At the same time, we are all learning to live in an increasingly electronic and digitalized world. All of these factors impact upon older people; on the mental disorders that they may

Preface

experience; and upon the way in which treatment, support, and care can be organized. Meanwhile, dementia has been rightly recognized as one of the most salient global public health issues. Increasingly, individual countries are producing their own national dementia strategies. These vary in detail and as to whether any resources are actually committed; the simple fact that strategies exist is an important step forward. Dementia research has gained increasing attention, although there are concerns that disease-modifying drugs have been slow to emerge, as well as criticism that not enough research benefits people who have dementia now as opposed to those who may or may not develop it in future. Furthermore, it is important that all the attention on dementia does not divert our focus from other pressing mental health issues like depression and anxiety that are also highly prevalent and can be equally disabling. Nonetheless, we continue to live in exciting times, and this is something we should celebrate.

Inexorably, the amount and complexity of the content of this book has increased with each edition; so, too, has the number of authors. Thus, we have moved in just over 50 years from a single-author volume to needing something akin to an American football squad or a national Olympics team. For this edition we have reverted to four editors and we are delighted to welcome Rob Stewart and John-Paul Taylor to the editorial team.

The 'Jacoby and Oppenheimer' structure has proved extremely durable and we have retained this approach. The sections of the book start with basic sciences (both neurobiological and social science), followed by clinical practice, specific disorders, and service provision, before finishing again with ethical and legal issues.

Since the previous edition, we have introduced new chapters on biomarkers, carers, and issues in low- and middle-income countries. These not only reflect suggestions made after the last edition, but also our desire to cover topics that are of growing importance. We have also increased the number of contributions from people with lived experience, as we believe that these contributions are among the most-read chapters in the book. For any reader, whether they are a lay reader, student, trainee specialist, or established professional, these accounts provide material that brings the science alive.

Our team of authors has been refreshed. We pride ourselves that everyone we invite to contribute has agreed to do so, which reflects both the impact that this book has had and its excellent reputation. We also have maintained our international focus, since the book has a worldwide readership.

Of course, without the help of all our contributors, this book would not be possible, so we gratefully acknowledge your expertise, time, and commitment. Thank you all. And many thanks to our editors at Oxford University Press, Pete Stevenson, Lauren Tiley, and Rachel Goldsworthy,

Preface

who have been a pleasure to work with. Finally, thanks to older people—our patients, their families, our families, too—who have educated us all and helped us in this venture.

motor neuron disease
MoCA
Montreal Cognitive Assessment
MOTYB
Months of the Year Backwards
MP4A
N-[(11)C]methylpiperidin-4-yl acetate
MRCPsych
examination for Membership of Royal College of Psychiatrists
MRI
magnetic resonance imaging
mRNA
messenger RNA
MRS
magnetic resonance spectroscopy
MSA
multiple system atrophy
MSNAP
Memory Services National Accreditation Programme
MSR
macrophage scavenger receptor
MSU
mid-stream specimen of urine
MTA
medial temporal atrophy
MTL
medial temporal lobe

Abbreviations

mTOR
mammalian target of rapamycin
MVC
motor vehicle crash
NAA
Narcotics Anonymous
NAA
N-acetylaspartate
NCD
neurocognitive disorder
NCEP ATP III
National Cholesterol Education Program Adult Treatment Panel III
NCI
neuronal cytoplasmic inclusion
NCS-R
US National Comorbidity Study Replication
NDSHS
Australian National Drug Strategy Household Survey
NER
nucleotide excision repair
NESARC
US National Epidemiologic Survey on Alcohol and Related Conditions
NFL
Neurofilament light chain
NFT
neurofibrillary tangle
NFTD
neurofibrillary tangle dominant dementia
nfvPPA
nonfluent or agrammatic variant PPA
NGS
next-generation sequencing
NHS
National Health Service
NIA-AA
National Institute on Aging and the Alzheimer's Association
NIA-RI
National Institute of Aging Nancy and Ronald Reagan Institute
NICE
National Institute for Health and Care Excellence
NIFID
neuronal intermediate filament inclusion disease
NIFID
neurofilament inclusion body disease
NIHR
National Institute of Health Research
NII
neuronal intranuclear inclusion
NINCDS-ADRDA

Abbreviations

National Institute of Neurological and Communicative Disorders and
Stroke-Alzheimer's Disease and Related Disorders Association
NINDS-AIREN
National Institute of Neurological Disorders and Stroke and
Association Internationale pour la Recherche et l'Enseignement en
Neurosciences
NLW
national living wage
NMDA
N-methyl-D-aspartate
NMS
neuroleptic malignant syndrome
NO
nitric oxide
NOAC
non-vitamin K oral anticoagulant
NP
neuritic plaque
NPI
neuropsychic inventory
NPV
net present value
NREM
non-REM
NSFs
National Service Frameworks
NSMHWB
Australian National Survey of Mental Health and Wellbeing
NT
neuropil thread
NTP
 α -, β -, and γ -nucleoside triphosphate
nv-PPA
non-fluent PPA
OABD
older-age bipolar disorder
OCD
obsessive-compulsive disorder
OFC
orbitofrontal cortex
OPCS
Office of Population Censuses and Surveys
OR
odds ratio
OSA
obstructive sleep apnoea
OSLA
Observational Scale of Arousal
OT

Abbreviations

occupational therapist
OTE
openness to experience
PA
psychological autopsy
PACS
partial anterior circulation stroke
PACSLAC
Pain Assessment Checklist for Seniors with Limited Ability to Communicate
PAINAD
Pain Assessment in Advanced Dementia
PAL
Paired Associates Learning
PALS
Patient Advice and Liaison Service
PAOS
pure progressive apraxia of speech
PART
primary age-related tauopathy
PATH
Problem Adaptation Therapy
PBS
positive behaviour support
PCA
posterior cortical atrophy
PCFT
Prudhoe Cognitive Function Test
PCr
phosphocreatine
PD
Parkinson's disease
PDB
Paget's disease of bone
PDD
Parkinson's disease dementia
PDE
phosphodiester
PDMCI
MCI in Parkinson's disease
PDNC
PD and normal cognition
PEACE
Palliative Excellence in Alzheimer Care Effort
PEDAL
Programa de Entrenamiento de Aptitudes para Latinos
PEG
percutaneous endoscopic gastrostomy
PET

Abbreviations

positron emission tomography
PET-PiB
positron emission tomography with Pittsburgh Compound B
P-gp
P-glycoprotein
pH
pondus hydrogenii
PHF
paired helical filament
Pi
inorganic phosphate
PiB
Pittsburgh compound B
PICALM
phosphatidylinositol binding clathrin assembly protein, involved in endocytosis
PiD
Pick's disease
PKA
protein kinase A
PLAN
Psychiatric Liaison Accreditation Network
PLD3
phospholipase D member 3
PLMS
periodic limb movements of sleep
PME
phosphomonoester
PNFA
progressive non-fluent aphasia
POA
power of attorney
POCS
posterior circulation stroke
POD
psychosis of dementia
POMH-UK
Prescribing Observatory for Mental Health
PORT
Patient Outcomes Research Team
PPA
primary progressive aphasia
PRNP
prion protein gene
PrP
prion protein
PS
Perry syndrome
PSP

Abbreviations

progressive supranuclear palsy
PST
problem-solving therapy
PSWC
periodic sharp wave complexes
p-tau
hyperphosphorylated tau at threonine 181
PTSD
post-traumatic stress disorder
PVI
perivascular astrocytic inclusion
PWD
person with dementia
QALY
quality-adjusted life year
QEEG
quantitative EEG
QoL
quality of life
RAGE
receptor for advanced glycation end products
RAVLT
Rey Auditory Verbal Learning Test
RBD
rapid eye movement sleep behaviour disorder
RCT
randomized controlled trial
REM
rapid eye movement
RLS
restless legs syndrome
RMT
reminiscence therapy
RNA
ribonucleic acid
RO
reality orientation
ROC
receiver operating characteristic
ROI
region of interest
ROS
reactive oxygen species
RR
relative risk
rs-fMRI
resting state functional magnetic resonance imaging
RSWA
REM sleep without atonia

Abbreviations

RTLA	right temporal lobe atrophy
rTMS	repetitive transcranial magnetic stimulation
RT-QuIC	real-time quaking-induced conversion
SAD	seasonal affective disorder
SALT	speech and language therapist
SAMD	senescence-associated mitochondrial dysfunction
sAPP	soluble ectodomain of APP
SARI	serotonin antagonist and reuptake inhibitor
SARS	severe acute respiratory syndrome
SASP	senescence-associated secretory phenotype
SAST	Short Anxiety Screening Test
SBP	systolic blood pressure
SBRT	Severe Behaviour Response Teams
SCA-17	spinocerebellar ataxia type 17
SCD	subjective cognitive decline
sCJD	sporadic Creutzfeldt-Jakob disease
SCLC	small cell lung cancer
SCN	suprachiasmatic nucleus
SD	standard deviation
SD	semantic dementia
SDB	sleep-disordered breathing
SE	supported employment
SERM	selective oestrogen receptor modulator
SF-36	36-item Short Form Health Survey
SIB	

Abbreviations

Severe Impairment Battery
SiP
Senses in Practice
siRNA
small interfering RNA
SIRT
sirtuin
SMC
Subjective Memory Complaint
SMI
severe mental illness
sMMSE
standardized MMSE score
SNAP
suspected non-Alzheimer's disease pathology
snoRNA
small nucleolar RNA
SNP
single-nucleotide polymorphism
SNRIs
selective serotonin and noradrenaline reuptake inhibitors
SOC
Selective Optimization with Compensation
SP
senile amyloid plaques
SPECT
single-photon emission computed tomography
SPMSQ
Short Portable Mental Status Questionnaire
SQiD
Single Question in Delirium
SQSTM1
p62/sequestome1
SQUID
superconducting quantum interference device
SRH
self-rated health
SSRI
selective serotonin reuptake inhibitors
ST
skills training
ST4, ST5, ST6
Specialist Training Years 4-6
STI
sexually transmitted infection
SUVr
standardized uptake value ratio
SVD
small vessel disease

Abbreviations

sv-PPA
semantic variant PPA
SWI
susceptibility-weighted imaging
TACS
total anterior circulation stroke
TAR
transactivation-responsive
TARDBP/TARDP
Transactive response DNA-binding protein 43
TBK1
TANK-binding kinase 1
TBP
TATA box-binding protein
TBSS
tract-based spatial statistics
TCR
transcription-coupled repair
TD
tardive dyskinesia
TD
topographical disorientation
tDCS
transcranial direct cortical stimulation
TDP-43
transactivation-responsive DNA-binding protein 43
TE
echo time
TFT
thyroid function test
tg
transgenic
THK5117
6-(3-18Fluoro-2-hydroxypropoxy)-2-(4-methylaminophenyl)quinoline
THK5351
(S)-6-(3-18Fluoro-2-hydroxypropoxy)-2-(N-methyl-2-aminopyridin-5-yl)quinoline
TM2D3
TM2 domain containing 3
TMEM106B
Transmembrane protein 106B
TMS
transcranial magnetic stimulation
TNF
tumour necrosis factor
TR
repetition time
TRAP

Abbreviations

tremor at rest, rigidity, akinesia (or bradykinesia), and postural instability
TREM2
triggering receptor expressed on myeloid cells 2
TSE
transmissible spongiform encephalopathy
TSI
Test for Severe Impairment
TSPO
translocator protein
t-tau
total tau
TYM
Test Your Memory
TYM-MCI
Test Your Memory for Mild Cognitive Impairment
Type I error
false positive error
Type II error
false negative error
U&Es
urea and electrolytes
UBQLN2
Ubiquilin 2
UNC5C
unc-5 homolog C
UPS
ubiquitin/proteasome system
UPS
Ubiquitin-positive
US
unconditioned stimulus
VaD
Veterans Administration
VaD
vascular dementia
VASS
Vulnerability to Abuse Screening Scale
VBA
voxel-based analysis
VBM
voxel-based morphometry
VBR
ventricle-to-brain ratio
VCI
vascular cognitive impairment
VCING
Vascular Cognitive Impairment Neuropathology Guidelines
vCJD

Abbreviations

variant Creutzfeldt-Jakob disease
VCP
valosin-containing protein
VD
vascular dementia
VEPs
visual evoked potentials
VGKC
voltage gated potassium channel
VLOSLP
very-late-onset schizophrenia-like psychosis
VLPO
ventrolateral preoptic nucleus
VP
ventriculoperitoneal
VRF
vascular risk factor
VT
validation therapy
WAIS-R
Wechsler Adult Intelligence Scale-Revised
WAY-100635
N-[2-[4-(2-Methoxyphenyl)-1-piperazinyl]ethyl]-N-(2-pyridyl)cyclohexanecarboxamide
WHELD
Improving Wellbeing and Health for People with Dementia
WHIMS
Women's Health Initiative Memory Study
WHO
World Health Organization
WMH
white matter hyperintensity
WML
white matter lesion
WPBAs
Work Place Based Assessments
YLD
years lost due to disability
YLL
years of life lost
YMRS
Young Mania Rating Scale

Oxford Textbook of Old Age Psychiatry (3 edn)

Edited by Tom Denning, Alan Thomas, Robert Stewart, and John-Paul Taylor

Previous Edition (2 ed.)

Publisher: Oxford University Press Print Publication Date: Oct 2020
Print ISBN-13: 9780198807292 Published online: Oct 2020
DOI: 10.1093/med/9780198807292.001.0001

Contributors

Author(s): Tom Denning

Dag Aarsland Professor and Head of Department (Old Age Psychiatry), Institute of Psychiatry, Psychology and Neuroscience, Kings College London, UK and Centre for Ageing Research, Stavanger University Hospital, Stavanger, Norway
32: The Lewy body dementias

Kirstie Anderson Consultant Neurologist and Honorary Clinical Senior Lecturer, Regional Sleep Service, Royal Victoria Infirmary, Newcastle upon Tyne, UK

48: Sleep and circadian rhythm disorders

Anonymous

38: The experience of depression

Johannes Attems Professor of Neuropathology Translational and Clinical Research Institute Faculty of Medical Sciences Campus for Ageing and Vitality Newcastle upon Tyne, UK

5: Neuropathology

Elena Baker-Glenn Consultant Psychiatrist, Liaison Psychiatry Service, Peterborough City Hospital, Cambridgeshire and Peterborough NHS Foundation Trust, UK

24: Liaison old age psychiatry

Contributors

Sube Banerjee Executive Dean and Professor of Dementia, Faculty of Health, University of Plymouth, Plymouth, UK

23: Memory assessment services

Robert Barber Consultant Old Age Psychiatrist, Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust; and Honorary Clinical Senior Lecturer, Institute of Neuroscience, Campus for Ageing and Vitality, University of Newcastle upon Tyne, UK

7: Clinical biomarkers in the diagnosis of dementia

Delia Bishara Consultant Pharmacist for Mental Health of Older Adults and Dementia, South London & Maudsley NHS Foundation Trust and Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK

13: Psychopharmacology

Martina Bocchetta Senior Research Fellow, Dementia Research Centre, Department of Neurodegenerative Disease, UCL Queen Square Institute of Neurology, University College London, UK

33: Frontotemporal dementia

Bradley Boeve Professor of Neurology, Department of Neurology and Center for Sleep Medicine, College of Medicine and Science, Mayo Clinic, Rochester, MN, USA

48: Sleep and circadian rhythm disorders

Carol Brayne Professor of Public Health Medicine, Department of Public Health and Primary Care; and Co-Director Cambridge Public Health, University of Cambridge, UK

4: Epidemiology of old age psychiatry; 28.3: The contribution of an early or timely diagnosis

René S. Bun Department of Neurology, Pitié-Salpêtrière Hospital, Paris, France

6: Biomarkers for Alzheimer's disease

Gerard Byrne Mayne Professor of Psychiatry, University of Queensland; Director, Older Persons' Mental Health Service, Royal Brisbane & Women's Hospital, Queensland 4029, Australia

42: Anxiety disorders in older people

Dennis Chan Consultant Neurologist and Principal Clinical Research Fellow, Institute of Cognitive Neuroscience, University College London

29: Mild cognitive impairment

Carolyn A. Chew-Graham Professor of General Practice Research, School of Medicine, Keele University, Keele, UK; Honorary Professor, Primary Care Mental Health, Midlands Partnership NHS Foundation Trust, UK

22: Primary care management of older people's mental health problems

Helen F. K. Chiu Emeritus Professor, Department of Psychiatry, the Chinese University of Hong Kong, Hong Kong, China

40: Suicide and attempted suicide in older people

Rachel Cowan Specialist Registrar in Geriatric Medicine, Nottingham University Hospitals NHS Trust, UK

11: Physical assessment

Contributors

Sarah Cullum Senior Lecturer and Consultant in Old Age Psychiatry, Department of Psychological Medicine, The University of Auckland, New Zealand

36: Management of dementia

Daniel Davis Principal Clinical Researcher, MRC Unit for Lifelong Health and Ageing, University College London, UK

37: Delirium

Marieke de Boer Senior researcher UNO-VUmc, Department of Medicine for Older People, Amsterdam University Medical Centers, location VUmc, Netherlands

53: Ethics of living and dying with dementia

Karen Harrison Denning Head of Research & Publications, Dementia UK, London, UK

27: Palliative care and end-of-life care

Tom Denning Professor of Dementia Research, Division of Psychiatry & Applied Psychology, University of Nottingham, UK

20: Principles of service provision; 26: Care homes for older people;

28: The experience of dementia: Introduction; 45: Severe and enduring mental illness

Claudio Di Lorito Research Fellow, Faculty of Medicine & Health Sciences, University of Nottingham, UK

56: Older people as victims and perpetrators of crime

Hilary Doxford Somerset, UK; co-founder, 3 Nations Dementia Working Group; member, World Dementia Council

28.2: After the diagnosis

Klaus P. Ebmeier Professor of Old Age Psychiatry, Department of Psychiatry, University of Oxford, Warneford Hospital, Oxford, UK

12: Neuroimaging

Ricca Edmondson Professor of Political Science & Sociology, National University of Ireland, Galway, Ireland

3: The sociology of ageing

Charlotte Emmett Associate Professor; Director of Education, Northumbria Law School, Northumbria University, Newcastle upon Tyne, UK

52: Mental capacity and decision-making

Nicolas Farina Research Fellow in Dementia, Centre for Dementia Studies, Brighton and Sussex Medical School, Brighton, UK

23: Memory assessment services

Peter Farnbach Consultant Psychiatrist, South Eastern Private Hospital, Victoria, Australia

14: Neurostimulation therapies

Cleusa P. Ferri Head of the Psychogeriatric Unit, Department of Psychiatry, Escola Paulista de Medicina, Universidade Federal de São Paulo (UNIFESP), São Paulo, SP, Brazil

21: Psychiatric presentations among older people living in low- and middle-income countries

Bianca Fileborn Lecturer in Criminology, School of Social and Political Sciences, University of Melbourne, Australia

50: Sexuality in older age

Contributors

Kuruville George Director of Medical Services, Peter James Centre and Wantirna Health; Clinical Director of Aged Persons Mental Health and ECT, Eastern Health; Adjunct Associate Professor Monash University, Victoria, Australia

20: Principles of service provision

Julie Gosling Director, Making Waves UK Lived Experience Network; Associate Lecturer, School of Health Sciences, University of Nottingham, UK; Survivor

44: Personal experience

Andrew Graham Consultant Neurologist, Ipswich & Addenbrooke's Hospitals, Ipswich/Cambridge, UK

34: Neurological dementias

Doug Gray Senior Scientist, Ottawa Hospital Research Institute; Professor, Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Canada

1: Biological aspects of human ageing; 2: The ageing brain

Harald Hampel Professor of Neurology at the Sorbonne University and Principal Investigator of the Sorbonne University Groupe de Recherche Clinique (GRC n°21) "Alzheimer Precision Medicine (APM)", Pitié-Salpêtrière Hospital, Paris, France; Founding President and Chief Executive Officer (CEO) of the Alzheimer Precision Medicine Initiative (APMI)

6: Biomarkers for Alzheimer's disease

Maria Luisa Hanney Consultant in Older Age Psychiatry, Northumberland, Tyne and Wear NHS Foundation Trust, Morpeth, Northumberland, UK

47: Older people with intellectual disability

Rowan H. Harwood Professor of Geriatric Medicine, Faculty of Medicine & Health Sciences, University of Nottingham, UK

11: Physical assessment; 37: Delirium

Catherine Hatfield Consultant Old Age Psychiatrist, Cambridgeshire & Peterborough NHS Foundation Trust, Cambridge, UK

45: Severe and enduring mental illness

Verena Heise NDPH Intermediate Fellow, Nuffield Department of Population Health, University of Oxford, Big Data Institute, Oxford, UK

12: Neuroimaging

Simone Hendriks Elderly Care Physician, Department of Medicine for Older People Amsterdam University Medical Centers, location VUmc, Netherlands

53: Ethics of living and dying with dementia

June Hennell Granted an MBE in 2016 in recognition of her services to the dementia world; Gloucestershire, UK

28.4: The end of the journey and life after dementia

Cees Hertogh Professor of Medicine for Older People and Geriatric Ethics, Department of Medicine for Older People, Amsterdam University Medical Centers, location VUmc, Netherlands

53: Ethics of living and dying with dementia

Sharron Hinchliff Reader in Psychology and Health, the Division of Nursing & Midwifery, University of Sheffield, UK

Contributors

50: Sexuality in older age

Baichun Hou Sam and Rose Stein Institute for Research on Aging, University of California San Diego, La Jolla, CA 92093, USA

43: Late-onset schizophrenia

Alan Howarth Consultant Clinical Psychologist, Cumbria Northumberland Tyne & Wear NHS Foundation Trust and Gateshead Health NHS Foundation Trust

19: Non-pharmacological interventions in care homes

Julian C. Hughes RICE Professor of Old Age Psychiatry, Population Health Sciences, Bristol Medical School, University of Bristol, UK.

51: Ethics and old age psychiatry; 52: Mental capacity and decision-making

Jonathan Huntley Consultant Psychiatrist and Clinical Research Fellow, Division of Psychiatry, University College London, UK

9: Psychiatric assessment of older people

Abdul Hye Post-doctoral Researcher, Department of Old Age Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

8: Molecular genetics and biology of dementia

K. S. Jacob Professor of Psychiatry, Christian Medical College, Vellore, India

21: Psychiatric presentations among older people living in low- and middle-income countries

Ian A. James Consultant Clinical Psychologist, Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust; Visiting Professor, University of Bradford, UK

19: Non pharmacological interventions in care homes

Kurt Jellinger Director, Institute of Clinical Neurobiology, Vienna, Austria

5: Neuropathology

Dilip V. Jeste Senior Associate Dean for Healthy Aging and Senior Care; Estelle and Edgar Levi Chair in Aging; Director, Sam and Rose Stein Institute for Research on Aging; Distinguished Professor of Psychiatry and Neurosciences, University of California San Diego, La Jolla, CA 92093, USA

43: Late-onset schizophrenia

Katy A. Jones Assistant Professor in Applied Psychology, Division of Psychiatry and Applied Psychology, School of Medicine, University of Nottingham, UK

46: Alcohol and substance misuse

Roy W. Jones Director, RICE (The Research Institute for the Care of Older People), Royal United Hospital, Bath; Honorary Consultant Geriatrician; and Honorary Professor, University of Bath and University of Bristol, UK

35: Pharmacological treatment of dementia

John Keady Professor of Older Peoples Mental Health, Division of Nursing, Midwifery & Social Work, The University of Manchester/ Greater Manchester Mental Health NHS Foundation Trust, UK

15: Person- and relationship-centred dementia care

Contributors

Tom B. L. Kirkwood Professor Emeritus, Newcastle University
Institute for Ageing, University of Newcastle upon Tyne, UK

1: Biological aspects of human ageing

Louise Lafortune Principal Research Associate, Cambridge Public
Health, University of Cambridge, UK

28.3: The contribution of an early or timely diagnosis

Ken Laidlaw Professor of Clinical Psychology and Programme
Director DCLinPsy; Director of Postgraduate Research Programmes,
Psychology; College of Life and Environmental Sciences, University of
Exeter, UK

*16: Psychological treatments; 17: Cognitive behaviour therapy; 18:
Interpersonal therapy*

Ellen E. Lee Assistant Professor, Department of Psychiatry, University
of California San Diego, La Jolla, CA 92093, USA

43: Late-onset schizophrenia

Simone Lista Senior Post-doctoral Fellow at the Sorbonne University
Groupe de Recherche Clinique (GRC n°21) "Alzheimer Precision
Medicine (APM)", Pitié-Salpêtrière Hospital, Paris, France; Chief
Scientific Officer (CSO) of the Alzheimer Precision Medicine Initiative
(APMI)

6: Biomarkers for Alzheimer's disease

Jill Manthorpe Professor of Social Work, NIHR Policy Research Unit
in Health and Social Care Workforce, King's College London

55: Elder abuse

Deepti Marchment NIHR Academic Clinical Fellow, Department of
Clinical Neurosciences, University of Cambridge, UK

29: Mild cognitive impairment

Alisoun Milne Professor of Social Gerontology and Social Work,
School of Social Policy, Sociology and Social Research, University of
Kent, UK

26: Care homes for older people

Thais Minett Department of Public Health and Primary Care; and
Director, Cambridge Institute of Public Health, University of
Cambridge, UK

4: Epidemiology of old age psychiatry

Brian Moore Department of Academic Psychiatry, Wolfson Research
Centre, Campus for Ageing & Vitality, University of Newcastle upon
Tyne, UK

47: Older people with intellectual disability

Jo Moriarty Senior Research Fellow, NIHR Health & Social Care
Workforce Research Unit, King's College London, UK

25: Social care

Urs Mosimann Medical Director, Inselspital, University Hospital
Bern, Switzerland

48: Sleep and circadian rhythm disorders

Lauren Mussen Assistant Professor, Geriatric Psychiatry, Schulich
School of Medicine & Dentistry, Western University, London, Ontario,
Canada

41: Manic syndromes in old age

Contributors

Mike Nolan Emeritus Professor of Gerontological Nursing, The School of Nursing & Midwifery, University of Sheffield, UK
15: Person- and relationship-centred dementia care

Daniel W. O'Connor Emeritus Professor, Monash University, Victoria, Australia

14: Neurostimulation therapies

Seán O'Dowd Consultant Neurologist, Tallaght University Hospital, and Academic Unit of Neurology, Trinity College, Dublin, Ireland

10: Clinical cognitive assessment

Keith Oliver Retired head teacher, living with dementia; Alzheimer's Society Ambassador, and Dementia Envoy, Kent and Medway NHS and Social Care Partnership Trust, Kent, UK

28.1: Getting a diagnosis

Desmond O'Neill Consultant Physician in Geriatric and Stroke Medicine and Professor of Medical Gerontology, Trinity Centre for Health Sciences, Tallaght University Hospital, Dublin, Ireland

57: Driving and psychiatric illness in later life

Jan Oyebo Professor of Dementia Care, Centre for Applied Dementia Studies, University of Bradford, Bradford, UK

54: Carers and dementia

Sahdia Parveen Senior Research Fellow, Centre for Applied Dementia Studies, University of Bradford, Bradford, UK

54: Carers and dementia

Christos Plakiotis Adjunct Senior Lecturer, Monash University, Victoria, Australia

14: Neurostimulation therapies

Carole Proctor Lecturer, Institute of Cellular Medicine, University of Newcastle upon Tyne, UK

1: Biological aspects of human ageing; 2: The ageing brain

Rahul (Tony) Rao Consultant Old Age Psychiatrist, South London & Maudsley NHS Foundation Trust; and Visiting Researcher, Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK

46: Alcohol and substance misuse

Mark J. Rapoport Professor, Geriatric Psychiatry, University of Toronto; Staff Psychiatrist, Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada.

57: Driving and psychiatric illness in later life

Louise Robinson Director, Newcastle University Institute for Ageing; NIHR Professor and Senior Investigator; Professor of Primary Care and Ageing, Campus for Ageing and Vitality, University of Newcastle upon Tyne, UK

22: Primary care management of older people's mental health problems

Jonathan D. Rohrer MRC Clinician Scientist and Honorary Consultant Neurologist, Dementia Research Centre, Department of Neurodegenerative Disease, UCL Queen Square Institute of Neurology, University College London, UK

33: Frontotemporal dementia

Contributors

Arvid Rongve Clinical Researcher, Department of Research and Innovation, Helse-Fonna, Haugesund, Norway; Associate Professor, Department of Clinical Medicine (K1), University of Bergen, Norway
32: The Lewy body dementias

Elizabeth Sampson Professor of Dementia and Palliative Care, Marie Curie Palliative Care Research Department, Division of Psychiatry University College London, UK
27: Palliative care and end-of-life care

Claire E. Sexton Postdoctoral Research Fellow, Department of Psychiatry, University of Oxford, Warneford Hospital, Oxford, UK
12: Neuroimaging

Blossom CM Stephan Professor of Neuroepidemiology & Global Ageing, Division of Psychiatry & Applied Psychology, University of Nottingham, UK
4: Epidemiology of old age psychiatry

Chapter: Biological aspects of human ageing

Author(s): Doug Gray, Carole Proctor, and Tom Kirkwood

DOI: 10.1093/med/9780198807292.003.0001

Introduction

The persistence of childhood memories in the mind of a centenarian is evidence enough of the remarkable durability of the brain at the tissue, cellular, and molecular levels, but it is beyond dispute that the brain of the most cognitively favoured centenarian will have suffered structural decline. For organisms in possession of a nervous system, such decline does not appear to be inevitable; though its nervous system is undoubtedly simpler, the freshwater cnidarian *Hydra* is able to escape such decline and, barring misfortune, is potentially immortal (Martinez, 1998). What separates *Hydra* from more familiar metazoans is not the simplicity of its nervous system, but rather its departure from the scheme of having specialized germline versus somatic cells. If (as in *Hydra*) all our cells had the qualities of multipotent stem cells, there would be no need for regenerative medicine. In humans, most cells (including neurons) are terminally differentiated somatic cells. Stem cells are rare, and for reproductive success, only the germ cells must be kept in pristine

Biological aspects of human ageing

condition. Kirkwood's 'disposable soma' theory posits that, with only finite resources available to an organism, there must be a trade-off between the resources allocated to reproduction and the resources allocated to repair (Kirkwood, 1977). Any reduction in repair will be accompanied by the accumulation of molecular damage, and it is the accumulation of damage that drives ageing (Fig. 1.1). The inherent stochasticity of damage is sufficient to explain the lack of uniformity in ageing in genetically identical organisms (discussed in Kirkwood, 2008), and the inevitability of decline in the face of unrepaired molecular damage precludes the requirement for any programme 'for' ageing (other arguments have been marshalled towards the conclusion that no such programme is required or indeed has been demonstrated (Kirkwood and Melov, 2011)).

Fig. 1.1

Molecular damage affects multiple systems in ageing neurons.

The structural decline of the brain that is a hallmark of human ageing arises from unrepaired stochastic damage to its components, and it is the purpose of this chapter to deal with such damage at the molecular and cellular levels. It is widely accepted that the source of much damage in the ageing brain is reactive oxygen species (ROS), a collective term for oxygen radicals and other entities that cause oxidative damage (Halliwell, 2006). There is no escaping ROS—it constitutes a necessary by-product of cellular metabolism and a necessary intermediate of a number of cell signalling cascades (Nathan, 2003). Because of its energy demands, the brain is a voracious consumer of oxygen and a prodigious producer of ROS. The brain contains sufficient quantities of metal ions (notably those of iron) to ensure the production of reactive hydroxyl anions through Fenton chemistry (the thermodynamically favoured process which,

Biological aspects of human ageing

through oxidation of metal ions, promotes the decomposition of hydrogen peroxide into hydroxyl anions and hydroxyl radicals) and, in addition, contains high levels of neurotransmitters such as dopamine, norepinephrine, and serotonin whose metal ion-catalysed oxidation can promote a vicious cycle of toxicity and further ROS release (Halliwell, 2006). The damage to biological molecules by ROS is not discriminating and will affect proteins, nucleic acids, carbohydrates, and lipids. Without discounting the importance of other molecular targets of ROS damage, the emphasis of the current chapter will primarily be on proteins and DNA, and the organelles and pathways most dependent on the continued integrity of these molecules (Fig. 1.2).

Fig. 1.2
Molecular damage underlies ageing.

Molecular aspects of ageing in the brain

Protein damage

To appreciate the consequences of oxidative damage to proteins and DNA within the ageing brain, one must first consider the very different fates of these entities. For the most part, proteins have limited half-lives and are constantly being replaced (an interesting exception being crystallin proteins within the lens; lens crystallins are permanent and, as such, can be used for accurate carbon-dating of individuals born during the era of atmospheric atomic tests!) (Lynnerup et al., 2008). DNA, on the other hand, must persist for the lifetime of the cell (temporarily leaving aside the more specialized case of mitochondrial DNA (mtDNA)). Though neurons, being post-mitotic, do not require pristine templates for DNA replicative purposes, the integrity of the genome is required for their

Biological aspects of human ageing

active programme of ongoing transcription. It is therefore not surprising that damaged proteins are generally eliminated from mammalian cells (again, excepting damaged lens crystallins, whose destiny is the lens cataract), whereas damaged nuclear DNA is actively repaired.

There exist two cellular systems for the degradation of proteins, one involving membrane-bound vesicular trafficking of substrates and the other providing access to substrates throughout the cytoplasm and nucleus. The autophagic system is reliant on the engulfment of cellular components into membrane-delimited compartments which, upon fusion with lysosomes, become autophagosomes. Through autophagy, substrates are typically degraded on a timescale of hours, but the system has the capacity to process entire organelles (oxidatively damaged mitochondria, for example) and degrade all of the macromolecules therein. The ubiquitin/proteasome system (UPS), on the other hand, is a more specialized system for the degradation of proteins and, without the requirement for membrane trafficking, can operate on a much more rapid timescale. The UPS has remarkable specificity, discriminating between short-lived and long-lived proteins, post-translationally modified versus unmodified proteins, and normally structured versus aberrant and/or damaged proteins. This specificity is mediated by more than a thousand ubiquitin ligase (E3) enzymes that, in concert with a lesser number of ubiquitin-conjugating (E2) enzymes, associate with particular proteins and assemble upon them a chain of ubiquitin proteins (Hochstrasser, 1996). Once the chain reaches a threshold length of four ubiquitin monomers, the chain has physical affinity for subunits of the 26S proteasome (Piotrowski et al., 1997), and delivery of the substrate to this degradation machine results in its proteolytic destruction.

The hallmark of age-related neurodegenerative diseases is the appearance of protein conglomerates within the cytoplasm or nucleus of neurons and, in some cases, glia. These entities are of sufficient size to be visible by light microscopy and, in general, are designated inclusion bodies (Woulfe, 2007), though more specific designations may be associated with particular diseases (for example, the Lewy body in Parkinson's disease (PD) and Lewy body dementia). The composition of the inclusion body may vary from one neuropathological state to the next, but there is often a major constituent that typifies the disease and is its aetiological agent (for example, α -synuclein in the case of the Lewy body (Eriksen et al., 2003)). Most inclusion bodies are immunoreactive for ubiquitin, which may signify the failure of the UPS to eliminate their constituent proteins (Gray et al., 2003). Indeed, the most parsimonious explanation for inclusion bodies is the passive agglomeration of aberrant proteins which, as a result of damage or misfolding, expose hydrophobic regions that would normally be concealed within structural folds. While this may be true for nuclear inclusions, the situation in the cytoplasm may be more complex. There is evidence that proteins are actively transported along microtubules to aggresomes (cytoplasmic inclusions assembled in the vicinity of the centriole) (Johnston et al., 1998). It has been suggested

Biological aspects of human ageing

that Lewy bodies may represent a form of aggresome (McNaught et al., 2002), though the behaviour and composition of aggresomes in cell culture models are not in complete agreement with findings from autopsy specimens (Waxman et al., 2009), and questions remain about the relationship of these entities.

Inclusion bodies can be detected in the brains of normal aged individuals (those not diagnosed with neurodegenerative disease), and it is reasonable to suggest that their presence denotes the age-related decline of proteolytic efficiency. Examples of such inclusions would include the rod-like and skein-like inclusions of the aged neostriatum, the granular cytoplasmic inclusions of the inferior olivary nucleus, and the colloid or hyaline inclusions of the hypoglossal and spinal motor neurons of the elderly (discussed in Gray et al., 2003). Though the protein constituents of these inclusions are at present poorly characterized, their age-related deposition points to the existence of a 'tipping point', beyond which the rate of accumulation of abnormal protein exceeds the capacity for its elimination, resulting in widespread protein aggregation and the ultimate accretion of aggregates into inclusion bodies. In the absence of heritable DNA mutations, the source of the abnormal protein would be stochastic damage and misfolding from intrinsic ROS production or ROS from environmental sources, coupled with the incessant production of misfolded protein from translational and post-translational errors (accounting for as much as a third of total protein production by some estimates (Schubert et al., 2000)). In the disease state, inclusions would occur precociously due to the added burden of abnormal protein, either genetically encoded or of idiopathic origin. The tipping point conjecture is surely consistent with the observation that the symptoms of pernicious inherited diseases (Huntington's disease, for example) do not become apparent until adulthood is attained, and often not until late in life. The correlation (Gusella and MacDonald, 2006) between disease onset in Huntington's disease and the length of the expanded polyglutamine tract in the affected protein also fits with the tipping point conjecture; the longer the repeat, the greater the burden to the UPS and the earlier it is likely to be overwhelmed. The greater prevalence of inclusions within neurons, as opposed to glia, of Huntington's disease patients is also in agreement with the conjecture or is at least in agreement with findings from cell culture model systems of these cell types. UPS activity was found to be lower in cultured mouse neurons than in cultured glia and shows a more pronounced age-related decline (Tydlacka et al., 2008). Mutant huntingtin protein was efficiently degraded in cultured glia unless proteasome activity was pharmacologically inhibited (Tydlacka et al., 2008).

The functional basis of UPS decline in ageing individuals has yet to be fully elucidated. That UPS efficiency does decline is evident from the accumulation of UPS substrates in mouse brain lysates, typically visualized by probing western blots of such samples with an antibody specific for ubiquitin. What is observed is an age-dependent increase in

Biological aspects of human ageing

the intensity of a high-molecular weight smear (Gray et al., 2003; Ohtsuka et al., 1995), also observed in the brain of human Huntington's disease patients and mouse models thereof (Bennett et al., 2007). This smear arises from ubiquitin chains linked to a range of protein substrates (Bennett et al., 2007). The proteolytic deficit that generates this backlog of undigested UPS substrates could arise from the age-related decline in the expression of some key UPS component or components, and microarray studies (Blalock et al., 2003; Lee et al., 2000) have identified candidate UPS components whose levels were decreased in aged mouse brains (at least at the RNA level). Proteasome activity has been shown to decline in the ageing brain (Keller et al., 2002), but this decline has not been strongly correlated with a reduction of any of the proteasome subunits and may reflect damage to the proteasome, rather than the loss of expression.

The prospect of proteasome damage raises an interesting 'chicken and egg' problem. Does a growing burden of protein damage within the brain ultimately overwhelm the capacity of the proteasome, or does age-related damage to the proteasome itself (from ROS or other sources) eventually generate the backlog of undigested substrates? It is conceivable, perhaps likely, that a vicious cycle of inhibitions exists, and regardless of the entry point, the outcome will be deleterious for the cells in which the vicious cycle occurs (Fig. 1.3). Support for such an inhibitory cycle comes from time lapse imaging and stochastic computer modelling of cells expressing aggregation-prone proteins (Tang et al., 2010), wherein reciprocal inhibition is apparently mediated by ROS. This study also highlighted the importance of the stress-activated p38 mitogen-activated protein (MAP) kinase (MAPK) molecule in mediating the death of inclusion-bearing cells. Because it can be activated by oxidative conditions (via the redox-sensitive upstream ASK1 kinase) (Matsuzawa and Ichijo, 2008), p38 MAPK would be responsive to the operation of the proposed vicious cycle, and in the experimental system, cell survival can be enhanced by pharmacological or genetic inhibition of p38 (Tang et al., 2010), but not other MAPKs (Tsirigotis et al., 2008).

Fig. 1.3

Loss of balance in protein homeostasis typifies ageing at the cellular level.

For purely physical reasons, the formation of an inclusion body would seem a potentially catastrophic event, and the long association of

Biological aspects of human ageing

inclusion bodies with neuropathological conditions has cast them in an understandably negative light, but there is a body of work that would argue the converse—under some conditions, inclusion body formation appears to correlate with neuronal survival. The best evidence for the neuroprotective effect of inclusions comes from live cell imaging of neurons made to express fluorescent versions of an aggregation-prone protein. In these experiments, it is possible to track the fate of individual cells and, in so doing, to document the enhanced survival of neurons that formed inclusions early (Arrasate et al., 2004). The supposition (now widely accepted) is that smaller-order aggregates (oligomers) are the more toxic entities, perhaps because of their propensity to bind promiscuously to essential cellular proteins. By sequestering such dangerous entities into inclusions, their potential for promiscuous interactions is diminished and neuroprotection is hence conferred. While the beneficial effect of inclusions in the cell culture model system is indisputable, the time frame of such experiments is necessarily short and may not reflect the fate of neurons laden with inclusions *in situ*. Inclusions are known to concentrate iron and may serve as centres of Fenton-mediated ROS production (Firdaus et al., 2006). The long-term effects of localized ROS production around inclusions are unlikely to be beneficial.

A final, rather terrifying aspect of the aberrant proteins and protein aggregates that accumulate in the ageing brain is their potential to spread to adjacent and/or distant cells and wreak havoc in a prion-like manner. The spreading or ‘seeding’ of protein aggregates has been the subject of great interest and has been discussed in the context of a growing list of aggregation-prone proteins, including β -amyloid, α -synuclein, tau, huntingtin, superoxide dismutase, fused in sarcoma (FUS), and transactivation-responsive (TAR) DNA-binding protein 43 (TDP-43) (Brundin et al., 2011; Dunning et al., 2012; Jucker and Walker, 2011; Polymenidou and Cleveland, 2011). Aggregates may be actively secreted through exocytosis into the extracellular milieu or within membrane-delimited exosomes that could travel through the vasculature to distant sites. Aggregates may also be released passively during cell death and be taken up by endocytic pathways of nearby cells, or may travel through tunnelling nanotubes to access adjacent cells, as has been documented for prions (Gousset et al., 2009). Aggregate seeding has been proposed as a possible mechanism for the propagation of pathology in a number of age-related conditions in which localized neurodegeneration becomes more widespread. In Alzheimer’s disease (AD), the tau tangles stereotypically occur first in the locus caeruleus and transentorhinal area, then spread to the amygdala and connected cortical regions (Braak and Braak, 1991). In PD, though not in all Lewy body diseases, there may be a spread of pathology through anatomically connected regions of the brainstem, limbic system, and neocortex, but it has been hypothesized that this pathology is preceded by degenerative changes in olfactory structures and the enteric plexus, perhaps due to exposure of these tissues to an environmental agent such as a virus (Jang et al., 2009). If

Biological aspects of human ageing

with ageing, there is a relentless loss of protein-degradative capacity, as described earlier, it would follow that the aggregate 'seeds' would find increasingly fertile soil in the neurons of the aged brain.

DNA damage

It is beyond the scope of this chapter to summarize the extensive literature on age-related damage to the DNA genome (a subject that merits book-length treatment on its own (Vijg, 2007)), but the extensive reliance of DNA repair systems on ubiquitin-mediated proteolysis leads to the necessary conclusion that age-related decline of the latter will ultimately compromise the former. Ubiquitin is employed in some forms of DNA repair in a non-proteolytic role as a scaffold or molecular switch (Chiu et al., 2006), but in post-mitotic cells such as neurons, it is the proteolytic function of the UPS in nucleotide excision repair (NER) that is of paramount importance (Nospikel, 2011). In particular, it is the transcription-coupled repair (TCR) system, a subsystem of NER, that is of greatest relevance. TCR is charged with maintaining the integrity of the transcribed strand of DNA; for metabolically active cells such as neurons, a lesion within a coding region can block transcription, with disastrous consequences, and such lesions must be detected and rapidly repaired. A second form of NER (global genome repair, or GGR) maintains genomic integrity at sites throughout the genome but, for post-mitotic cells, is much less critical. The TCR and GGR pathways have shared components and components that are unique, but both sense distortions of the double helix and ultimately utilize common ubiquitin-mediated degradation machinery (based on cullin 4A complexes) to remove multicomponent repair systems from the repaired lesion. As a last resort, stalled RNA polymerase II can itself be degraded by the ubiquitination machinery of the TCR system to 'reboot' gene transcription. The importance of TCR to neuronal homeostasis was suggested by the neuronal deficits of individuals bearing mutations in TCR-related genes, and has been confirmed experimentally by the age-related neurodegenerative phenotypes of mice engineered to be deficient in TCR components (Jaarsma et al., 2011). As the efficiency of ubiquitin-mediated proteolysis declines, so too should the efficiency of TCR. Should TCR efficiency fall below a critical threshold, the subsequent shutdown of transcription could only imperil the functioning of the ageing brain.

Ageing at the cellular and systems level

Genetics and epigenetics

There is strong evidence for the role of genetics in age-related diseases, especially cardiovascular diseases, diabetes, AD, and PD (Ruse and Parker, 2001). A systematic review of published family, twin, linkage, and association studies found evidence for the role of several genes in successful ageing (Glatt et al., 2007). These genes included *APOE*, *GSST1*, *IL6*, *IL10*, *PON1*, and *SIRT3*. The role of *APOE* in AD is well known. It exists as three different alleles: *APOE2*, *APOE3*, and *APOE4*,

Biological aspects of human ageing

with the E4 isoform being the most recognized genetic risk factor for late-onset AD (Saunders et al., 1993). Conversely, the rarer E2 isoform is associated with a protective role (Corder et al., 1994), and the most frequent E3 isoform shows an intermediate effect in terms of both disease risk and age of onset. Many genome-wide association studies (GWAS) have been carried out for individual age-related diseases. However, a more effective approach has been recently demonstrated in which information from GWAS and candidate gene studies were combined to find allelic variants that simultaneously increase the risk of several age-related diseases (Kulminski et al., 2016).

There are many model systems to address the role of genetics in ageing, including nematode worms (*Caenorhabditis elegans*), fruit flies (*Drosophila melanogaster*), mouse, and yeast. These species are short-lived, and so it is feasible to measure the effects of different genetic strains on maximum and average lifespan. The first 'longevity gene' found in *C. elegans* was *AGE-1* (Friedman and Johnson, 1988), and since then approximately 750 genes have been discovered which affect lifespan in *C. elegans*. A set of genes which have attracted a lot of attention are those involved in an insulin-like signalling pathway and which regulate the activity of the transcription factor DAF-16. Genes involved in insulin signalling are also known to affect the lifespan of *D. melanogaster* and mice. In humans, a variant at the FOXO3A locus has been linked with longevity (reviewed in Martins et al., 2016). Other proteins and pathways that have been shown to have effects on ageing are the Sirtuins, the insulin/insulin-like growth factor signalling (IIS) pathway and the mammalian target of rapamycin (mTOR) pathway (reviewed in Pan and Finkel, 2017). For example, mutations that decrease TOR activity have been shown to extend lifespan in *C. elegans*, *D. melanogaster*, yeast, and mice (Jia et al., 2004; Kapahi et al., 2004; Powers et al., 2006; Selman et al., 2009).

Epigenetic alterations with age has recently been categorized as one of the hallmarks of ageing (López-Otín et al., 2013). Epigenetic mechanisms involve changes in gene expression which are not due to changes in the DNA sequence, but rather in gene regulatory mechanisms such as DNA methylation, histone deacetylation, and non-coding RNAs. Epigenetic changes are essential during development and differentiation but can also occur later in life in response to changes in the cellular environment or as a result of random errors. These changes are passed on when cells divide but are generally not passed on through the germ line. DNA methylation is the most studied epigenetic modification and is the subject of many reviews in the context of ageing (for example, Gravina and Vijg, 2010; Jones et al., 2015; Xiao et al., 2016). Approximately 40% of promoters in mammalian genes contain clusters of unmethylated CpG pairs, known as CpG islands. These islands are targets for transcription factors. During ageing, changes in methylation status of CpG islands occur which can lead to either hypermethylation or hypomethylation. Recently it has been shown in mice that DNA methylation of certain CpG sites may be a

Biological aspects of human ageing

predictor of chronological age (Petkovich et al., 2017). In human ageing, epigenome-wide association studies (EWAS) have tried to identify an epigenetic clock whereby methylation changes at certain loci consistently change with age in different individuals. The CpG island of the gene *ELOVL2* is highly ranked as an age-differentially methylated region (a-DMR) in nearly all EWAS in a variety of tissues (reviewed in Bacalini et al., 2017). However, only a few a-DMRs have been associated with changes in gene expression, for example, *BDNF* and *SST* have lower gene expression in the orbital frontal cortex of older individuals (McKinney et al., 2015). Stochastic changes in methylation lead to a divergence of the epigenome with age, a phenomenon known as epigenetic drift, that is particularly evident in studies of monozygotic twins (for example, Fraga et al., 2005). A link between epigenetics and the senescence pathway (discussed in Cellular mechanisms of ageing) has received much attention in recent years (reviewed in Sidler et al., 2017). MicroRNAs (miRNAs) are short non-coding RNAs that interact with target genes by enhancing degradation or preventing translation of messenger RNA (mRNA). A comprehensive discussion of miRNAs in ageing is beyond the scope of this chapter, but we refer the interested reader to a recent comprehensive review (Williams et al., 2017) and to a brief discussion of the role of miRNAs in the ageing brain (Chapter 2).

Cellular mechanisms of ageing

Mitochondria

Mitochondria are the powerhouse of the cell, producing most of the cell's supply of adenosine triphosphate (ATP). They also produce ROS as a by-product of respiration, which can damage cellular components. Mitochondria are themselves particularly prone to damage since they are close to the source of ROS, and it has long been considered that mtDNA mutations contribute to ageing (Linnane et al., 1989). Mitochondria are very dynamic organelles and undergo turnover (independently of the cell cycle), fusion, fission, and movement through the cell. Movement of mitochondria is particularly important in neurons since they are required at synapses, and so they are continually transported from the cell body to axonal synapses (anterograde transport) and back again (retrograde transport) for degradation. There is evidence for impaired movement in age-related neurodegenerative diseases. A mouse model of Huntington's disease reported impairment in both anterograde and retrograde transport in cells in specific neurons which are known to be susceptible to cell death in the human disease (Her and Goldstein, 2008).

In AD, it has been shown that amyloid beta impairs anterograde transport, resulting in degeneration of synapses (Calkins and Reddy, 2011). Furthermore, the mitochondrial protein Pink1, which is mutated in some familial forms of PD, has been shown to play a role in mitochondrial transport (Weihofen et al., 2009). Mitochondria are degraded by lysosomes by a process known as mitophagy (mitochondrial autophagy). For many years, this was considered a random process, but there is

Biological aspects of human ageing

increasing evidence that mitophagy is selective (reviewed by Wei et al., 2015). For example, it has been shown that Pink1 is recruited to mitochondria with Parkin (an E3 ubiquitin ligase), inducing mitophagy (Kawajiri et al., 2010) and a vesicular pathway to selectively remove damaged mitochondrial proteins (McLelland et al., 2014). The latter study showed that PD-associated Parkin mutants lost the ability to perform this role. Since lysosomal degradation pathways decrease in efficiency with age, there is also impaired degradation of mitochondria, which could lead to an increase in the levels of dysfunctional mitochondria. Degradation of mitochondria must be balanced by biogenesis of new mitochondria in order to maintain mitochondrial numbers, but this has been shown to be diminished with age (Fannin et al., 1999). In addition, PGC-1 α , an intracellular mediator of biogenesis, has been shown to be decreased in age-related diseases such as diabetes and neurodegeneration (reviewed by Wenz, 2011). Mitochondria form networks and continuously undergo fission and fusion whereby an individual mitochondrion either leaves or joins the network, respectively. The purpose of fission and fusion is still unclear, but the general consensus is that it allows exchange of mtDNA and mitochondrial proteins and helps to segregate damage prior to fission and degradation. In neurons, fission and fusion of mitochondria take place in the cell body and also along axons and has been widely studied using live cell imaging (Jahani-Asl et al., 2007; Twig et al., 2008). Disturbances in the balance of fission and fusion, resulting in abnormally long or short mitochondria, have been implicated in age-related neurodegeneration (Knott and Bossy-Wetzel, 2008).

The importance of mitochondria in ageing was highlighted in 1991 by the proposal of the mitochondrial theory of ageing (Miquel, 1991), an extension of the free radical theory (Harman, 1956), being based on the idea that ROS generated by mitochondria induce mutations in mtDNA which leads to more ROS, and a vicious cycle ensues. There is a wealth of evidence to support the mitochondrial theory of ageing. For example, studies have shown that an excess production of ROS leads to more mtDNA damage in human tissues (Cortopassi and Arnheim, 1990; Hayakawa et al., 1991; Hayakawa et al., 1992). Conversely, targeting catalase to mitochondria led to lower levels of mtDNA mutations and extended lifespan (Schriner et al., 2005). There is evidence for an accumulation of mtDNA mutations with age (Wallace, 1999). In particular, high levels of deleted mtDNA were found in substantia nigra neurons from both aged controls and individuals with PD (Bender et al., 2006; Kraytsberg et al., 2006). These mtDNA mutations are somatic, with different clonally expanded deletions in individual cells, and high levels of these mutations are associated with respiratory chain deficiency. Respiratory activity has been shown to be decreased with age in several human tissues, for example in the liver (Yen et al., 1989) and skeletal muscle (Conley et al., 2000; Trounce et al., 1989). In addition, it has been shown that accelerating the mtDNA mutation rate can result in premature ageing. For example, mice with a mutant *POLG*, the gene that encodes the only mtDNA polymerase, prematurely exhibited many

Biological aspects of human ageing

phenotypes associated with human ageing and had shorter lifespan (Kujoth et al., 2005; Trifunovic et al., 2004). Age-related increases in the frequency of cytochrome c oxidase (COX)-deficient cells, which are associated with mtDNA mutation, have been reported in human muscle (Brierley et al., 1998; Muller-Hocker, 1989), brain (Cottrell et al., 2000; Cottrell et al., 2001), and gut (Taylor et al., 2003). Cells in which mtDNA mutation reaches a high level are likely to suffer from impaired ATP production, resulting in a decline in tissue bioenergenesis. However, there is also controversy about the role of mitochondrial damage in ageing and some studies in mice show that there is no effect of mitochondrial antioxidants on lifespan (reviewed by Jang and Remmen, 2009). Interestingly, although the *POLG* mice model demonstrated that an increase in mitochondrial mutations was associated with a variety of ageing phenotypes, the mice did not show any signs of increased oxidative stress (Trifunovic et al., 2005). This puts into question the idea that oxidative stress plays a major role in the ageing process. A study that counters the mitochondrial theory of ageing is a long-lived mouse, heterozygous for *CLK1* (CDC-like kinase 1), a mitochondrial enzyme necessary for ubiquinone biosynthesis, despite having massive mitochondrial dysfunction starting early in life (Lapointe and Hekimi, 2008). Therefore, the link between mitochondria and ageing is complex. In particular, mitochondria cannot be considered alone, as they affect many other cellular mechanisms. For example, a study suggests interplay between mitochondrial and proteasome activity in skin ageing (Koziel et al., 2011).

Telomeres

Telomeres are repetitive sequences of non-coding DNA that protect the ends of chromosomes from degradation and end-to-end fusions. In humans, telomeres end with a stretch of single-stranded DNA, known as G-overhangs which form a T-loop structure. This structure is bound and stabilized by proteins to form a so-called cap to distinguish it from a DNA break. Telomeres shorten with each cell division due to the end-replication problem (Olovnikov, 1971) and also oxidative stress which has been shown to accelerate telomere shortening by causing single-strand breaks in telomeric DNA (von Zglinicki, 2002). Further evidence for the role of oxidative stress is that the addition of antioxidants to cell cultures slows telomere shortening (Serra et al., 2003). Telomeres need a minimum length in order to maintain their capped structure; however, the exact threshold required is not known. Short uncapped telomeres are seen by the cell as DNA damage, leading to induction of the DNA damage response. This can result in permanent cell cycle arrest, also known as cellular or replicative senescence, which is discussed in more detail in Cellular senescence.

Telomerase is an enzyme that elongates telomeres. In humans, it is active in most embryonic tissues during early development. However, it is down-regulated during cellular differentiation in most somatic cells, apart from endothelial cells and some adult stem cells. Therefore, telomeres shorten

Biological aspects of human ageing

with age in most human tissues and organs (Djojosebroto et al., 2003). Telomere shortening was not observed in the brain during ageing in a study which analysed whole-organ biopsies (Allsopp et al., 1995); however, this does not preclude the possibility that telomere shortening occurs during ageing in specific regions of the brain or that telomere shortening in other cell types affects brain function (Jiang et al., 2007). For example, patients with AD have abnormally short telomeres in lymphocytes, when compared to age-matched controls (Panossian et al., 2003).

A meta-analysis of telomere length in PD for eight published studies indicated that there is no consistent evidence of shorter telomeres in this disorder (Forero et al., 2016). However, a more recent study which was not included showed that telomeres of PD patients were shorter in buccal epithelial cells, but identical in blood cells, compared to age-matched controls (Kolyada et al., 2016).

Studies have investigated whether telomere length could be used as a biomarker of ageing and age-related diseases; however, it has been shown that data are inconsistent (reviewed in Sanders and Newman, 2013). More recently, an interesting study indicated that telomere length and the DNA methylation epigenetic clock are independently associated with chronological age (Marioni et al., 2016). To conclude, despite the inconclusive evidence so far, research into the role of telomere shortening in ageing continues, and with the advancement of new techniques, conclusive evidence of a correlation between telomere length and healthy ageing may be obtained in future (Sanders and Newman, 2013).

Cellular senescence

The fact that human fibroblast cells can only divide a limited number of times was first discovered by Leonard Hayflick and Paul Moorhead in the early 1960s (Hayflick and Moorhead, 1961). The maximum proliferative lifespan of cells is called the Hayflick limit, and the irreversible loss of division potential of somatic cells is known as replicative cellular senescence. Telomere shortening has long been thought to be the biological counter for replicative senescence. However, it is not telomere length per se that triggers cell arrest, but rather some property of the telomere such as uncapping (von Zglinicki, 2003). As well as replicative senescence, cells can also undergo telomere-independent senescence via the DNA damage response (d'Adda di Fagagna, 2008), protein damage (Castro et al., 2012), and mitochondria dysfunction (Miwa et al., 2014). Cellular senescence acts as a tumour suppressor mechanism (Bartek et al., 2007) and is also involved in tissue remodelling after an acute damaging event, after which the senescent cells are cleared by the immune system (reviewed in Childs et al., 2015). However, senescence which has been triggered by chronic stress contributes to a loss of tissue homeostasis in human ageing. This is evident by the increase in senescent cells with age in various tissues (Dimri et al., 1995; Farr et al., 2016; Jurk

Biological aspects of human ageing

et al., 2012; Wang et al., 2009) and in age-related diseases (reviewed in Childs et al., 2015).

There is evidence for a link between mitochondrial dysfunction and senescence (reviewed in Korolchuk et al., 2017) and, in particular, a recent study showed that loss of mitochondrial sirtuins (SIRT6) induced senescence with a distinct senescent phenotype involving the NADP-AMPK-p53 pathway (Wiley et al., 2016). On the other hand, senescence induction of the DNA damage response contributes to mitochondrial dysfunction, known as senescence-associated mitochondrial dysfunction (SAMD), leading to higher ROS production through a signalling pathway involving p53, p21, p38, and TGF β (Passos et al., 2010). In addition, this study showed that ROS contribute in a stochastic manner to the long-term maintenance of DNA damage foci, leading to permanent cell cycle arrest.

Senescent cells have a detrimental effect on neighbouring cells and the surrounding extracellular matrix, a phenomenon known as the bystander effect. This has been demonstrated *in vitro* in senescent human fibroblasts, and possibly *in vivo* in mouse liver hepatocytes (Nelson et al., 2012). The bystander effect may be due to senescent cells secreting not only inflammatory cytokines and growth factors, termed the senescence-associated secretory phenotype (SASP), but also reactive species, such as ROS and nitric oxide (NO), which then diffuse into neighbouring cells and cause DNA damage (Sokolov et al., 2007). A recent study in MRC fibroblasts provided evidence that both SASP and SAMD are involved in the bystander effect (Nelson et al., 2017) by showing that the DNA damage response induces SAMD, which leads to a further increase in ROS, activation of SASP via NF κ B, and induction of DNA damage in bystander cells. However, they found that neither interleukin (IL)-6 nor IL-8 played a major role in the bystander effect and concluded that more work is needed to identify the signal transducers (Nelson et al., 2017). In view of the detrimental effects of senescence in ageing, there has been recent interest in the possible benefits of senolytics (drugs that selectively induce apoptosis of senescent cells). Studies have been carried out in mice (for example, Baar et al., 2017), but the potential for human health is not yet known.

Apoptosis

Apoptosis, or programmed cell death, is an essential process during development. Apoptosis is also required to remove damaged cells which can then be replaced by the division of healthy cells to maintain tissue homeostasis. The processes of cell death and proliferation need to be finely balanced. Too much cell death leads to loss of tissue and has been implicated in many age-related diseases such as neurodegenerative disorders, osteoporosis, and atherosclerosis. On the other hand, too much cell proliferation can lead to cancer. Apoptosis is highly regulated and can be activated by either intrinsic or extrinsic signals. The extrinsic pathway is triggered by extracellular signal proteins binding to cell membrane

Biological aspects of human ageing

death receptors such as the tumour necrosis factor (TNF) receptor or the Fas death receptor. After binding, death receptors recruit intracellular adaptor proteins which, in turn, recruit procaspases, leading to a caspase cascade and finally cell death. There is evidence for altered caspase activity with ageing, which may contribute to dysregulation of the extrinsic pathway (Zhang et al., 2003). Cells can also activate apoptosis from signals within the cell such as DNA damage, lack of nutrients, or hypoxia. The intrinsic pathway requires the release of cytochrome c from mitochondria, which binds to Apaf-1 and procaspase-9 to form the apoptosome. This pathway can be triggered directly or indirectly by ROS, which may explain the increase in apoptosis with age (Simon et al., 2000). There are many proteins involved in regulating the intrinsic pathway, including Bcl-2, Bax, Jnk, p38MAPK, and p53, and all these are known to play a role in ageing. For example, Bcl-2 and Bax are anti- and pro-apoptotic factors, respectively, and their ratio determines cellular outcomes. Cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) upregulates Bcl-2 to promote cell survival, and it has been shown that CREB family members are critical for neuronal survival *in vivo* (Mantamadiotis et al., 2002). Many other pathways are involved, some of which are neuron-specific and are the subject of a recent review (Pfisterer and Khodosevich, 2017).

Age-related neurodegenerative diseases are associated with death of neurons in specific regions of the brain caused by too much apoptosis (Mattson, 2000). It has been shown that p53 is up-regulated in AD, which may contribute to the increase in apoptosis (Hooper et al., 2007). Since neurons are mostly post-mitotic, cells cannot be replenished and brain atrophy results. Skeletal muscle and heart are also post-mitotic tissues that are affected by age-related disturbances, leading to overactive apoptotic pathways (Pollack et al., 2002). On the other hand, cancer cells and senescent cells are resistant to apoptosis, so that they accumulate with age. In addition to apoptosis, other forms of cell death such as necrosis and overactive autophagy may contribute to ageing (reviewed in Tower, 2015).

Stochasticity

It has been observed that there is wide variation in lifespan in genetically identical organisms raised in a constant environment, which therefore must be due to random effects (Herndon et al., 2002; Kirkwood et al., 2005). Finch and Kirkwood (2000) proposed intrinsic chance as a third factor to the conventional two-factor model of ageing which attributes genetics and the environment as the main determinants of lifespan. The accumulation of molecular damage is random both in terms of when and where damage occurs. Chance events also occur in many other processes such as reproductive ageing, development, cell numbers, thresholds for dysfunction, cell fates, telomere shortening, and control of gene expression (Finch and Kirkwood, 2000). For example, it is known that there is large stochastic variation in telomere length (Martin-Ruiz et al.,

Biological aspects of human ageing

2004), and epigenetic changes are also highly stochastic and have been shown to explain why identical twins age differently (Petronis, 2006).

Dietary restriction

Dietary restriction (DR) is the most robust intervention known to extend lifespan and reduce morbidity in a range of species, including rodents, *C. elegans*, *D. melanogaster*, and yeast. The extensions in lifespan are quite substantial. For example, a study showed that the average lifespan of mice in the top decile was 53 months in the group fed on a diet with a 35% reduction of the *ad libitum* intake, compared to 35 months for the control group (Weindruch et al., 1986). Another rodent study attributed an increase in lifespan of dietary-restricted animals to a reduction in age-related diseases such as diabetes, atherosclerosis, respiratory disease, and cancer (Fontana and Klein, 2007). On the other hand, DR studies in non-human primates have failed to show any clear effect on the ageing process per se, although there have been indications of health benefits, most probably associated with the fact that *ad libitum* feeding may have adverse effects on metabolic disorders (Selman, 2014).

DR does not necessarily involve a reduction in calories (as in calorie restriction) but includes other interventions such as restriction of specific macronutrients or intermittent fasting in which the overall calorie intake may or may not be reduced. Intermittent fasting, although not new, has recently received a lot of attention in terms of its benefits for healthy ageing. However, the evidence is not yet conclusive and requires further investigation (Patterson et al., 2015). The mechanisms underlying the beneficial effects of DR are not fully understood, but the general consensus is that metabolic pathways are involved with down-regulation of the IIS, TOR, and/or glucose protein kinase A (PKA) signalling pathways (reviewed by Santos et al., 2016). A recent study showed that DR protects against age-related changes in DNA methylation (Hahn et al., 2017), and calorie restriction has also been shown to affect the circadian cycle (for example, Patel et al., 2016), indicating that many interrelated mechanisms are involved.

Systems biology

The reader may rightly conclude that ageing is very complex and involves multiple mechanisms. The overlap between mechanisms is very evident from the previous sections. For example, mitochondrial dysfunction has an impact on all energy-dependent cellular mechanisms. While reductionist approaches have predominated in the past, the realization for the need of an integrative approach was recognized near the start of this century (von Zglinicki et al., 2001). Reductionist approaches are still required to generate detailed data, but the emphasis is now on integrating new findings with previous discoveries. In addition, powerful new technologies, such as functional genomics, produce large volumes of data that need sophisticated computer software packages for analysis. Therefore, a multi-disciplinary framework of systems biology is essential

Biological aspects of human ageing

to advance our understanding of ageing (Kirkwood, 2011). Systems biology involves close interaction and collaboration between biologists, mathematicians, computer scientists, engineers, and statisticians. The emphasis is on an iterative cycle of experiment, theory, and quantitative modelling (Fig. 1.4).

Fig. 1.4
An iterative cycle of modelling and experimentation.

Mathematical and computer modelling is now being increasingly used in biomedical research. However, many scientists are still unclear on the use of models in this area, and so we summarize the main advantages of using models as an additional research tool. Model building requires a specific hypothesis, and each element of the model and how it interacts with other elements must be specified. This often highlights unknown elements and uncertainties about specific reactions. In this case, more than one model can be built to investigate different possibilities. The model can be used to make both qualitative and quantitative predictions which may suggest further experiments. Modelling is relatively inexpensive and quick, compared to laboratory experiments, and so it can provide a low-cost rapid test-bed for candidate interventions.

A wide range of models have already been developed to investigate the molecular mechanisms of ageing (reviewed in Mc Auley et al., 2017) such as telomere erosion (Proctor and Kirkwood, 2002 and 2003; Rodriguez-Brenes and Peskin, 2010), the accumulation of defective mitochondria (Elson et al., 2001; Kowald et al., 2014; Kowald and Kirkwood, 2011; Tam et al., 2015), the breakdown of protein homeostasis (Proctor et al., 2005; Proctor et al., 2007; Proctor and Lorimer, 2011), and signalling pathways such as the Forkhead box protein O (FOXO) response (Smith and Shanley, 2010), the DNA damage response (Passos et al., 2010), stem cells (Glauche et al., 2011; Ro and Rannala, 2001; Taylor et al., 2003), and network models to explore the interactions between different mechanisms (Kowald and Kirkwood, 1996 and 2000; Sozou and Kirkwood, 2001). Many models have also been developed to specifically examine the processes involved in brain ageing and age-related neurodegenerative disorders (reviewed in Lloret-Villas et al., 2017).

Biological aspects of human ageing

As well as modelling, systems biology involves the use of bioinformatic tools in order to try to understand how the many components involved in ageing interact (for example, genes, proteins). A recent review highlights some of the databases related to the ageing process (Tacutu et al., 2018). Vast amounts of high-throughput omics data are being generated, and this has led to new challenges in terms of data storage and analysis. Bayesian statistical techniques are being increasingly used to extract the maximum amount of information from data that are subject to errors and intrinsic noise (Wilkinson, 2007). Data storage and analysis require high computational power and need the use of parallel computer clusters or cloud computing. Software tools also need to be continually upgraded, and new tools developed, to keep pace with new technologies for data acquisition.

Conclusion

This chapter has given an overview of some of the biological aspects of human ageing, with a particular emphasis on damage to molecular and cellular components by ROS. The mechanisms involve many complex interactions, and as we have seen, vicious cycles of damage leading to more damage are a common theme. Our understanding of the processes involved in ageing are still far from complete, but the vast improvements in experimental techniques and computing power have greatly advanced our knowledge over recent years. However, this has brought new challenges with regard to making sense of the increasing amounts of data. It is also necessary to be able to integrate data and hypotheses in order to gain a better understanding of the ageing process.

Therefore, research into ageing now requires a multi-disciplinary team of bioinformaticians, statisticians, computer programmers, and mathematical modellers, in addition to clinicians and experimental scientists.

The ageing brain

Chapter: The ageing brain

Author(s): John Woulfe, Doug Gray, and Carole Proctor

DOI: 10.1093/med/9780198807292.003.0002

Introduction

Cross-sectional and longitudinal studies have convincingly demonstrated evidence for a slowly progressive decline in cognitive abilities, including memory performance, processing speed, and flexibility with age (Alberts et al., 1997). Age-associated deficits in several other spheres, including motor dexterity, are also referable to declining function within the central nervous system (CNS). The aetiology of progressive age-related CNS dysfunction has remained elusive. Post-mortem studies have revealed that, in many cases, microscopic changes identical to those found in classical neurodegenerative disorders are present in the brains of aged individuals without dementia. For example, Alzheimer-type neurodegenerative changes in vulnerable brain regions are virtually universal in individuals aged 60 and over. In this context, a pathophysiological continuum bridging brain ageing with classical neurodegenerative disease seems axiomatic, wherein the functional deficits accompanying 'normal' brain ageing are simply consequent upon

The ageing brain

the development of disease-specific neurodegenerative pathology, occurring at a level below the threshold of full-blown clinical manifestation. However, this concept is problematic. It ignores the large body of evidence for neuronal (and glial) changes at the cellular and molecular levels that occur in the setting of brain ageing per se and that can be divorced from canonical disease-specific cellular pathologies (e.g. plaques and tangles). So understanding the mechanisms underlying pure brain ageing is predicated on elucidating the factors underlying the development of these 'quasi-pathological' age-associated changes. Moreover, there are important implications for understanding the relative mechanisms underlying ageing and AD. Specifically, these age-related changes may lower the threshold for canonical neurodegenerative pathologies to manifest morphologically and clinically. Although studies in non-human primates and other animals have contributed substantially to our understanding of the ageing brain, the following discussion will focus on human studies.

Morphological changes

Gross changes

Features commonly encountered on gross external inspection of the aged brain include thickening and opacification of the leptomeninges, prominence of the arachnoid granulations, atherosclerosis, and tortuosity of the arteries comprising the circle of Willis, as well as variable degrees of cortical atrophy. Internal examination of the cut surfaces of slices reveals varying degrees of white matter loss and ventricular dilatation. The age-associated decline in brain weight provides a quantifiable index of diminishing volume. Autopsy studies suggest a relatively stable weight in the fifties and sixties after which brain weight declines progressively. However, there are caveats inherent in these unselected cross-sectional studies in which the contributions of confounding factors (such as nutrition, for example) are not universally taken into consideration. Moreover, more recent studies of cortical thickness have indicated minimal changes in the absence of cognitive dysfunction (Mouton et al., 1998). Finally, there may be differential involvement of cortical layers. For example, non-human primate studies have revealed that atrophy in advanced age is relatively confined to layer I, possibly reflecting age-related simplification of the axons and dendrites projecting into this layer from deeper strata (Peters et al., 1998). In contrast to the controversy concerning gross cortical alterations, there is widespread consensus that white matter atrophy and pathology represent a common accompaniment of ageing and that much of this is related to arterial pathology with attendant white matter ischaemia (Smith et al., 2000).

Histological changes

Comparative microscopic studies have revealed changes in neuronal number and size, organellar alterations, and reorganization of synaptic elements, including modifications in the shape and number of synaptic

The ageing brain

terminals, dendrites, and dendritic spines. There are age-associated alterations in glial cells and blood vessel elements as well. Evaluating the extent and significance of these changes is complicated by the phenomenon of selective vulnerability whereby some regions are more severely affected than others.

Quantitative neuronal changes

It has been estimated that there are 8.6×10^{11} neurons and 10^{14} synapses in the human brain (Pakkenberg et al., 2003). There has been considerable controversy concerning whether, and to what extent, there is a significant depletion of neurons in the non-diseased ageing brain. Much of this controversy derives from technical discrepancies and lack of methodological standardization among studies. The application of contemporary unbiased stereological techniques, including, for example, use of the 'optical fractionator' (West et al., 1991) which minimizes double counting of neurons, has addressed some of these issues. For the cerebral cortex, the degree of age-associated neuronal loss is not commensurate with cortical atrophy, suggesting that depletion of neuropil elements play a significant role in the latter. A study of 94 autopsy brains by Pakkenberg and Gundersen (1997) indicated a lifetime loss of only 10% of cortical neurons. Other studies, for example of the temporal (Gomez-Isla et al., 1997; Terry et al., 1987), frontal (Terry et al., 1987), parietal (Terry et al., 1987), and entorhinal cortices (Gomez-Isla et al., 1996; Morys et al., 1994a), were unable to document any depletion of neurons. The ageing hippocampus exhibits only a subtle loss of neurons, contrasting with the massive depletion which characterizes Alzheimer's disease (Simic et al., 1997; West et al., 1994). Like the cerebral cortex and hippocampus, many of the subcortical structures that have been examined in the ageing human, including the medial mammillary nucleus (Begega et al., 1999), hypothalamus (Morys et al., 1994b), and nucleus basalis of Meynert (Chui et al., 1984), display negligible neuronal loss. Whether there is a significant loss of noradrenergic neurons from the locus coeruleus, a phenomenon which could have implications for age-related behavioural and emotional changes (including age-related depression), is a matter of controversy (Manaye et al., 1995; Mouton et al., 1994; Ohm et al., 1997).

One area of the brain in which there is general consensus regarding a significant age-associated loss of neurons is the substantia nigra pars compacta. This nucleus harbours the dopaminergic neurons that project to the basal ganglia and that degenerate in Parkinson's disease (PD). Estimates of nigral neuronal loss are in the order of 10% per decade (Ma et al., 1999). The selective vulnerability of this neuronal population is interesting in the context of the unique age-related cellular changes that it exhibits and that are distinct from those found in classical neurodegenerative diseases (see below).

The ageing brain

Loss of neuronal synapses, irrespective of cell body depletion, has been described in ageing and may represent a key substrate underlying the loss of 'cognitive reserve', a phenomenon that reduces the threshold for dementia in the setting of superimposed Alzheimer-type neurodegenerative changes. In a study of the frontal cortex from 25 individuals without dementia aged 16–98 years, Masliah et al. (1993) described a significant inverse correlation between presynaptic terminal density and age and a 20% loss using the age of 60 years as cut-off. Importantly, the authors concluded that this was independent of beta-amyloid deposition. Post-synaptic alterations in ageing, which seem to correlate with the degree of functional impairment, have also been described, including decreased spine density (Anderson and Rutledge, 1996). Age-related changes in spine morphology and volume (Kasai et al., 2010) have also been described. Notably, some studies in lower animals have documented age-related increases in synaptic density at both the presynaptic (Benice et al., 2006) and post-synaptic (Connor et al., 1980) level.

Finally, glial cell changes are common in ageing. Increased proliferation of astrocytes and increased expression of their constituent intermediate filament protein GFAP have been demonstrated in the human brain (David et al., 1997; Hansen et al., 1987). Studies have also indicated evidence for progressive microglial activation in the ageing primate brain (Sheffield and Berman, 1998; Sloane et al., 1999).

Cellular inclusions in brain ageing

Ageing neurons and glial cells are characterized by the accumulation of substances within their cytoplasm and sometimes their nuclei. It is generally acknowledged that this reflects age-associated dysfunction of the catabolic mechanisms which normally eliminate these substances, culminating in the formation of microscopically visible 'inclusion bodies'. These can comprise lipid or proteolipid components, complex carbohydrates, or proteins. The latter are analogous to the inclusions that define classical neurodegenerative disorders, and their formation invites speculation regarding the mechanistic overlap between brain ageing and pathological neurodegeneration.

Lipofuscin and corpora amylacea

Lipofuscin, also known as 'ageing pigment', is a membrane-bound complex mixture of oxidized protein and lipid degradation residues, along with lesser amounts of carbohydrates and metals. It accumulates in post-mitotic cells such as neurons (Fig. 2.1A). The topographic pattern of distribution of lipofuscin accumulation displays a particular predilection for certain areas. It is prominent in areas of the brain and spinal cord involved in initiating, monitoring, and controlling movement, including the inferior olivary nucleus (Fig. 2.1A), the dentate nucleus of the cerebellum, the globus pallidus, and the motor neurons in the anterior horn of the spinal cord and brainstem (Gray and Woulfe, 2005).

The ageing brain

Lipofuscin abundance increases with age in the cerebral cortex as well. Like some of the age-associated inclusion bodies discussed below, accumulating evidence suggests that lipofuscin is not benign but can impair cellular functions, including the ubiquitin-proteasome system.

Fig. 2.1

Distribution of lipofuscin and corpora amylacea. A) Neurons in the inferior olivary nucleus show distention of their cell bodies by intracytoplasmic accumulation of lipofuscin. B) Corpora amylacea in layer I of the entorhinal cortex. Both sections stained with hematoxylin and eosin.

Bars=50µm.

Corpora amylacea (Fig. **2.1B**) are spherical, laminated structures composed of complex carbohydrate and localized within the distal processes of astrocytes in the brain of elderly individuals (Mrak et al., 1997). They are most frequently localized at the surface of the brain and around blood vessels. They are particularly abundant in a disease known as adult polyglucosan body disease, but whether they have any pathological significance in the non-diseased ageing brain is unknown.

Proteinopathy in brain ageing

Neurodegenerative diseases are characterized pathologically by the abnormal accumulation of proteins in neurons and/or glial cells. These protein aggregates form microscopically visible ‘inclusion bodies’, the morphology, distribution, and biochemical composition of which inform neuropathological diagnosis. A blurring of the interface between neurodegeneration and ‘normal’ brain ageing owes much to the identification in the brain of clinically non-diseased aged individuals of changes that define classical neurodegenerative diseases. Extracellular plaques (Fig. **2.2A**) and intraneuronal tangles (Fig. **2.2B**) comprising beta-amyloid and tau protein, respectively, are the histopathological hallmarks of Alzheimer’s disease (AD). These lesions predate the manifestation of cognitive symptoms by several years. Consequently, they are also commonly encountered on post-mortem examination of the brain of non-demented (presumably pre-symptomatic) elderly individuals. Modern imaging studies, most notably positron emission tomography (PET) imaging using beta-amyloid tracers such as Pittsburgh compound B, have confirmed the presence of significant beta-amyloid deposition

The ageing brain

within the brain of a large proportion of non-demented elderly individuals (Fjell et al., 2013; Gordon et al., 2016). Such studies, combined with magnetic resonance imaging (MRI) assessments of cerebral atrophy (regarded as a proxy measure of neurodegeneration), have been used to develop a clinical classification scheme for assigning individuals into one of four categories—those with beta amyloidosis (A) and neurodegeneration (N) are designated A+N+ and represent patients with AD; A-N- and A-N+ subjects represent non-diseased individuals and those with suspected non-AD pathology ('SNAP'), respectively (Gordon et al., 2016). In general, the A+N- group is thought to consist of subjects with preclinical AD, suggesting that this classification scheme advocates the concept of a pathological continuum of beta-amyloid deposition, beginning in the pre-symptomatic stages of the disease.

Fig. 2.2

Histopathological hallmarks of Alzheimer's disease. A) Extracellular plaques in the frontal cortex of a non-demented elderly individual revealed by immunohistochemical staining for beta-amyloid protein. B) Intraneuronal neurofibrillary tangles in the entorhinal cortex of a non-demented elderly individual revealed by immunohistochemical staining for tau protein.

Bars=100µm.

However, there is also evidence that Alzheimer-type neurodegenerative changes can develop in the setting of brain ageing per se and do not necessarily portend progression to AD or even dementia. For example, it appears that not all A+N- individuals progress to clinical AD. Also, neuronal tau pathology has been described in the brain of non-demented elderly individuals. Specifically, 90% of non-demented subjects under 30 years of age show pathological tau deposition in certain brain areas, most notably the noradrenaline-producing locus caeruleus in the brainstem (Braak et al., 2011). More widespread neuronal tau deposition is frequent in advanced age. The term 'primary age-related tauopathy' or 'PART' has been proposed for those individuals with tau-immunoreactive neuronal tangles but lacking beta-amyloid deposition (Crary et al., 2014). This is thought to be a correlate of the clinically assessed SNAP. Moreover, astrocytic tau pathology in the form of a recently described entity known as age-related tau astrogliopathy ('ARTAG') has been identified as a very common accompaniment of non-pathological brain ageing predominantly, though not exclusively, in individuals over 60 years of age (Kovacs et al.,

The ageing brain

2016). Thus, like the phenomena discussed below, PART and ARTAG represent neurodegenerative changes that could conceivably contribute to the development of the progressive cognitive and motor deficits that are commonly accepted as being within normal limits among aged subjects.

Mention should also be made of transactive response DNA-binding protein 43 (TDP-43). Accumulation of this neuronal RNA-binding protein to form intraneuronal cytoplasmic, and sometimes nuclear, inclusion bodies is the defining histopathological hallmark of amyotrophic lateral sclerosis (ALS) and some forms of frontotemporal dementia (Neumann et al., 2006). However, it has also been described in a significant proportion of brains with Alzheimer's disease and dementia with Lewy bodies, as well as in up to 18% of neurologically intact controls (McAleese et al., 2017), suggesting an independent role in age-related neurodegeneration. The TDP-43 protein has domains that are intrinsically disordered (lacking any stable three-dimensional structure), a recurrent theme in RNA-binding proteins. FUS (fused in sarcoma) is a second example of a highly disordered RNA-binding protein that has been associated with ALS (Daigle et al., 2013). This family of intrinsically disordered proteins seems particularly prone to aggregation upon accumulation and/or post-translational modification, and the particular vulnerability of neurons to dysregulation of this family of proteins may relate to their recurring roles as critical hubs of scale-free regulatory networks (reviewed in Gray and Woulfe, 2013). Although they are still in their infancy, studies of the role of RNA-binding protein aggregation in cellular ageing are producing provocative results (Lechler and David, 2017).

Unlike the examples discussed above, the protein composition of several inclusion bodies encountered in the aged brain remains unknown. These can be identified microscopically on the basis of their tinctorial properties using conventional histological stains and/or their immunostaining for ubiquitin. Ubiquitin is a small protein which binds to cellular proteins destined for proteasomal degradation. Because inclusion body proteins are ubiquitinated, their localization using immunohistochemistry can be exploited to visualize neuronal and glial inclusions whose principle protein constituent is as yet unknown. A variety of ubiquitinated inclusion bodies have been described in specific regions of the brain of non-diseased aged individuals (Dickson et al., 1990; Gray et al., 2003). These are generally perceived as benign, non-pathological entities. However, by analogy with their morphological similarity to disease-associated inclusions, it is tempting to ascribe a role to them in age-associated neurological dysfunction (Gray et al., 2003). Marinesco bodies are instructive in this regard. These are ubiquitinated spherical intranuclear inclusion bodies which accumulate with age in substantia nigra dopamine neurons in the non-diseased human substantia nigra (Fig. 2.3A) (Dickson et al., 1990). They were traditionally considered to be benign, non-pathological entities. However, more recent studies indicate that their formation may contribute to the motor deficits that accompany 'normal'

The ageing brain

ageing (Abbott et al., 2017; Beach et al., 2004; Kanaan et al., 2007). In this context, Marinesco bodies could reasonably be considered 'quasi-pathological' entities. Similar (although less intensively studied) ubiquitin-positive inclusions in the normal ageing brain include granular cytoplasmic inclusions in neurons of the inferior olivary nucleus (Fig. 2.3B) (Dickson et al., 1990), spider web-like cytoplasmic inclusions in large (presumably cholinergic) neurons in the neostriatum (Fig. 2.3C) (Kawashima et al., 2000; Oyanagi et al., 1994), and 'colloid' or 'hyaline' inclusions often found in hypoglossal and spinal motor neurons in the elderly (Mendell and Markesbery, 1971). Ubiquitin-positive axonal swellings are seen with increasing age in certain parts of the CNS (Dickson et al., 1990), most predominantly in the cuneate and gracile nuclei, which are targets of sensory information arising in the arms and legs, respectively. Ubiquitin-immunopositive granular bodies and dot-like structures are also commonly encountered in the ageing brain (Dickson et al., 1990, 1992). The granular bodies are believed to be located in the distal aspects of dystrophic neurites. They are most commonly encountered in the middle and upper cortical layers, especially layer II of the entorhinal cortex. This is potentially important, because these neurons form a crucial link in the circuit responsible for short-term memory. Ubiquitin-positive dot-like structures can be prominent in the ageing white matter and appear to be located in oligodendroglia and myelin lamellae (Dickson et al., 1990). Finally, there are age-associated cytoplasmic inclusion bodies of unknown protein composition that do not stain for ubiquitin, including eosinophilic cytoplasmic inclusions in neurons of the thalamus (involved in relaying sensory information), substantia nigra (involved in motor control) (Pena, 1980; Pena and Katoh, 1989), and the external cuneate nucleus (involved in relaying information from the upper limbs) (Fig. 2.3D) (Ito et al., 2016), as well as neuronal intranuclear rodlets (Woulfe and Munoz, 2000). The extent to which these cellular changes contribute to progressive age-related deficits referable to the various nuclei remains to be explored. Proteomic studies of these structures could be informative in this regard.

Degenerative changes in the enteric system and potential propagation of pathology to the central nervous system

The focus of this chapter has been the plethora of age-related changes within the CNS, but the enteric nervous system (ENS) is not exempt from age-related deterioration, and the possibility exists for prion-like transmission of molecular agents of pathology between these nervous systems (as will be elaborated later). The human ENS comprises 400–600 million neurons, a sizeable population roughly comparable to the neuronal content of the spinal cord (Furness, 2012). These neurons coordinate motility through the gastrointestinal (GI) tract, as well as secretion and absorption. It is reasonable to assume that the GI complaints (dysphagia, reflux, constipation, and incontinence) that are prevalent in the elderly to some extent arise from age-related dysfunction of the ENS, though the data are surprisingly inadequate for detailed specification of the affected neurons and their loss of function over time. At a gross level, a 40% increase in transit time through the human GI tract has been documented in older subjects, compared to a younger cohort (Madsen and Graff, 2004). This figure is in close agreement with a mouse model in which functional inactivation of UCHL1 results in precocious loss of function of ENS neurons (Coulombe et al., 2014). Unlike the CNS, which exists in the stable and privileged environment

The ageing brain

conferred by the blood-brain barrier, the ENS is situated in close proximity to a highly variable stream of ingested substances and microbes, some of which can be acutely toxic or have cumulative pathogenicity. The homeostatic mechanisms that promote a uniform environment in the CNS, with respect to oxygen tension, glucose levels, reactive oxygen, and so forth, could not prevail in the gut, which contains a topologically exterior environment hosting microbes with their own metabolic agenda. In healthy individuals, the microbiome (a collection of prokaryotes, eukaryotes, and viruses) exists in a mutually beneficial (commensal) relationship, providing catabolic services that are beyond the capacity of the host, in return for a supply of complex macromolecules and a thermally regulated environment. Given the proximity of the ENS to the microbiota of the gut, it would not be surprising if dysbiosis (a detrimental alteration in the constituents of the microbiome) affected ENS function, and dysbiosis is common in GI diseases such as Crohn's disease, irritable bowel syndrome, and coeliac disease (Clemente et al., 2012). The diversity of the microbiome may decrease with age and is reduced upon feeding of institutional meals in long-term care facilities (Claesson et al., 2012). Dysbiosis may have deleterious effects on the ENS, which could increase transit times in a feed-forward loop of enteric dysfunction.

An intermittently hostile environment and exposure of ENS neurons to passing toxins and pathogens can be expected to wreak havoc on cellular constituents. As previously described (above and in Chapter 1), proteins are sensitive to misfolding and subsequent aggregation as a consequence of environmental insults. If, upon misfolding, such proteins can template the misfolding of additional protein molecules of the same type, there is the possibility of an accumulation of the misfolded entity with time. If a misfolded protein with this templating property can escape the cell and enter an adjacent or distal cell, there is the further possibility of prion-like transmission. There has been a proliferation of publications in the recent literature supporting such a mechanism in prominent age-related neurodegenerative conditions, including AD and PD (reviewed in Goedert et al., 2017). In the case of PD, oligomeric aggregates of α -synuclein have been postulated to act as the prion-like entity. α -synuclein is particularly abundant in the vermiform appendix (Gray et al., 2014) where inflammatory episodes and close proximity to gut contents could initiate aggregation within enteric neurons. The vagus nerve would provide a conduit for prion-like spread of aggregated α -synuclein from the appendix or other enteric sites to the brain, and in accordance with this model, truncal vagotomy has been found to reduce the incidence of PD (Svensson et al., 2015). Various mechanisms have been proposed for the transmission of prion-like proteins from one neuron to the next, including direct transmission through tunnelling nanotubes or indirect transmission through secreted exosomes. Validation of such mechanisms *in vivo* is an area of current research.

Neuroinflammation

The ageing brain

Microglia

Microglia are resident innate immune cells and comprise about 16% of the human brain. The distribution of these cells throughout the brain is not uniform, with higher density in the white matter. Microglia are normally in a resting state, taking on a ramified appearance with long, thin processes extending from the cell body, with which they survey the surrounding environment. In the normal healthy brain, on detection of any abnormalities, microglia become activated (primed) and respond to restore homeostasis, e.g. by phagocytosis of cellular debris. Although microglia are neuroprotective under non-pathological conditions, overactivation of microglia leads to an increase in oxidative stress and inflammation.

It has been shown that there is increased priming of microglia in the ageing brain (reviewed in Norden and Godbout, 2013) and in age-related neuropathological conditions, e.g. in AD (Hoeijmakers et al., 2016). This may be due to an increase in pro-inflammatory stimuli such as lipopolysaccharide (LPS), protein aggregates, and neuronal damage. The chronic activation of microglia is accompanied by the release of pro-inflammatory cytokines, reactive oxygen species (ROS), and nitric oxide, and also the up-regulation of surface receptors, e.g. complement receptors and major histocompatibility complex (MHC) (Norden and Godbout, 2013).

There is evidence of overactivation of microglia in both PD (reviewed in Block and Horn, 2007; Long-Smith et al., 2009) and AD (reviewed in Mandrekar and Landreth, 2010; Solito and Sastre, 2012). The first evidence of this was shown by an increase in the MHC class II cell surface receptor HLA-DR in the substantia nigra of post-mortem brain of both AD and PD patients (McGeer et al., 1988). Since then, many inflammatory markers have been found in human PD post-mortem brains, e.g. tumour necrosis factor (TNF)- α , interleukin (IL)-1 β , and IL-6 (reviewed in Lull and Block, 2010). In particular, dopaminergic neurons (found in the substantia nigra) are damaged by cytokines and loss of these neurons is associated with PD. It has been shown that LPS is only toxic to dopaminergic neurons in the presence of activated microglia which release pro-inflammatory mediators, e.g. NADPH (Qin et al., 2004). It is not yet known why dopaminergic neurons are more susceptible to damage via microglial activation, but it has been speculated that they may be more vulnerable to oxidative stress (Block and Horn, 2007). Notably, recent studies have demonstrated that these neurons are capable of expressing MHC class I protein (Cebrián et al., 2014). These neuroinflammatory factors may account (at least in part) for the susceptibility of substantia nigra neurons to age-related degeneration, as discussed earlier. In AD, it has been shown that microglia are only associated with dense plaques, not diffuse plaques, suggesting that they do not initiate aggregate formation (Itagaki et al., 1989). Amyloid plaques are normally cleared by microglia, but on the other hand, microglia may cluster around plaques and become activated (Sasaki et al., 1997). In

The ageing brain

particular, macrophage scavenger receptor (MSR) A-positive microglial cells have been shown to form these clusters and a positive association between pathological amyloid and the number of MSR A-positive clusters has been found (Zotova et al., 2013).

An interesting study into the role of microglia in dementia with AD pathology was carried out on 299 post-mortem brains donated by participants of the MRC-Cognitive Function and Ageing Studies (CFAS) (Minett et al., 2016). Using immunohistochemistry, they examined five markers of microglial function: Iba1 (microglial motility); CD68 (phagocytic activity); HLA-DR (immune response and a genetic risk factor for AD); MSR A (clustering of microglia around plaques); and CD64 (systemic immunity). They found that high levels of CD68, MSR A, and CD64, and low levels of Iba1 were significantly associated with dementia.

Some immunotherapy approaches use antibodies that facilitate the clearance of amyloid plaques via microglia, and it has been suggested that this is mediated via Fcγ receptors and autophagy (reviewed in Valera et al., 2016).

Complement

The complement system is part of the innate immune system and can be activated by three different biochemical pathways: classical complement; alternative complement; and lectin pathway. Each pathway is activated by different factors but, in each case, leads to the formation of the membrane attack complex (MAC). Over 30 factors (C factors) make up the system, many of which have been shown to be upregulated with ageing (Cribbs et al., 2012). It has been suggested that this may be a protective response to an increase in cellular debris with age. However, chronic activation of complement could be harmful as the MAC can damage cell membranes. Immunohistochemical studies in the 1980s showed that C factors are associated with amyloid (reviewed in Veerhuis et al., 2011). There is also direct evidence that plaques activate complement *in vitro* (Rogers et al., 2012), and indirect evidence that this occurs *in vivo* (Rogers et al., 2012). C factors are expressed at different Braak stages. For example, C1q, C4d, and C3d are found in plaques at early stages, but at later stages, these factors are increased in plaques and also appear in tangles. On the other hand, C5b-9 is only found at late stages in plaques and tangles (Veerhuis et al., 2011). However, fewer complement genes change their expression in AD, compared to non-pathological ageing (Cribbs et al., 2012). A GWAS study identified that, like APOEε4, polymorphisms in the clusterin (*CLU*) and C3b/C4b receptor 1 (*CR1*) genes are risk factors for AD (Lambert et al., 2004). A follow-up study showed that the CR1-S isoform is associated with an increased risk of AD and has more binding sites that increase co-factor activity to inhibit complement activation; however, further functional studies are required (Brouwers et al., 2012). In summary, the evidence suggests an increase in complement activation in normal brain ageing as a compensatory mechanism. On the other hand, either chronic activation or down-

The ageing brain

regulation of complement pathways is detrimental and contributes to pathology in the ageing brain.

Variability in brain ageing

Genetic risk factors

Many genetic risk factors that contribute to brain ageing and neurodegeneration have been identified and contribute to the inter-individual variability that characterizes age-associated cognitive decline. Mutations in particular genes, e.g. *APP* and *UCH-L1*, increase the risk of familial early-onset diseases, whereas polymorphisms, e.g. *APOE*, increase the risk of late-onset disease. GWAS have identified many gene variants associated with neurodegeneration at a genome-wide significance level, suggesting that these disorders are polygenic. This means that an individual's susceptibility to disease depends on a large combination of genetic factors contributing to a wide variation in the actual underlying molecular mechanisms that initiate the disease process.

One study used an integrative genomics approach, called differential ageing, to quantify the ageing rate in the human cerebral cortex (Rhinn and Abeliovich, 2017). They followed this up with a genome-wide scan and identified *TMEM106B* and *progranulin* (*GRN*) variants that interact in the same pathway and are associated with inflammation, neuronal loss, and cognitive deficits in older individuals (over 65 years) without known neuropathology. Individuals with these variants had a higher rate of biological ageing. Interestingly, both of these proteins are involved in microglial function.

Epigenetics

Epigenetic factors, such as methylation, acetylation, and non-coding RNAs, regulate gene transcription and have an important role in brain ageing. As epigenetic mechanisms are reversible and linked to lifestyle factors, such as diet and physical activity, there has been a lot of interest in their potential as therapeutic targets to ameliorate cognitive decline (Delgado-Morales et al., 2017). In the following discussion, we give some specific examples, but this is by no means exhaustive and is a rapidly expanding field of research.

The process of DNA methylation results in the covalent addition of methyl groups to DNA molecules at cytosine residues, especially at CpG dinucleotides. If methylation occurs in the promoter region of a gene, transcription is repressed. However, the human genome contains CpG-rich sequences, known as CpG islands, which are normally unmethylated. These regions are usually found in gene promoters or within gene bodies and regulate transcription. During ageing, there is a global decline of DNA methylation, but in specific genomic regions, there is an increase in both hypermethylation (in CpG islands) and hypomethylation events (in repetitive tandem and interspersed elements), which are termed age-differentially methylated regions (a-DMRs). These events occur due to

The ageing brain

environmental or stochastic factors. This leads to an increase in DNA methylation variability at certain CpG sites, a phenomenon known as epigenetic drift with age. Interestingly, at older ages (75+), epigenetic convergence has been observed in the human brain (Oh et al., 2016).

Epigenome-wide association studies (EWAS) on ageing have been used to identify an epigenetic clock by examining tissue-specific a-DMRs (Bacalini et al., 2017). In addition, there have been many studies comparing the DNA methylation age (DNAmAge), as determined by the epigenetic clock and the chronological age of an individual. This has shown that the estimated DNAmAge tends to be higher than the actual chronological age in several age-related conditions, including AD, PD, and Down's syndrome (reviewed in Bacalini et al., 2017).

Age-associated alterations in gene expression have also been described at the post-transcriptional level. As discussed earlier, there are changes in the solubility, localization, and activity of RNA-binding proteins which may underlie age-related alterations in the stability and splicing of RNAs. In addition, non-coding RNAs are RNA molecules that are not translated into protein and include microRNAs (miRNAs), small nucleolar RNAs (snoRNAs), small interfering RNAs (siRNAs), and long non-coding RNAs (lncRNAs), all of which are involved in regulating mRNA transcription and translation. The most extensively studied of these, miRNAs, are short RNA molecules (~22 nucleotides) and function to silence gene expression by either enhancing mRNA degradation or inhibiting translation. Each miRNA targets a specific set of genes and each gene may be regulated by several different miRNAs, providing a complex network of gene regulation. The effect of miRNAs in gene regulatory circuits has been extensively studied with the aid of mathematical modelling and includes fine-tuning of gene expression, prevention of leaky gene transcription, generation of pulse-like responses, and induction of switch-like behaviour (Lai et al., 2016). Many miRNAs are tissue-specific, and several are highly enriched in brain, such as miR-124 that downregulates polypyrimidine track binding protein 1 (*PTBP1*), a repressor of neuronal differentiation (Makeyev et al., 2007).

The involvement of miRNAs in neurodegeneration may be either direct via repression of genes such as *APP* (Hébert et al., 2009), *BACE1* (Hébert et al., 2008a), or α -synuclein (Doxakis, 2010) or indirect via repressing genes important in maintaining protein homeostasis (Sin and Nollen, 2015). In AD patients, several miRNAs have been shown to be consistently dysregulated (reviewed in Femminella et al., 2015), including miR-9, miR-34, miR-107, and miR-29.

miR-9 is highly expressed in the developing and adult brain and has an important role in promoting neural differentiation (Coolen et al., 2013). Many studies have shown it to be decreased in AD, and it has been demonstrated to be down-regulated by A β (reviewed in Van den Hove et al., 2014). The targets of miR-9 include FGFR1, NF κ B, SIRT1, and REST. SIRT1 is important in the brain due to its role in energy metabolism, the

The ageing brain

circadian rhythm, stress response, and cell survival pathways (reviewed in Ng et al., 2015).

miR-34 regulates the expression of the transcription factor p53. In AD patients, miR-34 is present at high levels in the hippocampus and leads to increased expression of p53 (by targeting a p53 inhibitor, e.g. HDM4). p53 indirectly induces tau phosphorylation (Hooper et al., 2007) and also induces the expression of miR-34, so that there is a positive feedback loop between miR-34 and p53. So the increased levels of miR-34 in AD may contribute to hyper-phosphorylation and aggregation of tau.

miR-107 is normally abundant in the temporal cortex but is decreased in the early stages of AD (Wang et al., 2008). The same group later found a correlation between decreased miR-107 and levels of neuritic plaques and tau tangles (Nelson and Wang, 2010). BACE-1, an endopeptidase that cleaves amyloid- β precursor protein (APP) to produce neurotoxic amyloid peptides, is a target of miR-107 and it has been speculated that the decrease in miR-107 contributes to disease pathology through increased levels of BACE1 (Wang et al., 2008).

miR-29 is significantly down-regulated in AD and targets beta-site amyloid precursor protein-cleaving enzyme 1 (BACE1) at the protein level, not the mRNA level (Hébert et al., 2008b). In this study, Hébert et al. found that in a subgroup of AD patients with high BACE1 levels, miR-29a, and miR-29b-1 are significantly reduced.

Environmental/lifestyle factors

It is well known that there are interactions between genetics, epigenetics, and environmental/lifestyle factors (Jaenisch and Bird, 2003). In particular, there is evidence to suggest that the ageing brain retains functional plasticity and can be affected by lifestyle factors such as diet and physical activity (Fig. 2.4). It has been shown that physical activity may slow down the progression of neurodegeneration (e.g. Rolland et al., 2008). In addition, physical activity can modify genetic risk factors such as APOE ϵ 4 in a mouse model (Nichol et al., 2009). As well as physical activity, cognitive activity and social interactions have been shown to slow down ageing of the brain (e.g. de Frias et al., 2014).

The ageing brain

Fig. 2.4

Lifestyle and environmental factors lead to a gradient of pathology (as shown with the arrows) with age. The figure is a digitally generated composite of histological sections from healthy and diseased brains.

Studies in animals have clearly shown that environmental enrichment potentiates learning and memory and show increased expression of neurotrophic factors in several areas of the brain (reviewed in Mora, 2013). The experimental data demonstrate the plasticity of the brain and explain the benefits of cognitive and physical activity in older persons to prevent or delay the onset of dementia. Confirmation of findings in model systems could come from population-based studies in humans. Towards this end, variability in brain ageing is currently being analysed in a German cohort (Caspers et al., 2014). The aim of this study is to investigate the influence of genetic, environment, and health status on structural and functional variability in the ageing brain.

Conclusion

By the simple metric of oxygen consumption, it is clear that the brain displays a very high level of metabolic activity relative to other tissues, but despite the molecular damage that this activity necessarily entails (and the very limited and spatially restricted replacement of constituent neurons), the brain can execute its functions for more than a century. Careful analysis of aged brain tissue from 'healthy' centenarians (those not diagnosed with neurodegenerative diseases) reveals perturbations in cell numbers and cell morphology generally associated with pathologic states, so it would appear that with the passage of time, there is no escape from molecular mayhem. The proper functioning of neurons and associated cells relies on intact layers of molecular machinery from the

The ageing brain

genome (and its complex epigenetic regulation) to RNA (with its increasingly baroque processing and homeostasis) to proteins (and all manner of post-translational modifications and their consequences). There is much here that can go wrong. Given enough time, it invariably will, but much remains to be learnt about which perturbations are most critical for brain ageing and what effective interventions can be contemplated.

Ageing as a social process

The sociology of ageing explores the social circumstances and choices that shape, support, or distort life-course developments, from large-scale social structures through to the micro-interactions that make up people's experiences of their own ageing and the cultural practices generating shared expectations about what ageing involves. The field itself has evolved over time, as it tries to come to terms with the complexity of these phenomena and the ways in which they affect each other.

Social environments and relationships impinge on ageing in all its aspects, both positively and negatively. They also, in part, *constitute* it. Physical, conceptual, and experiential aspects of ageing depend in different ways on the social settings in which they occur. Healthy ageing is associated with status and relative power; the higher someone is in a social structure, the more likely that person is to live longer (Donkin et al., 2002; Woolf et al., 2015), as well as to feel that ageing makes it

The sociology of ageing

possible to fulfil personal goals (McGee et al., 2011). Much of this applies too between societies and over time. Standard life-courses in the West—and in large part elsewhere—contrast with those before the Industrial Revolution, partly because modern societies involve new living conditions, not least practices relating to nutrition, hygiene, and housing. ‘Viewed in the early 1950s as shaped almost entirely by biological processes and medical care, physical health and illness are now understood to be as much or more a function of social, psychological, and behavioural factors’ (House, 2001: p. 125; Marmot et al., 2012). But social resources, attitudes, and habits also affect what it means to be an (older) person. If older people are envisaged as feeble and incompetent, even publicly described as such (Fealy et al., 2012), these expectations will constrain their activities; they may ‘auto-stereotype’ themselves (Stuckelberger et al., 2012). Social ideas about ageing impact decisively on older people, opening or closing possibilities open to them (Bytheway, 2011). But the fact that societies themselves constantly change makes ageing a variable process, in which life-courses are enacted in contrasting ways. There is no neutral baseline for ‘normal’ ageing, since forms of senescence are so heavily affected by social settings.

The social circumstances of late industrial societies are certainly historically untypical as far as human lifetimes are concerned. Ironically, this has not led to broader public awareness of the ways ageing is socially constructed. Ageing is often portrayed simply in terms of risk and danger, depicted as generating an alarming social burden. Purportedly objective calculations buttress this vision. In reality, social and political choices mould the shapes that ageing takes and whether it presents problems or opportunities. On the one hand, ‘population ageing’ is described without context as threatening in itself; on the other, modern science may be envisaged as a source of potentially ageless vitality, the mythological ‘fountain of youth’. These debates themselves are social phenomena, attesting to contrasting conceptions of ageing in different arenas.

Examining human ageing in different cultural and temporal contexts illuminates recent changes. By the 2030s, the shape of the human population ‘pyramid’ will have taken just over a century to shift from the broad-based triangle typical of most mammals to an approximate rectangle, with roughly equal numbers of individuals at each life-stage (Treas, 1995). Yet this does not mean that older adults in past societies were necessarily rare—the most drastic changes in survival rates have affected children under 5. In the early sixteenth century, an English aristocrat who had survived to be 21 could expect to live to 72—‘three score years and ten’ (Lancaster, 1990). A profound, but often ignored, impact of population ‘rectangularization’ is its dissociation of *death from birth*. In the past, death was a constant threat in childbirth or childhood; mothers and children who survived still had to contend with the deaths of other infants or siblings. Now, death is envisaged as happening at the opposite end of life from birth. This is a massive shift in social perception

The sociology of ageing

—death is no longer perceived as an ever-looming possibility, but as something that happens when one is *old*.

Older people often now receive considerable support, in that welfare states offer them degrees of protection never previously known; on the other hand, in western societies, ageing is often seen as a uniform mass process, which should not be allowed to become over-expensive. To counteract this homogenization, the 'life-course' approach to the sociology of ageing explores interactions between work, health, family membership, and other entwined experiences of individuals and groups over time. It highlights both the variability of these pathways and their connections to the social and political contexts that determine what should be expected from, and supported in, later life. For instance, taxation policy on pension funds is a matter of political decision, yet the decline of occupational pensions is often presented as inevitable (Macnicol, 2015), with impacts on employees' anxiety at all stages of their life-courses.

Popular debate ignores, too, the fact that modern societies could not contain relatively large proportions of older people without an equally striking global development—dramatic decreases in the readiness to have children (Samir and Lutz, 2017). If the UK birth rate returned to the level of the third quarter of the twentieth century, 'the population' might no longer count as 'ageing', whether longevity rates increased or not (Bytheway, 2011: p. 163ff). But social views on the desirability or otherwise of having children fluctuate. In the 1930s, fears about European population decline bolstered official support for family growth in some countries. Now, public discourses supporting the choice to remain 'child-free' compete with exhortations about the 'social responsibility' to have children (Institut für Demoskopie Allensbach, 2003). Individuals' views of their own life-courses, both prospectively in terms of the choices they make and retrospectively when they look back on them, also change. Older women who have raised families may look back on lives without careers and conclude they have 'done nothing' (Edmondson, 2015). Social changes, including ambiguous social attitudes to childbearing, can make it harder for individuals to interpret their own life-courses, and this applies at the level of whole societies too.

Since infant, child, and maternal mortality rates are now so low in the West, they offer little room for dramatic improvement; leaps in population-wide life expectancy seem unlikely to occur here in future (Dong et al., 2016). Increased life expectancy among adults has changed significantly, but more slowly. In Ireland, for example, where social change was relatively limited between the 1920s and the 1980s, especially for older generations, there was little change in the age at death of older men at all (Fahey et al., 2007: p. 12, Fig. 4). Adult life expectancy rates needed appropriate circumstances and policies if they were to improve.

The sociology of ageing

Life-course analyses accentuate awareness that much that happens to individuals in later life, as well as how they regard their own lifetimes, follows from what they have done, or what has happened to them, at earlier stages. These impacts range in scale from the effects of war or peace to educational arrangements in the past, and from health-related conditions in places of former work to expectations about family life. To be a single, middle-class woman, '29 and unmarried', 'a failure' without children—as Virginia Woolf put it in 1911 (Woolf, 1975: p. 466)—was to be engaged on a different life-course trajectory from that of a single woman of similar age a century later.

The social conditions of children and adolescents in a given society are related to the way adulthood and old age is perceived in that society; and, conversely, the role and position of adults and older people is affected by the treatment and roles of those in earlier stages of life.

(Hareven, 1982: p. 3)

Ageing, therefore, must be understood in context (Cole et al., 1992). 'Against the backdrop of history, changes in people's lives influence and are influenced by changes in social structures and institutions'; these, in turn, are 'linked to the meanings of age, which vary over time' (Riley et al., 1999: p. 327). In other words, views of what it means to be old change all the time (Featherstone and Hepworth, 1995), heavily affected by social and political developments.

Having a life-course itself is changing, affected by shifting global and local economies and patterns of work, family, and community relations, as well as religious and other sources of meaning. Yet older people are often constrained by stigmatizing expectations, attributed *because* of their age (Kunow, 2010)—'ageism'. The stereotypical perception and treatment of older people may actually have hardened during the twentieth century (Hareven, 1982; Katz, 1996), affected by states' bureaucratic practices and their impacts on the 'social imaginaries' of entire societies (Gaonkar, 2002)—how they perceive ageing. Age became treated as a 'master trait', a feature dominating perception of the person who has it. It is hard to disguise, signalling a chronological trajectory against which individuals' achievements and qualifications can be measured. A whole concatenation of official documents, birthdays, and time-related social expectations make age seem crucially important (Bytheway, 2011). Yet this trope in social judgment grossly oversimplifies the 'multidimensional' ways in which life-courses are actually lived out, 'structured by virtue of the order and timing of multiple social roles over the life span' (Macmillan, 2005: p. 6).

'Ageing' thus takes different forms; it is imagined and experienced in contrasting ways, in social settings that change over time. It is a variable, lifelong process, intertwined with the life-courses followed by contemporaries and by earlier and later generations. This chapter now

The sociology of ageing

explores impacts on ageing made by a key feature of contemporary change—globalization—before interrogating theories of ageing and their impacts on the ways in which different aspects of ageing can be explored sociologically.

Global(ized) ageing: migration, cultures, policies, and perceptions

Examining ageing in global terms underscores the contrasting statuses, constraints, opportunities, and expectations associated with being ‘old’ in different societies. And contemporary globalization itself, with its accentuated levels of social and economic interdependence and its distribution of work and workers beyond national boundaries, has heightened ‘explosive’ degrees of inequality (Beck, 2013). As Hyde and Higgs (2016: p. 1) put it, while now ‘most people throughout the world can expect to live into their 60s and beyond’, that world has also changed—while it has grown wealthier, it remains profoundly unequal, and for vast numbers of older people, it remains extremely precarious. While there are declining opportunities for traditional forms of employment through which older people in the past tried to protect themselves, global markets and neoliberal policies portray as a luxury the social security spending protecting those in later life (Dorling, 2015; Macnicol, 2015).

Efforts to evade precarity produce global migration paths, stretching family networks and life-courses between continents. Older people may be left without family carers in their place of origin or migrate to new destinations and grow older there, contributing to the cultures of their new societies but affected by local cultural tensions and inequalities in social structure (HelpAge International, 2000; Yeates, 2005). Thus, ‘global care chains’ can arise in which:

an older daughter from a poor family ... cares for her siblings while her mother works as a nanny caring for the children of a migrating nanny who, in turn, cares for the child of a family in a rich country.

(Hochschild, 2000: p. 131)

Such ‘care chains’ impinge on the staffing of nursing homes, an industry that, in the United States alone, employs more people ‘than the auto and steel industries combined’ (Folbre, 2002: p. 186). This brings together two potentially vulnerable groups—older people and migrant, often female, workers—and adds the potential for cultural and linguistic strain to dangers of financial exploitation (Walsh and O’Shea, 2010). These strains may be accentuated by changes in family structures in nations with decreasing numbers of children. In Japan, for example, a need is growing for migrant labour to provide elder care; this does not sit easily with traditional attitudes to immigration (Powell, 2011: p. 47). In Austria, Weicht (2015) describes how foreign carers for older relatives are interpreted by families in contradictory ways—describing them as ‘angels’ applauds, but at the same time objectifies, them.

The sociology of ageing

'Host' nations may receive 'waves' of migrant workers from different origins; the circumstances and lifestyles associated with ageing in their countries of origin may differ from possibilities available in their new settings (Wingens et al., 2011). In the UK, Bangladeshi migrants, among others, may feel torn between appreciating economic survival and health support and, on the other hand, wishing to maintain ideals of family belonging vis-à-vis relatives many thousands of miles distant. Attitudes to space and place have become 'underlain by deep feelings of rift and division' (Gardner, 2002: p. 220). Silverstein and Attias-Donfut (2010: p. 185) argue that:

older adults who migrate to new international locations with, or following, their adult children, often lack the linguistic and cultural capital to integrate fully into their new surroundings and consequently suffer from loneliness and depression.

These are complex phenomena with mixed, and sometimes contradictory, impacts on individuals. A proportion of UK older people have chosen to live abroad for their retirement, rather than live in nursing homes (Warnes, 2009), but they may regard these choices differently as they age and as political circumstances change. A new research agenda now explores how family dynamics may stretch across continents, with ties and networks maintained or lost (Baars et al., 2017; Phillipson, 2010).

Globalization itself can have highly stratified effects on older generations (Estes and Phillipson, 2002). Welfare-state and other forms of social support have become precarious, not least where governments and employers embrace neoliberal policies, partly in response to expectations from global institutions. Older people may more often be expected to manage their own financial protection in age, though under conditions of heightened insecurity (Phillipson, 2009).

In such circumstances, cultural resources may either exacerbate or mitigate their predicaments (for a selection of such resources, see Sokolovsky, 2008). Fox (2005: p. 482), for example, seeks 'to illuminate the active, constructive work' older people do 'to find ways to age in their culture' (Fox, 2005: p. 484), contrasting Thailand with Australia. In the strongly Buddhist context of Thailand, filial care is experienced as a 'normative expectation'; in Australia, views of the life-course are much less strongly related to religious values, and older people in nursing homes may see care as 'a service to be provided in a professional manner' (Fox, 2005: p. 493). In divergent ways, social settings offer cultural resources affecting ageing (Torres, 2011), here enabling recipients of care to ascribe themselves a measure of autonomy, rather than perceiving themselves solely as dependent.

Cultural responses form part of the broader impact of sociopolitical factors on ageing, reflected in survival rates in different national settings, which are far from uniform internationally. In contrast with, say, Japan, until 1990, figures for the Czech Republic and East Germany were very

The sociology of ageing

low. After the fall of the Iron Curtain, rates for the Czech Republic remained modest, but East Germans, inhabiting a transformed sociopolitical context, have now caught up with West Germans. In the United States, in contrast, the rising trend is less certain—survival rates for the oldest women are not improving at all (Rau et al., 2008: pp. 757, 764–5), and life expectancy *fell* in 2015 (Kontis et al., 2017). The oldest forms of ageing can, in principle, become healthier. But trends do not continue automatically; they are affected by social circumstances and public policy decisions.

Thus, Christensen et al. (2009) stress that what used to be seen as objective ‘ageing processes’ are ‘modifiable’ through policy choice. They stress capacities to live both longer and better—‘most evidence for people aged younger than 85 years suggests postponement of limitations and disabilities’, despite increases in chronic conditions (Christensen et al., 2009: p. 1204). They attribute this to progress in factors such as housing standards, transport, education, gender roles, and social attitudes to disability; overall, 30–40% of people in their nineties live independently (Christensen et al., 2009: pp. 1204–5). Lubitz et al. (2003) show that although older people aged 70 have a longer life expectancy if they are in better health than if not, this need not necessarily mean that their total health care requires more expenditure. Improving the health of middle-aged populations could, in principle, enable them to live longer without costing health services more (Evans et al., 2001).

Here the globalized politics of economics impacts on local forms of ageing through affecting both action and inaction in national policies. Estes and Phillipson (2002) point to globalized policies actively undermining institutions protecting older people, for instance by favouring privatization in elder care. Such policies penetrate directly to individual level. If profit-driven forms of elder care invoke accountancy based rigidly on time spent on particular tasks, for instance, informal practices in care homes change, diverting time away from casual, but friendly, everyday practices that are crucial in making residents feel at home. Conversely, longevity is affected by factors associated with race and education, especially both combined; the survival rates of less educated black Americans are little better than 50 years ago (Olshansky et al., 2012). Yet overtly egalitarian policy changes are discouraged in a neoliberal global policy climate.

Since modes of ageing are so responsive to context, portraying ‘global ageing’ as a problem *in itself* is a vast oversimplification:

Alarmist demography and gerontological knowledge came together in the social surveys of the late nineteenth and early twentieth centuries that decried the growth rate and poverty of the elderly generation as an economic and moral crisis.

(Katz, 1996: p. 69)

The sociology of ageing

There are reasons for assuming that the global population will not simply develop exponentially into the future (Samir and Lutz, 2017), but 'alarmist demography' depends heavily on producing 'calculations' where age and 'dependency' are conflated. Global dependency ratios are themselves a form of social perception, 'measured' by counting proportions in a population who are (say) below 15 and above 65 years of age. This assumes, counterfactually, that all those in between are gainfully employed. It omits people who may be disabled and those on 'home duties'. It also equates 'dependency' with not earning a monetary wage, ignoring other forms of social input such as childcare or mutual care among family members or neighbours. This has the political effect of erasing perception of a wide variety of forms of social support and citizenship. Bytheway (2011: p. 173) points out that people who are economically employed also 'depend' on older people (and children) for unpaid domestic and caring work. Lastly, it assumes that productivity rises and falls simply according to the numbers of people in employment, which is not the case.

McGee (2002) contends for Canada that even if crude calculations of 'dependency' are made on the basis of age alone, dependency ratios are not necessarily rising. Macnicol (2015) shows that the so-called 'old-age dependency ratio' in the UK is counterbalanced by decreasing numbers of children. According to Spijker and MacInnes (2013), even if we define people as 'dependent' when they have 15 years or fewer to live, the 'dependency ratio' has fallen by a third over 40 years; the total proportion of people in work in the UK (now 48%) has barely changed since 60 years ago, when it was 46%. In any case, as Macnicol points out, assuming that *young* people can easily access productive employment is highly questionable at a time of rapid changes in the world of work. Using age ratios to generate 'moral panic' thus amounts to an 'ageist' campaign against older people, which itself demands analysis from a sociological viewpoint. Calculations about global ageing may *appear* objective, but they depend on decisions about what needs to be counted and how that exposes deep-rooted contestation about how the life-course itself is regarded.

Perspectives on ageing: theories and stances

Seeking insight into different facets of ageing, sociologists have explored not only its social circumstances, but also the discourse about ageing itself—including their own past and present debates. The wish to avoid, suppress, or disguise ageing can be accentuated by the 'social imaginaries' of the time—that is, the underlying

ways in which people imagine their social existence, how they fit together with others, how things go on between them and their fellows, the expectations that are normally met, and the deeper normative notions and images that underlie these expectations.

(Taylor, 2002: p. 106)

The sociology of ageing

Achenbaum (1995) stresses that the development of academic attention to ageing, just after World War II, occurred at a time of flight from trust in politics towards faith in science as a harbinger of progress. This accentuated the 'biomedicalization' of ageing (Estes and Binney, 1989), in which ageing is perceived not just as a problem, but as a medical problem. The 'anti-ageing' movement remains an attempt to 'cure' it through biomedical means.

Since ageing has so many dimensions, from its physical parameters to the ways it impinges on experience, sociological theories of ageing are constantly developed and adjusted in efforts to capture evolving interactions. They also reflect developing accents and methods within sociology itself (Bengtson et al., 2009; Phillipson and Baars, 2007). But underlying reasons for adjustments in the theoretical approach embody conflicting views on social causality—how social structures and power affect an individual's agency, and vice versa—and the locus of responsibility for life-course events. Theoretical stances differ in terms of how they take account of these complexities and in terms of the extent to which they endorse critical stances vis-à-vis social impacts on ageing (cf. Biggs et al., 2003).

An early attempt to theorize ageing, the 'disengagement' approach taken by Cumming and Henry (1961), adopted the functionalist analysis common among sociologists at the time. The authors envisaged separate sections of society in terms of contributions to the 'functioning' of the whole, seeing individuals' ageing as adapting to changing functions over the life-course. Ageing and retirement represented the secession of older generations from productive social roles, making room for younger ones. Their work attracted objections for methodological reasons, but its moral and political implications *for individuals* caused particular contention. Cumming and Henry were read as accepting that people of retirement age are of negligible social importance and ignoring the meaning of older age to individuals (Hochschild, 1976).

The career of disengagement theory illustrates the slippage between theories of how social ageing arises and prescriptions for individuals' own ageing. In contrast to Cumming and Henry, 'activity theory' (Havighurst and Albrecht, 1953; Havighurst et al., 1963) focused on positive social 'roles' played by older people, for instance in grandparenting or belonging to a church (cf. James et al., 2006). Identifying such contributions seemed to adjure older people to keep involved and energized, using leisure time creatively. Relatedly, the 'continuity' approach to ageing (Atchley, 1989a: p. 183) saw maintaining continuity with past subjective and social experiences as 'a grand adaptive strategy', by which individuals can defend themselves from structural disadvantage and ageism; this was interpreted as advice for preserving individual identity over time (Atchley, 1989b; cf. Nuttman-Shwartz, 2008). These positions share three features. All contain prescriptive elements; all have implications on the micro- as well as the macro-scale, with individuals expected to bear the burden of problems stemming from social

The sociology of ageing

structures. And each contains observations that are convincing in part —‘disengagement’ applies to some people in some circumstances, while supporting ‘continuity’ of lifestyle for, say, nursing home residents has considerable appeal. As heuristics directing attention in research practice, though not as universal accounts of ageing, each has productive potential.

Theories of ageing thus vary in terms of their scale, prescriptiveness, power, and views of social determinism. Modernization theory (Cowgill, 1974), for example, contends that industrial societies devalue the experience and knowledge of earlier generations, impressed instead by fast-changing new skills associated with younger people. This position too has been criticized as unduly universalistic, homogenizing multiple different experiences and situations, as well as idealizing the position of older people in earlier, rural societies. We might add that its large-scale imputations are heavily inspired by induction from individual experience, though certainly it sometimes seems convincing. This applies too to exchange theory, which connects older people’s social status to resources they can offer others (Dowd, 1980). Though older people’s social resources may seem depleted from an ‘exchange’ viewpoint, in the semi-traditional rural society of Ireland in the 1930s, to give one example, many (especially older men owning farms or small businesses) did possess powerful resources in terms of others’ life-courses, with status to match (Arensberg and Kimball, 1940/2001). In contrast, ‘age stratification theory’ interrogated more varied types of social pressure on behaviour, identifying roles prescribed for people in different age ‘strata’ and the ideological pressures involved, while at the same time it advocated resistance to such pressures (Dannefer et al., 2005; Riley and Riley, 2000).

These contrasting approaches cumulatively stress how strongly social processes affect ageing at all levels. Increasingly, therefore, possibilities for influencing these processes were explored. The ‘political economy of old age’ (Estes, 1991) focused on exploring state decisions about distributing economic resources among different age groups—in effect creating forms of ‘structured dependency’ (Townsend, 1981: p. 77). Inequality in old age needed to be understood at least partly in terms of socio-economic processes tending to marginalize older people (Walker, 1981, 1996). They should not be regarded as a homogenous group defined in terms of chronological age, for their different problems had different causes, to be tracked empirically. Poverty among older people resulted from their labour-market positions and subsequent exclusion from it, or from low levels of social benefits. Ageing in any given society was fundamentally affected by the economy, state, and employment, but also by class, gender, and ethnicity. This approach harnessed interdisciplinary resources to explore such impacts on ageing under the aegis of ‘critical gerontology’ (Phillipson, 1998).

The sociology of ageing

In this tradition, H.R. Moody (1988: p. 32) argues that gerontology itself should offer an 'emancipatory discourse', with 'a positive idea of human development: that is, ageing as a movement toward freedom beyond domination (autonomy, wisdom, transcendence)'. Thomas Cole (1992: p. 237) too contends that analysing ageing in purportedly technical terms amounts to a moral and political position in itself, relegating ageing to a (futile) attempt to evade disease, rather than confronting 'conflict, mystery and suffering in late life'. Thus 'ageing' is an irreducibly moral concept. This 'humanistic' understanding of ageing includes explicating how moral positions are generated, endorsed, or precluded by particular social constellations. Theories of 'moral economy' show that social norms, for instance prescribing obligations we owe each other within families or between generations, are themselves influenced by political economies of ageing (Kohli, 1987; Minkler and Cole, 1991). Public views on the desirability of certain ways of behaving reflect ideas about power and justice, not least justice between generations. To what extent should older generations sacrifice their interests for those of younger ones, or vice versa?

Stress on society-wide phenomena needed counterbalance where variations were explored among forms of ageing and their social settings. Hareven (1984) opposed seeking linear patterns of development in accounts of ageing, given the differential impacts of race, class, family form, and ethnicity on intergenerational relationships in different times and circumstances. Using the adaptation of Schutzian phenomenology introduced by Berger and Luckmann (1966), subsequent accounts of ageing stressed 'the social construction of reality'—the impact of social practices on how ageing and older people are envisaged, and how their opportunities and constraints evolve. Constructionist forms of analysis disentangle everyday interactions to track how daily practices and 'unwitting routines' build up worlds of experience (Gubrium 1997: p. 1) which partly interlock and simultaneously diverge. People may, for example, use common narratives to perform different functions in the ways they attach meaning to their ageing and that of others (Gubrium, 2011).

Such interpretive efforts by no means entail a relativistic approach to the philosophy of science. Most sociologists of ageing show an assiduity in seeking optimal forms of evidence and argument that is implicitly compatible with critical realism (Sayer, 2000) in respect of their views about the empirical world. Thus, Corner and Bond (2006), discussing effects of the diagnosis of 'mild cognitive impairment', point to potent social effects of applying this 'label' to older individuals—they may both be treated differently and come to regard themselves differently as a result. As Phillipson's exposition of critical gerontology stresses (Edmondson and von Kondratowitz, 2009; Phillipson, 1998), this means attending to *both* economics and power *and* meaning and the social processes by which it is created and changed.

The sociology of ageing

The variety of approaches summarized as 'cultural' gerontology thus accentuate attention to social origins of meaning and experience, and their effects on ageing in contemporary societies. Stories and images relating to ageing (de Medeiros, 2014; Hepworth, 2000) cast light on the ways in which people develop a sense of who they are as they age and how older people are seen by others. This ascription of cultural meanings profoundly affects people's experiences, even of their own bodies (Katz, 2002); culture, in other words, involves power (Andersson, 2002; Tulle, 2008). Yet exploring the operation of symbolic processes in practice can also draw attention to the dialogical nature of human experience (Biggs, 2004) and older individuals' capacities to use social meanings in creative ways. Blaikie (2002) argues that, as an alternative to cultures of 'consolation' or 'incorporation', older individuals can adopt 'cultures of resistance' to homogenizing social processes. For Kunow (2009), the 'transformative power' of ageing sometimes depicted in the literature highlights special forms of resistance, in which older people may reach heights of courage they were unable to attain at earlier life stages.

Such work signals eagerness to underline the potential for older people's active intervention in their own predicaments. Gilleard and Higgs (2000) and Rees Jones et al. (2008: p. 1) view consumption, what people buy, not as a mere side effect of work, but as possessing 'a significance of its own'; they see modern retirees not just as 'pensioners', but as 'a putative leisure class'. They explore whether at least some older people can situate themselves powerfully in society, with heightened resources for defence against ageism, profiting from bodily appearances that are socially acceptable and health and resources enabling them to engage in leisure activities formerly associated with younger generations. This approach potentially modifies Mannheim's earlier work on generations, not seeing them as discrete, opposed horizontal groups, but postulating that succeeding generations both take with them elements of previous generations' views and contribute new, contrasting habits and behaviour.

Reference to 'generations' connects sociological approaches to ageing explicitly with conceptions of time (Baars, 2012). Elder (1998) stresses that trajectory over time gives their form and meaning to life-course transitions; 'life-course theory' tracks intertwining trajectories that intersect through individuals' lifetimes, both responding to social contexts and affecting them (see Wingens et al., 2011 for a life-course approach to ethnicity). Early work in this tradition deployed biographical methods to yield insights into the life-worlds of people living out comparable trajectories, notably artisan bakers in France (Bertaux and Kohli, 1984). Bengtson et al. (2005: pp. 493-4) stress the life-course approach's potential not only to explore 'linked lives' within cohorts and between generations, within their historical contexts, but also to highlight 'agency and the idea that planfulness and effort can affect life outcomes'. People may be profoundly affected by the same overall historical circumstances but react differently to them in lasting ways (Elder, 1974).

The sociology of ageing

In practice, life-course analyses have offered a range of positions on the issue of what freedom individuals have to affect the course of ageing. Kohli (2007: p. 254), for instance, sees the life-course approach as focusing 'on the patterning of time in the various life domains', intended to result in 'an account of the *longue durée*'—the way 'typical' life-courses have changed as between pre- and late-industrial societies in the West, pre-eminently in response to changes in the structure of work. This analysis sees 'the experience of the temporality of life' as 'a feature of an evolved structural order' in which individuals move through sequences of social positions, prescribed to them via rules and norms in succeeding historical settings (Kohli, 2007: p. 255). Questions concern the role of 'individualization' in contemporary societies and the extent to which it 'frees' individuals from 'the bonds of status, locality and family of origin' (Kohli, 2007: p. 255)—or, on the contrary, merely exposes them to larger-scale social pressures.

Longitudinal data collected across national settings yield material tracking life-courses across ever larger numbers of birth cohorts, adding information on the strong input of state decisions to life-course developments (Mayer, 2004, 2009). Attempts can be made to isolate relatively stable socio-economic characteristics and behaviour, as well as interactions between life stages; how 'set' are trajectories by early life circumstances? 'Can events and conditions in adulthood significantly alter further trajectories and outcomes?' (Mayer, 2009: p. 417). Laub and Sampson (2003) contest assumptions of childhood determinism, but Mayer (2009: p. 423) underlines the continuing nature of this debate. Brückner and Mayer (2005) warn too against imputing overall unidirectional trends to entire societies—some social patterns may be 'destandardized', but others are not. Using half a century's data for West Germany, they confirm 'de-coupling' between trajectories of family formation and those of school, training, and work (Brückner and Mayer, 2005: pp. 48–9). But women's life-courses have converged with men's in terms of education and participation in the labour force, in that respect increasing life-course *homogenization*. This is not to deny that social structures generate inequalities that accumulate not only through individuals' life-courses, but also even between generations (Ferraro et al., 2009).

These analyses of ageing and time are complemented by accounts derived from the work of Foucault (1978), stressing relations between power and discourse that extend deep into the ways individuals internalize structures of control, through to their experiences of their own bodies. A Foucauldian approach to 'biopolitics' explores states' efforts to monitor and control citizens' life processes, from birth to death, supported by the power of 'experts', and the corresponding framing of older people as 'dependent' (Powell, 2006: p. 98ff). Foucault sees elements of social life otherwise supposedly exceptional, such as the constant surveillance exercised in prisons, as core to processes involved in social power and control (Tulle, 2008). Thus, Katz's work on *Disciplining Old Age* (Katz,

The sociology of ageing

1996) interprets the rise of gerontology itself at a particular historical juncture in terms of Foucauldian patterns of control.

Time is necessarily central to accounts of ageing (Baars, 2012; Edmondson, 2015). Constructionist approaches to time explore how interaction and talk *produce* changing realities among which people negotiate as they age. They may, for instance, disclose how retirees struggle between alternative directives for the future, torn between socially powerful 'busybody' ideals of active life versus solidarity with vulnerable older people (Lundgren et al., 2018). By describing and reacting to age-related phenomena as we do, we help them to be that way (Gubrium, 2011), producing identities via the narratives we choose (de Medeiros, 2014).

Welfare states and changing societies

The circumstances and experience of ageing, and the ways it is socially conceptualized, represent entwined patterns of advance, regression, and unintended consequences. Support from welfare states has saved millions from the rigours of poverty affecting older age, but because work has become a dominant source of status, preventing them from working also marginalizes older people.

Bismarck's efforts in connection with old-age pensions in Germany after the 1870s represented an attempt to curtail ills associated with developing industrialism, social problems with which families, neighbours, churches, and private charities could not cope. As Thane (2005: p. 9) emphasizes, past societies often contained large proportions of older people—'At least 10% of the populations of England, France and Spain were aged over 60 even in the 18th century.' But their lives were often precarious, even miserable, particularly if children did not survive to adulthood or moved to far-flung locations in search of work. While industrialization initially affected many older people for the worse, capacities for enacting larger-scale social policies had also expanded and could be used with the aim of protecting them.

It was therefore to be expected that older people should depend more than most other 'groups' on welfare states for economic and health security (Komp and van Tilburg, 2010)—but in a range of ways. Those most likely to be economically vulnerable in older age include older women, members of minorities, and those with lifelong low incomes. When older people become poor, they are likely to remain so in the absence of state intervention (Scharf, 2009: p. 45). But contrasting forms of welfare state provision affect citizens differently (Motel-Klingebiel, 2006). Esping-Anderson (1999) suggested distinctions between welfare regime types, according to the relative responsibility allocated to markets, states, and families. Liberal welfare states, such as the United States and the UK, provide means-tested benefits to a limited extent; socio-democratic regimes, such as Norway and Sweden, offer higher benefits (currently under modification); conservative-corporatist regimes,

The sociology of ageing

such as Germany, France, and Italy, offer benefits on insurance principles; 'Mediterranean' regimes, such as Spain, are in the process of evolving away from 'residualist' systems whose major reliance for older care rested on the family. While such structures impact differentially on social relationships, particularly between older individuals and their families, these impacts are not always those anticipated (or feared). Motel-Klingebiel *et al.* (2005), on the basis of a five-country study, rebut suspicions that welfare states 'crowd out' family relationships. They do not automatically cause families to withdraw from elder care, abdicating responsibility to the state. As Künemund and Rein (1999) had predicted, high volumes of state help may encourage family members to follow suit. Indeed, Daatland (2009) argues that developed welfare state provision offers opportunities for newly respectful and independent family relationships.

Relations between patterns of ageing and welfare states thus depend on complex blends of social attitudes and opportunities, not always apparent on the surface. Care for older people is often represented as a generational compact—those who are currently younger pay for older generations, assuming that they too will eventually be supported. This image can be misleading, seeming to justify later retirement as a matter of fairness. Macnicol (2015) shows that this measure, rather than relieving burdens on the young, depresses wages and weakens labour power. Moreover, welfare states rely on implicit *gender* contracts (Ginn, 2001; Ginn and Arber, 2000); the gender distribution of paid versus unpaid labour means that caring for children and older people tends to fall to the share of women. Women's unpaid work affects welfare systems directly, freeing men to work and assuming responsibility for those who are young, old, or sick. Ginn and Arber acknowledge welfare states' efforts to compensate for caring over the life-course, but this cannot outweigh the results of employment patterns. Especially if they are members of ethnic minorities, women's employment records are likely to involve part-time work or include breaks for family-related reasons. Thus, reducing public pensions in favour of private and occupational ones accentuates gender inequality in later life.

Christensen *et al.* (2009) suggest that if, in future, people are permitted to choose to work to later ages, this could involve more part-time employment, part of a pattern of the 'redistribution of work' (Christensen *et al.*, 2009: p. 1205). This could, they argue, benefit both genders and all generations, militating against the effects of 'long hours' work cultures on families. Yet this suggestion could be hard to realize in a climate where individuals are expected to save for their own old age, itself unrealistic in low-interest, technically complex financial regimes. While, in the very recent past, it was possible for individuals with modest career trajectories to fund their own eventual nursing-home care, in many countries, owing to mounting costs, this is no longer feasible, even for those with substantial pensions (the international variations here illustrate the impact of public policy on care regimes). This change has had an impact

The sociology of ageing

on the ways the life-course is both envisaged and experienced that is seldom acknowledged—planning for contingencies in one's own old age has become impossible for many people. Older people may in any case experience multiple precarities in older age (Lain et al., 2019). What Hacker (2006) describes as a 'shift of risk' from institutions to individuals has undermined many twentieth-century advances in sharing risks that are too great to be borne individually.

Generations and gender

Welfare state support for older generations emanates from resolve to mitigate the insecurity to which old age has, throughout history, been subject (Hudson, 1999; Walker, 1996). In popular opinion, the support for older people on which this is based seems relatively intact (Frommert et al., 2009). In any case, Albertini et al. (2007), among many others, stress that, taking account of all forms of financial transfer between generations, including family transfers, older generations give more to younger ones than the other way round, contributing actively to local economies throughout their whole life-courses.

Attias-Donfut and Arber (2000) explore the many different uses of the term 'generation' itself, blending different approaches to historical timing and periodization and to the genealogical rungs of family ladders. Bengtson (2001: p. 8) posits six interacting dimensions of intergenerational relations, distinguishing affectual and associational measures, and consensual, functional, normative, and structural forms of solidarity. Contemporary generations also share more years together than in the past (Hank and Buber, 2009). The term 'the Third Age' denotes the active later lives that now healthier older generations might anticipate, with new impacts on families and society (cf. James and Wink, 2007; Laslett, 1987). The notion of the 'Fourth Age' arose as a counterbalance, indicating an eventual period of infirmity remaining unavoidable for some. Sociologists such as Haim Hazan (2009) warn against imposing demands for 'successful' ageing and 'positive' forms of conformity on this period of life especially. Cavalli et al. (2007) confirm the importance of health in transitions between these life 'stages'—it is in response to declining health that the octogenarians they study disengage from social interaction with family and friends, rather than life events such as the loss of relatives or entering nursing homes. Social choices supporting older generations' health thus remain key to their future capacities for well-being, but much work remains to be done to understand and support the 'Fourth Age' and the processes surrounding death (Higgs and Gilleard, 2015).

Arber and Ginn (2005: pp. 527–8) point out that the numerical domination by older women over older men is now diminishing, as survival rates begin to converge, but the 'feminization of ageing' is still marked by women's systematic disadvantages under current social conditions, not least with regard to pensions, health, and access to care (Attias-Donfut and Arber, 2000). Even marriage affects the genders differently. If older

The sociology of ageing

men are widowed, they tend to remarry; thus, most older men have partners for 'companionship, domestic service support and care should they become physically disabled' (Arber and Ginn, 2005: p. 529). But nearly half of women over 65 are widowed, and over four-fifths at 85 and over; in consequence, many more women than men live in nursing homes (Arber and Ginn, 2005: p. 531). Older women in Europe and the UK are more likely to be poor, owing both to family (child-) care patterns and the prevalence of part-time work during their working lives (cf. Arber et al., 2007).

Gender relations are thus entwined with power relations, suffusing cultural attitudes and images (Bernard et al., 2000). Older women's experiences derive, in part, from expectations about their social presence and roles; discourses about gender are entwined with those about age, and the two sets of expectations can reinforce each other (Krekula, 2007; Wilińska, 2010). Much work on women and ageing centres on the body and how women feel pressured to present themselves—the ways in which social identities are constructed and contested through choices and conventions involving clothing and other aspects of appearance (Twigg, 2012; Ylänne, 2012). Susan Sontag's observations are still quoted on the absence of public dignity and status for older women (Teuscher and Teuscher, 2007):

Growing older is mainly an ordeal of the imagination—a moral disease, a social pathology—intrinsic to which is the fact that it afflicts women much more than men. It is particularly women who experience growing older ... with such distaste and even shame.

(Sontag, 1972: p. 30)

If this is often the case, it does not preclude variations. In societies including the UK, older women's comparatively prominent role in supporting kin, though it imposes obligations, offers compensations (Finch and Mason, 1993; Wenger, 1987; Young and Wilmot, 1957). Nonetheless, being female and experiencing social exclusion in ageing continue to go together (Carney, 2017). This applies too to intersectional social divisions affecting LGBT older people (Cronin and King, 2010), subject to interacting forms of disadvantage and exclusion (Giunta and Rowan, 2015). Many of these can be addressed by community support (Hughes, 2016) and a reduction of heteronormative bias. Bias has affected studies of older men too, significantly by assuming their support for communal life is negligible, which is often not the case (Davidson et al., 2003). In Ireland, Timonen et al. (2011: p. 58) report that men older than 75 are more socially integrated than women of a similar age. This underlines men's contributions to community and care; it may sometimes attest to the old custom of 'visiting', 'rambling', or 'bringing the chat' among men, when Ireland was still a semi-traditional society. Health-related and cultural changes also impact on age and gender roles. In Africa, traditional expectations of older people centred on spiritual roles such as ensuring communal harmony; many such expectations are

The sociology of ageing

currently being shattered, not only by the impact of human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) on parental generations, leaving the responsibility for children on grandparents' shoulders, but also by the effects of westernized modernization (Nhongo, 2004).

Environments, families, and mutual care

Diversity in life-courses reflects variations in the environment, but in ways whose effects may differ from those anticipated. Rural settings in particular are often pictured as offering excellent surroundings for later life, but this overlooks a variety of possible exigencies, including poverty, isolation, and local social decline (Edmondson and Scharf, 2015; Keating, 2008). Rozanova et al. (2012: p. 25) acknowledge claims of 'positive associations between social engagement and well-being in later life' and that older people participate intensely in rural communities, but they underline the need to explore what type of participation is involved and how freely it is given. Rural areas may support specific forms of 'social capital', but these, however significant in their own terms, may not necessarily take liberal, democratic forms. Older people in the countryside may be respected for their knowledge and skills, an effect enhanced among groups familiar with the older individuals in question and to whose lives their achievements are relevant, as in music or sport. To what extent does this depend on rurality as such? Gallagher (2008) found that in Ireland—where the distinction between rural and urban areas remains relatively fluid—patterns of mutual social support among older people in Dublin and those in the country were surprisingly similar. Neighbourly relations and local networks and sharing the social landscape with familiar others contributed markedly to older people's lives.

Such phenomena help explain the common desire to 'age in place', now recognized in much social policy for older people. But Sixsmith and Sixsmith (2008) point to possible complications—the homes in which individuals have grown old may no longer be easy to inhabit, for reasons ranging from their physical structures to their locations (cf. Means, 2007). Environmental gerontologists explore complex interactions between social and physical elements of place in relation to older people (Andrews and Phillips, 2005; Peace et al., 2005), examining how settings come to be 'enabling' or 'disabling' to those who live in them (Smith, 2009). Older people with different needs may wish to age in place but require different sets of provisions there (van Dijk et al, 2015).

Environments are, in part, experienced through the medium of family structures and expectations, which themselves are changing in contemporary societies, though Bengtson (2001) insists that this does not make them less important. Multigenerationality and the role of grandparents in caring for grandchildren may be growing more significant, as grandparents survive longer. Families are often 'long and thin', 'beanpoles' (Bengtson et al., 1990), rather than networks with large

The sociology of ageing

numbers of siblings and cousins at each level. Bengtson stresses that there is great diversity across family practices and no entirely dominant type (cf. Matthews and Sun, 2006). Amid fears for the overall 'decline of the family', Stacey (1996) argues that diverse, 'post-modern' family forms have become normal. Normality does not entail freedom from all stress. Harper (2013) suggests that forming new sets of relationships in 'patchwork' families may be complex and challenging, but the impetus towards family solidarity continues nonetheless.

Fluid family forms do not automatically increase social and familial isolation; in principle, they may make more relatives available to individuals in modern societies. Uhlenberg (1996) calculates that, for children born in 1900, the chances of being orphaned before the age of 18 were 18%, and by the age of 30, only 21% had any grandparents still living. But for children born in 2000, 68% will have four grandparents still alive by the time they are 18. Today's 20-year olds are more likely to have a grandmother living than 20-year olds in 1900 were to have a mother. The social implications of such changes are diverse. As Hareven (1984) indicates, transitions in individuals' life stages at the start of the twentieth century depended not only on their own circumstances (for instance, waiting to find work before it was deemed possible to marry), but also on the circumstances of their families—marriage might be delayed by the obligation to support dependent kin. There followed a period in the mid-twentieth century when transitions were expected to conform to general norms; for example, only after marriage would people aim to have children. Such patterns are now re-forming. Where, in the nineteenth century, families were disrupted and reconstituted as a result of deaths, this now occurs via factors such as divorce and remarriage.

It has often been assumed that family forms contrast between the north of Europe, seen as more individualistic, but more inclined to favour social care, and the south, seen as more familistic, relying heavily on family care owing to a dearth of effective social services. This was interpreted as indicating weaker family ties in the north (Reher, 1998). Dykstra and Fokkema (2011) contest this, arguing that each of four family patterns is fairly common throughout European countries. They postulate two 'familistic' forms, both characterized by members living close to each other, with frequent contact and acknowledging norms of family obligation. In 'descending' forms, help in kind is given more by parents to children, whereas in 'ascending' forms, more help in kind is given by children to parents. Then there are 'supportive-at-a-distance' families in which members neither live nearby nor follow obligation norms, but do have frequent contact, with financial support given mainly by parents to adult children; and 'autonomous' families where members neither live in proximity nor acknowledge obligation norms or engage in frequent contact or assistance. Dykstra and Fokkema argue that 'autonomous' families are not most concentrated in the northern nations, which instead show high levels of 'support at a distance'. They found high levels of autonomy in France and Switzerland; autonomy was also likelier among

The sociology of ageing

families characterized by divorce and high socio-economic status. A single family might move through different patterns at various stages in the family life cycle—perhaps culminating in ‘ascending’ patterns when parents were most vulnerable. Families are developing *processes*, rather than fixed *structures*.

While family ties are crucial in ageing, particularly in terms of care and life satisfaction, more research is needed on other types of relationship too. Bengtson (2001) argues that friendships may support or even replace family ties (cf. Allan, 2010), although Sennett (1998) notes that many contemporary pressures militate against maintaining deep friendships. These include work- and life-course-related insecurities or professional pressures to move location continually, encouraging short-termism in personal connections. In western societies, more people are living alone in later life, as a result not only of widowhood, but also of choice—reluctance to enter nursing homes or a preference for ‘intimacy at a distance’ with family. In the United States, about a third of people over 65 live alone, and 40% of those older than 85 (Portacolone, 2015)—for reasons ranging from personal choice to isolation and precarity. In Northern Europe, some 50% of households consist of a single person, and the majority of women over 65 live alone (Jamieson and Simpson, 2013). This need not entail isolation. Ziegler and Schwanen (2011) argue that mobility, taking trips through physical space, enhances well-being via ‘mobility of the self’, willingness ‘to connect with the world and otherness, with people and places beyond oneself’ (Ziegler and Schwanen, 2011: p. 763). While it is sometimes argued that openness to experience decreases with age, Mühlig-Versen et al. (2012) suggest that appropriate contextual and personal resources can enhance it, as they do via volunteering work.

It is part of the stereotype of older people to picture them as lonely. In Sweden, nearly 90% of respondents may expect retired people to be lonely (Tornstam, 2007). In contrast, the highest rates of reporting feeling lonely ‘some of the time’ are found among young people, although those who say they feel lonely ‘all or most of the time’ do tend to be older than 70 (Victor et al., 2009). Victor and Bowling (2012) show that, in the UK, about 9% of people aged 65 and over say they are severely lonely, 30% sometimes lonely, and 61% never; loneliness can be assuaged not only by more social relationships, but also by improved physical health. The contributions of overall social circumstances to loneliness are underlined by the finding that it varies more by country than by age (Yang and Victor, 2011); forms taken by loneliness and loss vary too, according to social pathways connected with stigmatization, health, and social estrangement (Graham and Stephenson, 2010). Thus, Fokkema et al. (2012) find that older people in central and southern Europe are lonelier than those in the north and west, for reasons of singleness, poverty, and poor health. Contemporary researchers see loneliness as primarily based on having too few personal relationships or relationships, which is certainly significant. But it is possible to feel lonely when deprived of a social role

The sociology of ageing

or social meaning or of a cultural setting in which one can communicate one's own story or viewpoint, irrespective of the number of people one knows (Edmondson, 2015: p. 136). This argues for supplementing person-based analyses with sociocultural approaches to loneliness.

Older people themselves not only receive but also give care, both outside the family and within it, not least in terms of spousal care or grandparenting. In the contemporary world, about three-quarters will become grandparents at some time and will enjoy this status for longer than formerly. Hagestad (2006) explores grandparents' functions as 'supporting', 'saving', or 'rescuing' either grandchildren or their parents (often by enabling mothers to go out to work). Lüscher and Pillemer (1998) indicate the possibility of 'ambivalence' to grandparenthood, while Cherlin and Furstenberg (1986) describe detached, passive, supportive, authoritative, or influential styles of grandparenting. Yet Timonen and Arber (2012: p. 7) remark that such categories are 'not well suited to examining possible differences in how a grandparent relates to different grandchildren, and also overlook the possibility that grandchildren may exert an influence on the nature of the relationship'. They underline grandparents' roles in 'transmitting knowledge and values to younger generations', 'providing a sense of family heritage and stability', as well as influencing grandchildren's 'core moral values' and religious orientations (Timonen and Arber, 2012: p. 5). To the extent that women are expected to play more active roles than men in sustaining family relations, they may be 'more likely to become key figures in young grandchildren's lives' (Timonen and Arber, 2012: p. 8). Thus, the impact of gender on family experiences of ageing remains salient. It is heightened in crisis situations such as those involving HIV/AIDS, when older women may be compelled to rise to heights of resilience and activity in defence of their grandchildren (Casale, 2011). This does not make intergenerational understanding automatic, for instance when individuals become extremely infirm (Hazan, 2011) or when the family is affected by divorce (Doyle et al., 2010), poverty, or unemployment. The complexities operating at earlier life stages do not disappear in later life, and it is questionable if sociology has entirely come to terms with this life phase, as seen from the viewpoint of those experiencing it.

Social exclusion and ageism

A variety of factors might enhance the possibility of 'ageing well', including good health, adequate material standards, good social relations, and an agreeable neighbourhood—not omitting less tangible factors admired in contemporary cultures, 'independence, control, and autonomy' (Bowling, 2005). How easy is it to achieve ageing like this? Poverty and class, in particular, construct perennial barriers, excluding individuals from activities that are otherwise accepted as normal (Abrams et al., 2007). Social pathologies, including ageism, sexism, ableism, and others, play parts in elder abuse (Walsh et al., 2010), as do institutional pressures such as stress (Schiamberg et al., 2011) or the socio-economic predicaments of perpetrators (Lowenstein et al., 2009). On causes of

The sociology of ageing

exclusion, rather than abuse, Scharf et al. (2005: p. 78) highlight a lack of access to material resources, income, security, social relationships, civic activities, and basic services. These diminish capacities to manage everyday life, affecting people's senses of self and quality of life, as do their immediate residential settings. Forms of exclusion can cluster in particular places, impacting on residents' self-definitions, as well as the ways they are regarded by other people. In some urban areas of England, over a third of residents are socially excluded according to two or more of these measures; health and ethnic origin play parts here, as does educational level (Scharf et al., 2005: p. 83).

In different ways in cities and in rural areas, older people's settings may be changing around them, accentuating feelings of being pushed 'to the margins' (Abbott and Sapsford, 2005; Burns et al., 2012); as they age, their own preferences may change (van Dijk et al., 2015). Public settings can enhance older people's senses of self and mastery of their environments (as when they can assume that personal encounters can take place safely in familiar public spaces) or diminish it (as a lack of public transport may do). The World Health Organization (2011) has urged 'age-friendly' cities to develop social and material structures to heighten fit with older adults' needs and preferences.

A further key issue is the exclusion of (older) people from *socially meaningful life activities*. This effect is particularly pronounced in societies where social status is intimately connected with work. To envisage ageing merely as not working is contemptuous of the value of human life, constraining older people's capacities to see meaning in their own lives (Edmondson, 2015), though Gilleard and Higgs (2000, 2005) point out that leisure activities may offer some counterbalance in terms of social participation. High levels of voluntary work indicate that many older people wish to remain active but demand some degree of control over what they do. In societies where agriculture remains significant, individuals in the lowest income quintiles, many of them farmers, may continue to work until late in life—as do people in the highest, such as doctors (Mosca and Barrett, 2011). Such whole-life avocations offer access to meaningful activity and respected social participation, but they are relatively unusual; more commonly, employment ends suddenly and retirement is associated with the feeling of exclusion (Fairhurst, 2003; Wetzel and Mahne, 2016). This may be accentuated by ill-health. In particular, people living with dementia have traditionally been subject to social exclusion, though current approaches to this condition contribute to appreciating the lasting value of human dignity and the capacities of older people to support each other (Weeks et al., 2012; Zimmermann, 2017).

'Social exclusion' refers to barriers from activities regarded as normal in a given society; 'ageism', a term introduced by Robert Butler (1975: p. 22), refers to 'systematic stereotyping and discrimination against people because they are old' (cf. Nelson, 2004). Stereotyping may be so ingrained that it is hard to avoid. Perpetuating stereotypes can itself

The sociology of ageing

'increase psychosocial risk factors for ill health', including a cascade of confirmation bias, self-fulfilling prophecies among professionals, and stress induced by being part of a group that is discriminated against (Golub and Langer, 2007: pp. 9–10). Ageist stereotypes can impact strongly where older people are vulnerable, as in care homes, where managerial style is crucial. Cooney and Murphy (2009) are not alone in finding that residents' capacities to exercise a modicum of control over their lives range from broad to completely minimal; Knight et al. (2010) highlight the positive effects that participation in care homes' decisions can have. Gallagher and Edmondson (2015) argue that care settings for older people can be transformed by committed and ethical forms of personal leadership.

While ageism is experienced as a problem in the population at large (Stuckelberger et al., 2012), the study of ageing itself is not immune to it. Though researchers claim to reject 'deficit' approaches to the field, questionnaires often assume that older people's activities focus on personal relationships and immediate settings, treating activities of broader social significance as of no interest to respondents. This is despite the fact that 'three fifths of men and women over 60 in Britain are members of one or more social, leisure, community, or religious group' (Arber et al., 2002: p. 91). On the basis of 117 articles published in *Ageing and Society* between 1997 and 2000, Bytheway (2002: p. 73) argues that 'much of our research is embedded in ageist assumptions about the societal implications of an aging population.' He revives Townsend's (1981) diagnosis of 'acquiescent functionalism'; Townsend later objected to neoliberal expectations pervading sociological analysis (Macnicol, 2015). These include undue stress on the virtues of independence, which affects older people themselves. Jolanki (2009) reports that respondents in Finland felt compelled to demonstrate how 'active' they were, fearing that otherwise they might not even count as competent moral agents.

For such reasons, Tanner (2010) urges 'learning from older people' how to support their strategies for negotiating bodily and external changes while attempting to 'stay themselves'. The sociology of ageing has developed emphases on the variety of transitions in later life (Grenier, 2012) and on minority experiences of ageing such as LGBT+ perceptions (Hughes, 2016), or migrants' experiences of the life-course (Ghorashi and Vieten, 2012). Enhancing older people's social participation, for instance in lifelong learning institutions, can illuminate and explore the benefits to society at large of older people's membership (Manheimer, 2005). Endo (2020) contends in Japan that older people's participation in community activities may come to militate against the work-based paradigm of human value. Yet, for Gullette (2017), such efforts are dwarfed by the scale of ageism, which, she argues, is all-pervasive. To overcome it, an entire cultural world needs to be dismantled, a world in which growing older is insidiously equivalent to decline.

The sociology of ageing

Life-course development, social meaning, and wisdom

It is a perennial complaint that social expectations fail to emphasize older people's contributions or make good use of their skills and capacities (Riley *et al.*, 1994). Bond *et al.* (1993) suggest that people grow more individual as they age, after long personal life-courses in specific environments; rather than concentrating on loss in relation to ageing, therefore, Levenson *et al.* (2001) argue for a 'liberative' approach to it. Many people attach importance to learning through, and from, their life-courses; McGee *et al.* (2011) find that older people in Ireland not uncommonly feel they have increased in wisdom and maturity. Glück and Bluck (2013) explore how individuals' handling of their cumulative life experience can contribute to wisdom. The question is how contemporary societies respond to this.

Older people's roles in relation to life-course meaning have traditionally been conceptualized in connection with religion, but Coleman (2009) argues that they face contradictory problems here. On the one hand, they are expected to transmit traditional views down the generations; on the other, they must adapt to change. Older people themselves may face religious problems and doubts—in which, Coleman reports, churches themselves may take surprisingly little interest. Dillon (2009), analysing life-course trajectories of older people born in California in 1929, tracks their personal responses to religious issues. She distinguishes between 'spiritual seekers', occupied with trying to work out spiritual meanings in their personal lives, and those who are 'religious' in the sense of belonging to religious communities or networks, attending church and participating in connected social activities. Such prescriptive settings can offer constructive social resources; Mehta (2009) examines varying approaches to managing their own ageing among ethnic groups in Singapore with allegiances to Confucianism, Islam, or Hinduism. Contrary to arguments that older people should be treated no differently from others, these world views prescribe appropriate modes of life and personal growth for particular life stages; these can enable rich and satisfying responses. Religion thus plays a variety of complex roles in later life, though finding appropriate languages for expressing and recording the trajectories involved poses a challenge for collecting evidence (Coleman, 2011).

Lars Tornstam's work on 'gerotranscendence' explores the increasing sympathy felt by some older people with 'transcendental sources of happiness' (Tornstam, 2005: p. 59), also often difficult to express in conventional language. Often, he says, 'The experience of nature evokes the feeling of being at one with the universe, which is called at-one-ment in the Eastern tradition'; 'small everyday experiences of nature', or the experience of having grandchildren, are felt as deeply significant, 'a way in which the barrier between the self and the universe is transcended' (Tornstam, 2005: pp. 59–60). Tornstam argues that his respondents show identity changes in later life, often achieving a less self-centred 'modern asceticism' and 'broadmindedness, tolerance and

The sociology of ageing

humility' (Tornstam, 2005: pp. 68–89). Achenbaum and Orwoll (1991) also focus on increasingly transcendent attitudes in comparison with more worldly aims in earlier life stages. H.R. Moody (2002) explores the holistic, transformational notion of 'conscious aging', and Schachter-Shalomi and Miller (1995: p. 5) stresses its 'service to the community'. Rothermund and Brandstädter (2003) support a 'mindfulness' approach to ageing, focusing on continual growth and change, with evolving criteria for what individuals think of themselves as obliged to do. Thus, McKee and Barber (1999) argue that wisdom may be developed in response to loss, potentially decreasing egocentricity and heightening empathy.

Caspari and Lee (2006) portray older individuals as offering wisdom, as well as broadening other generations' personal and social networks. Wisdom is studied, in many cases inspired by positive psychology, by authors including Sternberg (1998), Baltes and Staudinger (2000), Ardelt (2004) (see Ferrari and Westlake, 2012), and Grossmann et al. (2012), who explore the influence of American versus Japanese culture on wisdom among older people, impacting on their abilities to deal with conflict. Understanding wisdom also demands reconstructing the types of reasoning it involves (Edmondson et al., 2009), as well as its variety of social forms (Edmondson, 2005, 2009, 2013). Here it is possible to use ethnographic methods to track contrasting forms of wisdom-in-use, including complex engagements in ordinary social settings (Edmondson, 2015). These everyday versions of wisdom include the ways in which social interaction can heighten the insights of individuals who, on their own, might behave less wisely. Exploring older people's roles in such processes has potential for impacting on 'deficit' models of what the life-course involves, for both individuals and the societies to which they belong (Edmondson and Woerner, 2019).

Older people's interactions with their immediate environments and their neighbourhoods, communities, and societies help them form, maintain, and develop their roles and identities. These environments can be crucial sources of support in times of loss or transition; in turn, older people contribute decisively to them, in ways that demand further emphasis and exploration. Ageing therefore needs to be understood in terms of interacting practices forming 'social ecologies', in which mutual relationships change over time within layers of social and physical space and power. As people grow older, their relations to where and how they live may change, but becoming physically more fragile need not necessarily undermine them (Peace et al., 2005; Vincent et al., 2006). The fact that social structures, interpretations, and decisions so strongly affect these developments makes the sociology of ageing a reflection by society on its own processes and on the extent to which they support 'civic, cultural, educational, and voluntary engagement', as well as 'social and spiritual wellbeing' (Eales et al., 2008: p. 111), throughout the life course.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Chapter:

Epidemiology of old age psychiatry: An overview of concepts and main studies

Author(s): Thais Minett, Carol Brayne, and Blossom C.M Stephan

DOI: 10.1093/med/9780198807292.003.0004

This chapter has two parts—the first where we discuss some of the major concepts and methodological issues in the epidemiology of mental disorders in old age, and the second containing a summary of many of the most important studies in this field.

Epidemiology is the foundation of public health and rational planning of services. In the field of old age psychiatry, the information provided by epidemiological research has been highly influential. This chapter reviews the methods used and key population-based and combined studies that inform current thinking. However, this work is a dynamic process, as cohorts now and in the future may differ in relation to cultural, psychosocial, and medical factors, which need to be understood as we move forward in time.

Epidemiology of old age psychiatry: An overview of concepts and main studies

In this chapter, we present demographic data and emphasize the changes in the age distribution witnessed in the last century around the world. Following this, we cover some of the basic epidemiological concepts. Diving further into epidemiology and neuropsychology, we raise the burden of the neuropsychiatric disorders under the new demographic scenario, methodological issues in calculating epidemiological measures, and the diagnostic methods of identifying such neuropsychiatric conditions. We include a historical perspective and the evolution of the neuropathological findings of the dementias, as well as some of the most influential epidemiological longitudinal studies and combined studies that focus on old age neuropsychological conditions.

Part 1 Epidemiology and neuropsychiatric disorders in old age

Demographic transition

The world population is ageing, with extraordinary reductions in mortality and fertility rates. As a consequence of this 'demographic transition', the older population is growing proportionally faster than the other age segments. Indeed, the number of people aged 65 years and older has tripled over the last 50 years and will more than triple again over the next 50 years.

According to the United Nations, in 1950, 5.1% of the population were aged 65 years and over worldwide. In 2020, this is estimated to increase to 9.3%. In 2050, it is projected that 15.9% of people will be aged ≥ 65 years worldwide (United Nations, 2019). This demographic transition is a global phenomenon. It was first experienced by high-income countries (HICs), though it has recently been observed in low- and middle-income countries (LMICs) (United Nations, 2010). Although the proportion of older aged individuals living in HICs is higher, most (approximately two-thirds) of the global older population have been living in LMICs. The fastest-growing portion of the older aged population are persons aged 80 years and over. The projection for 2050 is that six countries will have more than 10 million people aged 80 years or over: China (101 million), India (43 million), United States of America (32 million), Japan (16 million), Brazil (14 million), and Indonesia (12 million). Taken together, they will account for 55% of all those aged 80 years or over in the world (United Nations, 2010).

To describe the age demographic transition, four phases have been defined. In the first phase, fertility was high, and populations grew slowly, even in the face of a high level of mortality. Periodic epidemics of plague, cholera, typhoid, and other infectious diseases would, in 1 or 2 years, almost wipe out the gains made over decades. Because overall both rates were in balance, population growth was typically very slow in stage one. Many human populations are believed to have had this balance until the late eighteenth century when this balance ended in Western Europe.

Epidemiology of old age psychiatry: An overview of concepts and main studies

The second stage begins when epidemics were better controlled and improvements to food supply and sanitation started to emerge. As a consequence, death rates dropped quickly, increasing life span. In Europe, the decline in death rates started in the late eighteenth century and carried on for approximately 100 years. As fertility remained high at first, there was an excess of births over deaths which led to population growth.

In the third phase, the imbalance between births over deaths was reduced as fertility rates dropped for a variety of reasons. These include, for example, access to contraception, urbanization, a reduction in the value of children's work, greater security for the older population, an increase in parental investment in the education of children, in addition to other social changes.

In the fourth stage, mortality and fertility are in balance again, but at lower levels. In some countries, such as Germany, Italy, and Japan, birth rates have dropped below replacement level, leading to shrinking of the population.

Fertility rates are now well below the replacement level in many HICs and in 31 LMICs. The level considered to ensure the replacement of generations is about 2.1 children per woman. Total fertility rate in HICs has dropped from 2.8 children per woman in 1950–1955 to 1.6 children per woman in 2005–2010. In LMICs the decline has started later, in the last three decades of the twentieth century, but has progressed faster. From 1950–1955 to 2005–2010, total fertility in LMICs dropped by over half, from 6.0 to 2.7 children per woman. However, great disparities between HICs and LMICs still persist (United Nations, 2010).

Life expectancy at birth has increased globally by 23.8 years from 1950–1955 (i.e. life expectancy at birth 47 years) to 2010–2015 (i.e. life expectancy at birth 70.8 years). The average gain in life expectancy at birth is 24.6 years in LMICs and 11.1 years in HICs (United Nations, 2010). HICs have experienced an epidemiologic transition, in parallel with their demographic transition. In the epidemiologic transition, pandemics of infection are replaced by degenerative, neoplastic, and man-made diseases caused by the adoption of unhealthy behaviours such as tobacco use, poor dietary habits, and a decline in physical activity. This transition has also resulted in a change in the landscape of diagnosis and investigation of the modalities of disease, particularly in the dementias, including Alzheimer's disease (AD), Lewy body disease, and frontotemporal dementia, beginning in the early 1900s. Chronic diseases have become the primary causes of not only mortality, but also morbidity. This applies for HICs, as well as for LMICs where this process is under way.

With the shift in world age demographics, the population that will experience the greatest increase in risk of disease and disability will no longer be infants, but individuals aged 60 years and older. Both HICs and

Epidemiology of old age psychiatry: An overview of concepts and main studies

LMICs will therefore have to face the challenge of increases in chronic disorders, especially those disorders that are prevalent in the older aged population. This raises issues regarding prevention and treatment, as behavioural and genetic risk factors are a hallmark of this era; preventive measures are less effective, and treatments are more complex and can be lifelong, and therefore expensive.

Basic epidemiologic measures

(See Box 4.1.)

Box 4.1 Basic epidemiological concepts

- Prevalence:
$$\frac{\text{Number of cases in a population at a given period of time}}{\text{Population at the same given time}}$$
- Incidence:
 - Cumulative incidence:
$$\frac{\text{Number of new cases in a population at a given period of time}}{\text{Number of individuals at risk of developing the condition at the same given time}}$$
 - Incidence density rate:
$$\frac{\text{Number of new cases in a population at a given period of time}}{\text{Sum of the follow-up times for each individual at risk of developing the condition}}$$
- Lifetime risk:
 - Probability of someone of a given age and sex developing a condition during their remaining lifespan
- Disability-adjusted life years (DALYs):
 - Years of life lost due to premature mortality + years lost due to disability for incident cases

Prevalence

The prevalence of a condition in a population is defined as the total number of cases over the number of individuals in a population at a given time. It indicates how widespread the condition is, and it may be regarded as a snapshot of the number of affected cases in a population.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Prevalence is determined by the duration of a disease and the quantity of new cases. It is important for developing management and health service planning, as well as eradication programmes. As prevalence is measured at a given time, it is used to reveal cross-sectional associations with other variables. Such cross-sectional associations do not account for the temporal sequences of events and therefore cannot be used to establish causation. Furthermore, in neuropsychiatric syndromes, the prevalence figure is greatly influenced by operational and disease diagnostic/classification criteria.

Incidence

Incidence relates to new cases; it is a measure of the risk of developing a new condition within a specified period of time. The incidence rate is expressed either as a cumulative incidence with the number of new cases over some period of time, but also it can be expressed as a density rate when the denominator is the sum of the person-time of the at-risk population. The latter is a more precise estimate of the rate of occurrence of a particular disease, especially in cohort studies where the length of time that participants stay in the study varies. The density rate contrasts the number of new cases with the sum of the time that each person remained under observation and free from disease.

As incidence studies are more expensive and time-consuming, most of our knowledge about the epidemiology of neuropsychiatric conditions is based on prevalence, rather than incidence, studies.

Incidence can be used to determine the impact of management and treatment strategies, to identify risk factors and natural history, and to appropriately allocate future resources (e.g. public health initiatives, prevention and intervention strategies and funding for research). It is measured from data obtained in cohort studies; therefore, the temporal sequence of events is captured, allowing for the inference of not only associations, but also causation. However, estimates may be influenced by unexpected changes in the environment and the population tested (e.g. population-specific differences in risk and protective factors) and can be affected by difficulties in certainty of distinguishing new and old cases. The collection of data needed to calculate prevalence and incidence can be challenging and costly. Incidence is difficult to define in neuropsychiatric conditions, as these diagnoses are based on clusters of symptoms that vary in severity and fluctuate over time. Further, neuropsychiatric conditions are highly comorbid, with symptoms being shared by multiple diagnoses.

Lifetime risk

The definition of lifetime risk of a condition is the probability that a person who is currently free of the condition will develop it at some time during the remainder of their expected lifespan (Seshadri and Wolf, 2007). The lifetime risk of a disease is the risk over a long period, rather than the risk over a year, which is the age-specific annual incidence of the

Epidemiology of old age psychiatry: An overview of concepts and main studies

disease (Seshadri and Wolf, 2007). Operationally, the lifetime risk is the conditional probability of developing a disease when a person has reached the index age and is free of that disease. Its estimation enables a long-term perspective, which is especially useful for chronic conditions such as dementias where exposure to risk factors in mid-life can alter the incidence of disease in later life.

Disability-adjusted life years

The concept of disability-adjusted life years (DALYs) was designed to measure the global burden of a disease. It has the advantage of aggregating mortality and morbidity in a single tool. Consequently, it allows the evaluation of burden of diseases with low mortality. The DALY corresponds to the time lived with disability and the time lost due to premature mortality. This methodology uses epidemiological data and vital statistics, which are normally available even in LMICs, facilitating international comparisons and evaluations of the impact of international investments and health policies (Murray, 1994).

DALY is calculated as the sum of the years of life lost (YLL) due to premature mortality in the population and the years lost due to disability (YLD) for incident cases of the health condition:

$$\text{DALY} = \text{YLL} + \text{YLD}$$

The YLL is calculated from the number of deaths multiplied by the standard life expectancy at the age at which death occurs, which is derived from the model life-table West Level 26 which has a life expectancy at birth of 82.5 years for females and 80.0 years for males. The basic formula for YLL for a given cause, age, and sex is:

$$\text{YLL} = \text{number of deaths} \times \text{standard life expectancy at age of death in years}$$

To estimate YLD for a particular cause in a particular time period, the number of incident cases in that period is multiplied by the average duration of the disease and a weight factor that reflects the severity of the disease on a scale from 0 (perfect health) to 1 (dead):

$$\text{YLD} = \text{number of incident cases} \times \text{disability weight} \times \text{average duration of the case until remission or death (years)}$$

Additionally, 3% time-discounting and non-uniform age weights which give less weight to years lived at young and older ages might be incorporated into the calculation of DALYs. Unequal age weights are an attempt to capture different social roles at different ages. The young, and often older individuals too, depend on the rest of society for physical, emotional, and financial support. Given different roles and changing levels of dependency with age, it may be appropriate to consider valuing the time lived at a particular age unequally (Murray, 1994).

Epidemiology of old age psychiatry: An overview of concepts and main studies

The epidemiology of neuropsychiatric disorders

Neuropsychology aims to better understand the relationship between the brain and behaviour. This section will explore the epidemiology of neuropsychiatric conditions in ageing populations, with a focus on the dementias and depression, including their diagnosis, prevalence, incidence, and risk factors (where available). Evidence will be gathered from longitudinal population-based studies that have included a focus on ageing from across the world.

The global burden of old age neuropsychiatric conditions

Disability-adjusted life years

From a psychiatric point of view, recent estimates generated by the Institute of Health Metrics and Evaluation Global Burden of Disease 2010 suggest that neurological and mental disorders contribute to 6.6% of the total DALYs of the global population aged 60 years and older (Prince et al., 2015). More specifically, dementia accounted for 10.0 million DALYs in people aged 60 years and older, with 44% of the burden arising in LMICs. This figure is behind the contribution of ischaemic heart disease (77.7 million), cerebrovascular disease (66.4 million), chronic obstructive pulmonary disease (43.3 million), and diabetes mellitus (22.6 million).

Mortality of dementia

Guehne et al. (2005) conducted a review study of the mortality risk in dementia and potential influencing factors, based on population-based samples. They found that, apart from the methodological differences between longitudinal population-based studies, which this chapter will later cover intensively, all types of dementia, without exception, were associated with a considerably increased mortality risk. Moreover, the risk of death rises with advancing severity of the disorder. The authors recommended the use of incident dementia cases to calculate the course of dementia and the mean survival time more precisely. For incident cases of dementia, the time of onset of the disorder could be assumed to be the midpoint between the baseline and follow-up interview or date of death, provided that follow-ups were conducted at short intervals. However, only few studies have based their findings on incident cases. Aguero-Torres et al. (1999) calculated a mean survival time of 3.0 years among individuals aged 75 years and older with incident dementia, in contrast to a mean survival time of 4.2 years for persons without dementia. Helmer et al. (2001) reported a mean survival time in incident cases of 4.5 years among 65-year olds and a relative risk of 1.8 [95% confidence interval (CI) = 1.8–2.7]. Xie et al. (2008) observed a median survival time of 4.1 years (interquartile range 2.5–7.6) for men and 4.6 years (interquartile range 2.9–7.0) for women. Regarding the influence of education and occupation, some studies have found individuals with dementia and lower education having a *higher* survival time (Helmer et al., 2001; Qiu et al., 2001). A shorter survival time for highly educated individuals with dementia could

Epidemiology of old age psychiatry: An overview of concepts and main studies

be explained by their ability to continue living an independent life for longer, resulting in late recognition of the disease. It is presumed that there is a similarly fast progression of the underlying pathological processes, which means that, because of later recognition, highly educated persons may live with this condition for a shorter period of time and therefore present an apparently higher mortality rate (Guehne et al., 2005).

Mortality of depression

There is a well-established risk of suicide among individuals with depression and this risk is recognized not only among younger patients suffering from depression, but also among older people as well. However, depression, specially in older people, can be a consequence of medical illness and disability, and it may also influence morbidity and mortality through a variety of behavioural and biological mediators (Schulz et al., 2002). A systematic review examining the relationship between depression and non-suicidal mortality reported that there is evidence supporting an association between the two and the mechanisms that might account for this relationship (Schulz et al., 2002). The review found that rates of mortality were higher in studies: (1) with larger sample sizes; (2) where depression was assessed by a structured diagnostic interview, rather than a psychiatric examination (and, in turn, these were both higher than self-report measures); and (3) in matched control groups, compared to cohorts (and both more than general population studies). Of the studies that were restricted entirely to late-life population samples, ten (67%) disclosed positive reports and five (33%) negative reports. Among those positive studies, the relative risks for depression as a predictor of mortality varied from 1.2 to 4.0, with the majority of studies falling in the 1.5–2.5 range. Depression might increase the likelihood of dying through several factors such as poor adherence to treatment of comorbidities, poor maintenance of cognitive and physical function, and withdrawal from social networks.

Methodology

Prevalence and incidence are heavily influenced by study design, methodological differences, population uptake, and cultural factors (Brayne, 1993). This has hampered worldwide comparisons. However, there are strong examples of standardized methods across combined studies such as used in the 10/66 study discussed later in this chapter.

Case definition

To study disease incidence, prevalence, duration, and severity, the definition of what is a case is important. For some conditions, such as most infectious and parasitic diseases, this is a straightforward process. By isolating the aetiological agent or antibodies against the agent, the presence of disease can be determined. In some individuals, this may manifest in clinical symptoms, while in others it may not. However, with neuropsychiatric disorders, the diagnostic process is more involved, given

Epidemiology of old age psychiatry: An overview of concepts and main studies

each classification is based on a combination of symptoms and their quantity, duration, and intensity, and the fact that these symptoms vary across a spectrum in the population. There is therefore more difficulty in conceptualizing what a mental disorder is and in determining whether it is present or not. This is particularly difficult among the older population since medical comorbidity is common and may affect symptom profiles and interfere with functioning through, for example, polypharmacy or disease-related effects on mood and other mental functions.

Cultural aspects

Cultural concepts of diseases may lead to different expectations of what is considered mentally normal. World views towards ageing vary immensely, and as a consequence, cultural concepts influence the awareness of diseases, especially mental disorders, and the utilization of services. Furthermore, the application of standardized diagnostic instruments may not always be culturally appropriate.

In the clinical setting, patients or carers have to perceive a symptom as an abnormal feature to seek help and for the person to be defined as a case. In contrast, in most epidemiological studies, a case is defined by means of structured questionnaires in which responses will be balanced to check against a set of operational criteria; therefore, this does not rely solely on an informant's opinion, but also on informant standardized information, which, in essence, can minimize cultural bias.

There have been examples over time of studies examining indigenous and migrant populations. In a study of Cree Indians living on two reserves in Manitoba (Canada), the age-adjusted prevalence of dementia was equivalent to whites living in Winnipeg (4.2% for both groups), but AD prevalence was lower (0.5% versus 3.5% in whites) (Hendrie et al., 1993). In the UK, vascular dementia has been found to be more prevalent than AD in individuals of African Caribbean origin (versus British Caucasians) (Livingston et al., 2001; Richards et al., 2000). Paraiso et al. (2011) found that dementia in an urban area of Benin (West Africa) (3.7%; 95% CI 2.6–4.8) was slightly higher than the figure obtained in the city of Ibadan (Nigeria) of 2.3% (95% CI 1.7–2.9), but the rate was similar to that recorded in other cities in LMICs, including India (Kocki, Kerala) and countries in Latin America.

There are a number of factors which could explain the difference in prevalence estimates for dementia across different populations. First are methodological differences (i.e. in the screening tests used, the diagnostic criteria applied, sampling, etc.). Second are genetic factors and variations in risk genes across populations that could lead to differences in prevalence. Third, symptoms have to be perceived as an abnormal feature. Variations in the environment, including education and social meaning of cognitive changes with ageing, all influence how soon individuals seek medical help. Last are issues around cognitive testing which is typically biased towards those with higher levels of formal

Epidemiology of old age psychiatry: An overview of concepts and main studies

education, and therefore, those without may be directed towards a diagnosis of dementia when, in fact, the instrument was not culturally relevant to them. There have been a number of attempts to overcome this limitation such as the development of the Kimberley Indigenous Cognitive Assessment (KICA) for use with indigenous Australian populations. This is a modification of the Mini-Mental State Examination (MMSE) and asks culturally relevant questions/knowledge.

In a study of reflections of the onset and diagnosis of dementia among African American, Chinese, and Latino family caregivers in the United States, minority ethnic groups were found to convey striking cross-cultural similarities in the characterization of initial memory changes as normal ageing (Mahoney et al., 2005). As dementia symptoms progressed, however, cultural differences emerged. Normalization of cognitive symptoms until the precipitation of one critical event appeared to be most prolonged among African Americans; Chinese subjects seemed to be the most concerned about stigmatization.

Diagnostic methods

Numerous attempts have been made to deal systematically with the concepts and methods of assessment in neuropsychiatry. However, depending on the system of diagnostic classification used for a case definition, an individual can be identified as being a case according to one system, but not a case according to another. For most neuropsychiatric disorders, different diagnostic classification systems include different combinations of symptoms which reflect impairments in cognitive, emotional, and social abilities to inform the process of diagnosis. Furthermore, there is the issue of changes in diagnostic criteria over time [i.e. third (DSM-III) versus fifth (DSM-5) edition of the *Diagnostic and Statistical Manual of Mental Disorders*]. Therefore, the use of different criteria jeopardizes comparisons between studies, as they may classify the participants differently (e.g. diseased versus not diseased) (Erkinjuntti et al., 1997).

Erkinjuntti et al. (1997) examined the effects of six commonly used classification schemes on the prevalence of dementia in a population-based cohort of older people. The classification schemes used were the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) (American Psychiatric Association, 1980), the DSM-III-R (American Psychiatric Association, 1987), the DSM-IV (American Psychiatric Association, 1994), the ninth edition of the International Classification of Diseases (ICD-9) (World Health Organization, 1977), the ICD-10 (World Health Organization, 1992), and the Cambridge Mental Disorders of the Older Population Examination (CAMDEX) (Roth et al., 1986). They found that although there was substantial overlap among the groups of persons identified by the various systems, the frequency of dementia varied, depending on the scheme used. The frequency of dementia was 3.1% using the ICD-10, 4.9% with CAMDEX, 5.0% with ICD-9, 13.7% with DSM-IV, 17.3% with DSM-III-R, 20.9% according to the

Epidemiology of old age psychiatry: An overview of concepts and main studies

Canadian Study of Health and Aging (CSHA) clinical-consensus method (Canadian Study of Health and Aging Working Group, 1994), and 29.1% with the DSM-III criteria. However, while dementia prevalence varied, depending on the diagnostic criteria used, the frequency of dementia increased with increasing age for each classification method.

The ICD has existed for more than a century; it is global, multidisciplinary, and multilingual and is ratified by all 193 World Health Organization (WHO) member countries. On the other hand, the DSM was developed by the American Psychiatric Association, focuses specifically on mental disorders, and does not have such an international approach. As diagnosis in psychiatry is mostly descriptive and based on a collection of symptoms, the ICD and DSM diagnostic classifications are functionally equivalent in clinical settings. However, in epidemiological studies where structured interviews are usually employed, such differences become more important (Andrews et al., 1999).

Another methodological issue regarding the diagnosis of dementia or its subtypes is that diagnostic criteria have changed over the years, as new investigations became available. To illustrate this, the diagnosis of probable dementia with Lewy bodies (DLB) was initially based solely on clinical criteria such as the presence of dementia, visual hallucinations, fluctuations, and parkinsonism (McKeith et al., 1996). However, the third report of the Consortium on DLB International Workshop (McKeith et al., 2005) included dopamine transporter imaging among the diagnostic criteria. This technique is a functional imaging of the dopamine transporter and defines the integrity of the nigrostriatal dopaminergic system. Regarding neuropathological criteria, originally the only requirement for DLB was the presence of Lewy bodies somewhere in the brain of a patient with a clinical history of dementia. In contrast, the new criteria take into account the extent of Lewy body-related pathology and AD-type pathology in assessing the degree of certainty that the neuropathological findings explain the DLB clinical syndrome. Moreover, the use of new immunohistochemical staining techniques, such as α -synuclein which replaced the former ubiquitin immunohistochemistry for identifying α -synuclein, has been shown to be a more sensitive and specific method for detecting Lewy bodies.

Diagnostic criteria for vascular dementia and AD have also changed as a result of updates in scientific knowledge and technological advances. For AD, in the last 8 years, new guidelines, i.e. the National Institute on Aging and the Alzheimer's Association (NIA-AA) criteria released in 2011, as well as revisions of major diagnostic criteria have been released, including updates to the American Psychiatric Association's DSM-5, released in 2013; and WHO's ICD-11, released in 2018 (Stephan et al., 2014). The key aims have been to improve diagnosis in clinical/research settings, including: (1) identifying underlying causes; (2) capturing different diagnostic thresholds (e.g. prodromal, preclinical, and earlier clinical states such as mild cognitive impairment (MCI) and mild neurocognitive disorder); (3) reducing stigma; and (4) enhancing

Epidemiology of old age psychiatry: An overview of concepts and main studies

research. A part of the research criteria proposed by the NIA-AA guidelines was the introduction of biomarkers into diagnosis, including determination of brain amyloid-beta ($A\beta$) accumulation [e.g. low cerebrospinal fluid (CSF) $A\beta_{42}$ level and positive PET amyloid imaging] and neurodegeneration (e.g. MRI/PET evidence of whole brain/hippocampal atrophy, functional impairment identified using ^{18}F -fluorodeoxyglucose PET or functional MRI, and tau levels as indicated by CSF). As new promising biomarkers become available (e.g. blood-based biomarkers), it is likely that these will be introduced into updated diagnostic criteria.

For vascular dementia, in the early nineties, Roman et al. (1993) emphasized the importance of brain imaging to support clinical findings for vascular dementia. The term vascular cognitive impairment (VCI) has also been proposed that broadly encompasses cognitive deficits associated with vascular disease and its risk factors ranging in severity from mild to vascular dementia or mixed vascular dementia where cerebrovascular and AD pathologies co-occur (Harrison et al., 2016; Skrobot et al., 2018). In the updated edition of the American Psychiatric Association's DSM-5 (released in 2013), under the term 'Major Neurocognitive Disorder: NCD' are steps to assign aetiological categories to dementia such as Alzheimer's NCD or vascular NCD. Differentiation is based on clinical criteria that can be operationalized, including additional diagnostic markers such as neuroimaging (i.e. MRI/PET) and other biomarkers.

This instrumentalization of medicine impacts on epidemiology, as medical diagnosis theoretically becomes more accurate and effective, but at the same time these technologies might label individuals as diseased without them having experienced any symptoms at all and without knowing if they will ever present symptoms of the given disease. From an epidemiological perspective, the critical fact here is how these newly suggested criteria perform in samples representative of the general population. It is important to highlight that although dementia is considered a progressive disorder, in population settings, the course of symptomatology is hugely variable.

Classification problems also emerge when attempts to define the transitional state between 'normal' ageing, pathological decline, and progression into dementia are made. Although several classification systems claim to represent this intermediate stage, most prominently MCI, their criteria, and therefore outcomes, differ. To illustrate this, Matthews et al. (2008) compared the 2-year outcome of 16 different classifications in the same population-based setting. They found that the overall progression was highest in classifications in which impairment extended to memory and non-memory domains such as multiple domain mild cognitive impairment (m-MCI) (14.3%), mild neurocognitive disorder (MNCD) (31%), and mild cognitive disorder (MCD) (29%). On the other hand, the conversion rate for age-consistent memory impairment (ACMI) was 0.3% and for age-related cognitive decline (ARCD) 4%, showing that

Epidemiology of old age psychiatry: An overview of concepts and main studies

these classifications captured lower-risk groups in the population with greater stability and reversion to normality.

In many clinical research centres, the diagnosis of dementia is made based on a consensus approach, which relies on a multidisciplinary panel of expert clinicians who meet to review detailed information on various aspects of a given person such as clinical examination and informant reports of cognition, behaviour, functional impairment, and neuropsychological diagnosis. This process allows each study participant to be individually considered in detail (Weir et al., 2011). However, in such cases, the diagnosis process is inevitably influenced by the clinicians' philosophy, personality, discipline, culture, and inherent biases. Although clinical examination is of extreme importance, in the context of epidemiological research, to ensure cross-study comparisons, it is crucial to standardize the process of data collection such as cognitive function, activities of daily living, physical health, and behavioural and psychological symptoms of dementia. Otherwise, study validity might be jeopardized by between-clinician variability and changes in diagnostic criteria over time (Brayne et al., 2011).

In the context of psychiatric studies, the Present State Examination was developed as a standardized instrument (Wing et al., 1967). This instrument was adapted by Copeland et al. (1976) and renamed the Geriatric Mental State (GMS) Examination, which was designed to detect dementia, depression, and other mental illnesses in the older aged population by generating diagnostic algorithms (Copeland et al., 1986), validated against the clinical diagnostic process based on the DSM-III-R. The aim was to introduce a more structured approach to diagnosis that could be used by non-clinicians. Unlike clinicians who quickly narrow down to the presenting diagnosis, structured interviews systematically explore each diagnostic criterion before assigning a diagnosis. Studies with a large number of participants make a quasi clinical diagnosis possible by adopting this diagnostic algorithm, based on the assumption that interviewers are trained to administer questions or conduct examinations in a standardized manner (Brayne et al., 2011). Recently, there has been renewed interest in the algorithm approach (Weir et al., 2011).

Interviews

Data collection can be made by means of a written questionnaire, telephone interview, face-to-face interview with participants or their informants, or even extraction from case records and death certificates. Semi-structured interviews are preferred when there is the need to gather qualitative data, whereas in structured interviews, standardization is easily obtained to the detriment of qualitative information. In structured interviews, there is a tightly scripted text from which the interviewers are not supposed to deviate. Examples of highly structured interviews are the CAMDEX (Roth et al., 1986) and the Geriatric Mental State Examination/Automated Geriatric Examination Computer Assisted

Epidemiology of old age psychiatry: An overview of concepts and main studies

Taxonomy (GMS/AGECAT). The neurological examination in the CAMDEX is more comprehensive than the GMS. The 10/66 study, which demands high standardization due to cross-country data collection, has used two approaches for dementia diagnosis—one based on the GMS/AGECAT and the other based directly on the DSM-IV criteria.

Interviewers

In large-scale surveys, there is a tendency to recruit non-clinical interviewers to collect the data, provided the interview is structured. Naïve trained interviewers are known to be very adept at administering structured interviews in a consistent manner. Depending on what is included in the assessment protocol, there may still be a need for qualified professionals. For example, if a physical examination is intended, a doctor would normally be required (Butler and Brayne, 1998). In some multi-stage studies, lay interviewers are used in the first stage and medical doctors in subsequent stages, as in the ALPHA Liverpool study (Saunders et al., 1993) and the Nakayama study (Ikeda et al., 2001). In the Soham study, a clinician administered the CAMDEX to all participants (Brayne et al., 1997).

Sampling

To define the sampling frame of a study, the site of the study has to be defined, as well as the sample procedure. The study site might be defined geographically or, for example, be composed of individuals registered in a specific organization, such as a primary care trust, hospitals, a health care system, a retirement community, or a nursing home, or participants of an electoral register. The sample procedure might include the entire population above a certain age or use a sampling strategy to select a representative subgroup of manageable size such as random selection or systematic selection. Furthermore, stratification according to age groups, sex, or other variables (e.g. ethnicity) can also be used to not over-represent groups.

Population and community-based studies

Few studies are truly representative of the whole population. Many others would be more accurately described as population-derived, e.g. many exclude individuals in institutions. These are studies where a general population defined by geographical boundaries is the sampling frame (Poels and Last, 2008). It is well known that referral of patients can cause population bias, affecting the results of epidemiological studies (Sackett, 1979). According to the Goldberg-Huxley model of the pathway from the community to the hospital in terms of psychiatric care, there are five levels and four filters (Goldberg and Huxley, 1980). People with severe illnesses pass more easily through the filters to secondary professional care than do people with common mental disorders.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Not only is referral influenced by the condition itself, but it may also vary according to burden of symptoms, family recognition of a problem, access to health care, popularity of the condition, and the presence of specialized centres nearby (Brayne, 1993). Furthermore, specialized patient research groups derived from referrals typically use stringent selection criteria, so that patients are usually selected to have fewer comorbid conditions. As an example, the occurrence of behavioural symptoms among patients with dementia is often the triggering event for recognition and referral to health care, rather than the cognitive impairment itself (Lawlor, 2002). It is therefore important to differentiate between population-based studies and community-based studies. Where the first are potentially of use when generalizing the findings to the whole population, the latter often are restricted to members of a selected community which does not necessarily represent the population. An example is the Nun study where the entire community of nuns was involved in a longitudinal study (Snowdon et al., 1996). However, it is likely that this religious community is very different from any general population sample, and therefore, the nature of risk exposure and outcome may be different from the general population. However, depending on the research question, some findings might be suitable for generalizing purposes.

Another point that should be highlighted is that some studies may exclude individuals who live in institutions. Many countries do not have the possibility of sampling from both general and institutionalized populations. This may lead to underestimation of the prevalence and, in longitudinal terms, underestimation of decline or mortality. Larson et al. (2004) reported findings from a survival study on community-dwelling patients with AD (Larson et al., 2004) where men had a median survival of 4.2 years from their initial diagnosis and women had a median survival of 5.7 years. These estimates were longer than the ones of the Canadian Study of Aging (Wolfson et al., 2001) where the median survival was 3.2 years for men and 3.4 years for women. These differences are likely due to the Canadian Study of Aging including nursing home residents who were at a later stage of disease.

Stratification

Some epidemiological studies of dementia have used more than one-stage diagnostic procedures to optimize resources. In the first stage, a brief and inexpensive screening instrument (such as the MMSE) is administered, followed by more complex, time-consuming, and expensive tests in the second stage. Typically, all those people who screen positive (e.g. below a cut-off score on the MMSE), along with a random sample of the remainder, are seen again using more comprehensive diagnostic tools, which usually include a structured clinical assessment, a more extensive multi-domain test of cognitive function, and a structured interview with an informant. The second-stage assessment may also include a physical examination, a brain scan, and a collection of biological samples. Although a multi-stage design makes diagnostic procedures more efficient, it carries a serious problem of refusal or non-availability.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Furthermore, it is more prone to bias due to incorrect analysis of partially verified data where screened-negative participants who were not selected for the second stage are considered as true negatives or are simply excluded from the analysis. As a consequence, sensitivity and specificity are poorly estimated (Yu and Zhou, 2012). Other studies, to overcome these biases, randomly select the participants for the second stage, weighting towards cognitively impaired persons to allow for inferring the sample results back to the whole population (for example, The Medical Research Council Cognitive Function and Ageing Study (MRC CFAS), 1998). But the analyses are rarely indicated with full attention to the multiple stages and rates of dropout (Matthews, 2005). This over-inflates power in that the reported confidence intervals are, in fact, too narrow.

Screening tool: a focus on the MMSE

The MMSE is one of the most widely applied tools in clinical and research practice to screen for cognitive impairment and dementia. However, there are disagreements regarding the best cut-off score to distinguish impaired versus not impaired (e.g. 18, 21, 22, 24, or 26) and whether cut-off scores should be adjusted for age and education levels. In high-functioning samples, the MMSE is found to suffer from ceiling effects, and in low-functioning samples from floor effects. Both extended, such as the extended mental state examination (Huppert et al., 2005), and abbreviated versions, such as the 11-item version used in the European Prospective Investigation into Cancer (EPIC-Norfolk) (Matthews et al., 2011) have been created to overcome these issues. Further, due to copyright law restrictions, new brief and free screening tests that also measure cognitive function, such as the Sweet-16 (Fong et al., 2011), are becoming available and are likely to become more widely used.

Influence of other variables

Performance on cognitive tests may be influenced by many factors other than cognitive impairment such as educational background, cultural experiences, prior testing experience, emotional and physical states, the testing environment, use of medicines, and measurement error. This makes it difficult to control and compare such measurements in different studies, even if the same tool is used to assess cognition. Furthermore, most tests currently used are subject to ceiling and floor effects (Morris et al., 1999; The Medical Research Council Cognitive Function and Ageing Study (MRC CFAS), 1998).

Missing data

Almost all studies have some missing observations. Missing data can arise due to non-response at baseline, death, or dropout from the study, as well as item non-response. Longitudinal and multi-stage studies are especially prone to be subject to missing data due to death or dropout. The main concern is that in those cases, missing data are not at random and do affect final estimations. Participants with cognitive impairment are more

Epidemiology of old age psychiatry: An overview of concepts and main studies

likely to drop out from a study than healthy individuals. Chatfield et al. (2005) performed a systematic review to investigate large population-based studies of older individuals that reported on attrition between waves of a follow-up in a systematic manner. The review concentrated on dropout due to refusal, sickness, inability to locate individuals, or individuals moving away from a defined study area. They found that increasing age and cognitive impairment were the two main independent factors related to increased attrition. People who were very ill or frail had higher dropout rates, and people in worse health were less likely to be contactable on a second occasion. As these factors are not preventable, the authors suggested that over-sampling of these groups in the initial phases could be used to ensure that sufficient numbers of participants remain at follow-up. Also, the follow-up methods can be adjusted to ensure maximum participation in those individuals with cognitive impairment. The length of the interview can be modified, and a proxy interview can be used in a wider range of situations (Chatfield et al., 2005). Saxton et al. (2009) compared rates of MCI and rates of progression to dementia using different MCI diagnostic systems, and regarding dropouts, they found that MCI status at baseline was significantly associated with dropouts lost to follow-up. Obviously, loss of participants also reduces the power of a study.

Missing data are even more common in retrospective studies, in which routinely collected data are subsequently used for a different purpose. When information is gathered from participants' medical records, the notes often do not point whether or not a participant has the required risk factor. It is unwise to assume that the answer is not present when there is no indication that the risk factor was sought (Altman and Bland, 2007). There is no really satisfactory solution to the problem of missing data. The main ways of handling missing data in analysis are omitting variables or individuals who do not have complete data, or imputation whereby missing values are estimated from that individual's available data (Altman and Bland, 2007). Ignoring missing data in the analysis is a common approach; however, it might bias the results as data are rarely missing at random in cohort studies. Although imperfect, multiple imputation is recommended for handling missing data. Such models not only can control for the fact that dropout has occurred, but also, where available, may include information on the reason for dropout. Following imputation, sensitivity analysis can be run to check for similarity in observed associations in the restricted (e.g. complete-case analysis), compared to the imputation-derived, data set.

Age, period, and cohort effects

Age, period, and cohort effects are closely interrelated, as age is the result of a given year (period) minus the year of birth (cohort). Szklo and Nieto (2007) proposed a definition of age, period, and cohort effects where age effect is the change in the rate of a condition according to age, irrespective of birth cohort and calendar time; cohort effect is the change in the rate of a condition according to year of birth, irrespective of age

Epidemiology of old age psychiatry: An overview of concepts and main studies

and calendar time; and period effect is the change in the rate of a condition affecting an entire population at some point in time, irrespective of age and birth cohort. To better understand the definition of age and cohort effects, it is easier to approach them by fixing one parameter.

Age effect—let us suppose that the prevalence of a condition was measured in a single group of people born in the same year (single birth cohort) in wave-1. Five years later, the prevalence of the same condition was measured again (wave-2), and 10 years later (wave-3) in the same original group of people. If the prevalence of this condition changes between waves, this is a representation of an age effect.

Cohort effect—this can be obtained when a study is interested in looking at the prevalence of a condition only at a given age (let us say 60 years) and does so by recruiting 60-year-old individuals in wave-1, a different group of 60-year-old individuals in wave-2, and a third 60-year-old group in wave-3. If the prevalence of this condition changes between waves, this is a representation of a cohort effect, as, in fact, the different birth cohorts were compared longitudinally. The cohort effect can be seen as a result of the risk factors and environmental exposures that are present in early life or are typical for a given generation.

Period effects—these are the consequences of any phenomenon occurring at a specific point in time, which affects the entire population, reflecting changes in prevalence of a given condition across all age groups and birth cohorts (Szklo and Nieto, 2007). This is the case with wars, new curative treatments, vaccines, etc.

Regarding dementia, age effects are well established across studies, but cohort effects have historically been controversial. In the Lundby study, from 1947–1972 to 1972–1997, a decrease in the incidence of dementia was found in all age groups, except in the 40–49 interval (Bogren et al., 2007). Whether or not it is a true cohort effect or an artefact is not known. On the other hand, Rocca et al. (2011) analysed data from four studies to verify if declines in age-specific prevalence and incidence rates for dementia have occurred in recent years. Three of those were community-based studies—one conducted in Rochester, Minnesota (1975–1994) (Knopman et al., 2006); the Indianapolis branch from the Indianapolis-Ibadan Dementia Project (1992–2001) (Hendrie et al., 1995), the Chicago Health and Aging Project (1997–2008) (Hebert et al., 2010)—and a national survey the Health and Retirement Study (<http://hrsonline.isr.umich.edu>) (Juster and Suzman, 1995). In the Minnesota cohort, there were no differences in incidence across the ten birth cohorts, but a marginal decline for dementia was observed. The Chicago Health and Aging Project did not find a relationship between the calendar year of evaluation and disease incidence, which suggests no change in incidence over time. In the Indianapolis-Ibadan Dementia Project, although they found that the 2001 cohort had higher levels of hypertension, diabetes, and stroke, there were no differences in the

Epidemiology of old age psychiatry: An overview of concepts and main studies

prevalence of dementia. The Health and Retirement Study did not assess dementia directly, but 'cognitive impairment consistent with dementia' (CI-D) based on a 35-point cognitive scale or proxy's assessment of the respondent's memory for those who were not self-respondents. The authors reported that the prevalence of CI-D had an absolute decrease of 3.5 percentage points and a relative decrease of nearly 30.0%. Furthermore, the prevalence of some cardiovascular risk factors increased significantly, but higher levels of education were found in the most recent cohort.

The ZARADEMP project (Lobo et al., 2007) investigated possible cohort effects regarding the prevalence of dementia in Zaragoza, Spain for 1988 versus 1994. The authors found that there was stability in the global prevalence of dementia over time, but a decrease among men aged between 70 and 84 years. It is interesting to note that the prevalence of dementia in men found in the first cohort was also higher than in European pooled data reported during the EURODEM Concerted Action study (Lobo et al., 2000). Although in ZARADEMP, the two time points were probably too close together to detect differences in environmental exposure, the authors pointed out that the Instituto Nacional de Estadística had reported improved control of potential risk factors for dementia, such as smoking habits, diabetes, and cardiovascular disorders, in Spain.

More recent studies, summarized in three reviews (Prince et al., 2016; Stephan et al., 2018; Wu et al., 2017), suggest that in some (but not all) regions, an individual's risk of dementia may be declining or remaining stable, including, for example, studies from the UK (Matthews et al., 2013 and 2016), the United States (Satizabal et al., 2016), and France (Grasset et al., 2016). The evidence also suggests that in South East Asia, the risk of dementia is increasing—a result possibly linked to changes in health status (i.e. increases in the number of individuals with cardio-metabolic disease), lifestyle patterns (i.e. changes in dietary habits and reduced physical activity levels), and/or dementia awareness (including changes in diagnostic criteria).

Despite methodological challenges, considerable attempts have been made to compare and combine findings from epidemiological studies that focus on the most common and debilitating neuropsychiatric disorders in old age psychiatry, including dementia and depression. These studies will be presented in this chapter.

Importance of neuropathological studies in the epidemiology of dementia and its subtypes

'Plaques' in the cerebral grey matter were first described by Blocq and Marinesco in 1892 and related to the pathology of senile dementia by Simchowicz who named them as 'senile plaques' (Blessed et al., 1968). In 1907, the neuropathological findings of neurofibrillary tangles in degenerated neurons and senile plaques deposited in the cortex were

Epidemiology of old age psychiatry: An overview of concepts and main studies

first linked to a presenile dementia syndrome (Alzheimer et al., 1995). At first, this combination of presenile dementia, neurofibrillary tangles, and senile plaques, described by Alois Alzheimer, was thought to be a rare disease, separated as a distinct entity from senile dementia and was baptised as AD (Berrios, 1990; Zilka and Novak, 2006). These ancient reports were based on case reports and small groups of patients.

It was not until 1966 that an investigation of the nature and extent of the relationship between plaque formation and mental deterioration in old age was undertaken in a clinic-based study (Roth et al., 1966) conducted on patients admitted to a psychiatric hospital, a geriatric hospital, and several wards in a general hospital. The severity of dementia in individuals during life was ascertained to determine whether this bore any relationship with mean plaque counts in the cerebral grey matter. These assessments were repeated at 6-monthly intervals on survivors. Roth et al. concluded from the results of 37 patients that, far from being irrelevant to the pathology of old age mental disorder, the density of plaque formation in the brain highly correlated with quantitative measures of intellectual functioning. When the sample was expanded to 60 patients, the results were consistent, showing a highly significant correlation between mean plaque counts and scores for dementia and performance on psychological tests (Blessed et al., 1968). The plaques seen in authenticated cases of AD were indistinguishable on light microscopy from those investigated in their study. This observation led to the realization that half or more cases of senile dementia were associated with the same neuropathology that characterized the early-onset dementia of AD.

Significant knowledge of the clinical features and neuropathology of the different types of dementia has come from observations on the brains of individuals with dementia from nursing homes, acute medical units, hospitals, or ordinary post-mortem series (Zaccai et al., 2006). However, the nature of these services can lead to selection bias which influences the findings of the studies. Schneider et al. (2009) investigated the differences in neuropathological findings from persons with and without dementia in clinical versus community-based settings. They compared the neuropathology underlying no cognitive impairment, MCI, and dementia from two community-based cohorts and one clinic-based cohort. They found that community-based participants with probable AD showed less severe AD pathology and more often had infarcts and mixed pathologies, while those with MCI more often had infarcts and mixed pathologies. Also, clinic-based individuals had more Lewy bodies and atypical pathologies. Based on these results, the authors concluded that the spectrum of pathologies underlying cognitive impairment in clinic-based cohorts differs from community-based cohorts (Schneider et al., 2009). For extrapolation of results to the population to be valid, research must be conducted on a true population sample or on groups with well-characterized biases.

Epidemiology of old age psychiatry: An overview of concepts and main studies

As dementia is a chronic and progressive disorder, it is impossible to determine the exact point when an individual developed dementia. In addition to uncertainty regarding symptom onset is a lack of certainty in diagnosis. In inter-observer studies, the clinical diagnosis of AD is not 100% correct in all cases (Holmes et al., 1999; Richards and Brayne, 2010; Scheltens and Rockwood, 2011; Xuereb et al., 2000). Some classification criteria, such as the National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA), rely on histopathological confirmation to diagnose AD as a definite condition (McKhann et al., 1984). As a consequence, AD is therefore framed as a neuropathological entity in spite of the fact that the diagnosis of AD in living patients is made on the basis of clinical information (Richards and Brayne, 2010). In contrast, dementia is a syndrome, rather than a neuropathological diagnosis (Xuereb et al., 2000), and so a clinical diagnosis of AD assumes dominance of Alzheimer pathology as the cause of dementia in those patients.

The pathological criteria for AD were derived from brains originally from a highly selective clinical sample. However, the brains of people included in truly population-based neuropathological studies of dementia have a high percentage of mixed pathologies, which challenges the pathology-led model of diagnosing definitive AD. The first study to disclose such a pattern in a systematic way reported on autopsied brains of 101 participants (Xuereb et al., 2000). These findings were ratified when the sample was augmented to 213 brains (Brayne et al., 2009) where 22% of the brains of participants clinically diagnosed as having dementia had mixed pathologies. White et al. (2002) in the Honolulu-Asia Aging study also presented similar findings on 285 donated brains where 16% of the clinically demented decedents had mixed pathologies. The Hisayama study, based on 275 autopsied brains, reported an even higher proportion of mixed pathologies (34%) among those with clinical dementia (Noda et al., 2006). Also, the neuropathology group from the CFAS cohort have emphasized the high prevalence of vascular pathology in this population and the common occurrence of a mixture of both AD and vascular pathology (Neuropathology Group, 2001).

Part 2 Review of major studies in old age psychiatry

This section summarizes some of the most important and informative epidemiological studies on cognitive and other mental changes in old age. Three main types of study are discussed: combined studies; studies that have used a synthesis of the literature with data from several sources; and longitudinal studies. There are several difficulties in examining epidemiological studies in the context of dementia. For example, some studies report on overall dementia estimates, whereas others restrict their reports to AD, using this term almost as a synonym of dementia, disregarding the existence of diseases and mixed pathologies.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Combined studies

In this section, the following combined studies for the epidemiology of dementia will be presented: the EURODEM initiative; and the 10/66 Dementia Research Group.

The EURODEM initiative

In the early 1990s, there was a collaborative initiative of all major European groups working on the epidemiology of dementia, organized by EURODEM, EC Concerted Action on the Epidemiology of Dementia (Hofman et al., 1991). A total of 20 centres took part and contributed original data of 23 population studies published between 1980 and 1990, from which 12 were included in the analysis. Those studies which were methodologically similar and suitable for comparison were selected to describe geographical differences and to provide an overall estimate of the prevalence of dementia in Europe. The study confirmed the steep rise of dementia prevalence with age, showing that within 5-year age groups, the prevalence of dementia almost doubles from the age group of 65–69 onwards. No major differences were noted regarding sex; however, the overall estimates were somewhat larger for men than for women until the age of 75 years, and somewhat larger for women over the age of 75 years. These patterns were similar across the 12 studies (Hofman et al., 1991). Only 2% of cases were found in those less than 65 years.

An incidence phase of the EURODEM initiative was conducted and included results of analyses based on pooling the data from the studies conducted in Denmark, France, the Netherlands, and the United Kingdom (Launer et al., 1999). In Denmark, the Odense Study (Andersen et al., 1997) had a baseline cohort of 3346 persons; in France, the PAQUID study (Letenneur et al., 1994) included 3777 individuals at baseline; in the Netherlands, the Rotterdam study (Ott et al., 1995) had a baseline cohort of 5265 persons with age starting from 65 years; and in the United Kingdom, the MRC-ALPHA study (Saunders et al., 1992) had a baseline cohort of 5222 participants. In this pooled analysis of individuals aged 65 years and older, 528 incident dementia patients were reported over 28,768 person-years of follow-up. Incidence rates for dementia were similar across studies and increased with age; at 65 years of age, the incidence rate for dementia was 2.5 (95% CI = 1.6, 4.1), and at 90+ years, the rate was 85.6 (95% CI = 70.4, 104.0) per 1000 person-years. The study investigated potential risk factors for dementia and found that current smoking and low levels of education increased the risk of dementia significantly. A history of head trauma with unconsciousness, female gender, and a family history of dementia did not increase the risk significantly.

The 10/66 Dementia Research Group

The 10/66 Dementia Research Group (<http://www.alz.co.uk/1066/>) brings together researchers with an interest in ageing in LMICs, including

Epidemiology of old age psychiatry: An overview of concepts and main studies

determination of the prevalence and incidence of dementia and non-communicable diseases (Prince et al., 2007).

Cross-sectional comprehensive one-phase surveys have been conducted of all residents aged 65 years and over from geographically defined catchment areas in ten LMICs (India, China, Nigeria, Cuba, Dominican Republic, Brazil, Venezuela, Mexico, Peru, and Argentina), with a sample size of between 1000 and 3000 in each site. Overall, 14,960 individuals completed the prevalence study. Response rates varied between 72% and 98% (Llibre Rodriguez et al., 2008). Two approaches were used for dementia diagnosis. The first was based on a regression equation developed in the 10/66 International Pilot Study that uses coefficients derived from the GMS/AGECAT (Copeland et al., 1986), the Community Screening Instrument for Dementia, and the 10-word learning task (Prince et al., 2003). This approach has been validated for cross-cultural settings and is sensitive to educational status (a large proportion of older aged individuals in LMICs have little or no education) and regional variation, particularly associated with diversity in language and culture. The second approach applied DSM-IV criteria directly (American Psychiatric Association, 1994). For diagnosis of dementia subtypes, the following criteria were used: NINCDS-ADRDA AD criteria (McKhann et al., 1984), National Institute of Neurological Disorders and Stroke and Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) vascular dementia criteria (Roman et al., 1993), and DLB (McKeith et al., 1992).

10/66 Study: dementia

Across the 10/66 regions, dementia prevalence varied between 5.6% and 11.7%, using the regression equation. When DSM-IV criteria were applied directly, the prevalence varied between 0.4% and 6.4%. Prevalence determined by the 10/66 equation was higher at every site and generally double that estimated using direct application of the DSM-IV criteria (Llibre Rodriguez et al., 2008). Comparison of the prevalence of dementia reported in the EURODEM meta-analysis with that reported using the DSM-IV criteria in the 10/66 sites found large variation—the prevalence in urban Latin American sites was about four-fifths of that in Europe; the prevalence in the Chinese sites was just over half, and that in rural Latin American and Indian sites only between a quarter and a fifth (Llibre Rodriguez et al., 2008).

An incidence phase (3–5 years follow-up) was conducted in six of the study sites, including urban sites in Cuba, the Dominican Republic, and Venezuela and urban and rural sites in Peru, Mexico, and China. Of the 12,887 participants interviewed at baseline, 11,718 were free of dementia and 69% ($n = 8,137$) were re-interviewed, contributing 34,718 person-years of follow-up. The dementia incidence rate (per 1000-person years) was similar to that typically recorded in HICs but varied across country and with the diagnostic criteria used. When using the 10/66 equation, the incidence ranged from 18.2 (95% CI = 14.3–23.0, Peru) to 30.4 (95% CI =

Epidemiology of old age psychiatry: An overview of concepts and main studies

25.5–36.3, Mexico), and for the DSM-IV criteria, the incidence ranged from 9.9 (95% CI = 7.5–12.9, Venezuela) to 15.7 (95% CI = 12.2–19.8, Mexico) (Prince et al., 2012). In terms of risk factors, incidence was associated with age (increasing), gender (female), education (inverse association), having less assets (substantial heterogeneity in finding across sites), literacy, and poorer baseline cognitive function (assessed using verbal fluency and motor sequencing tasks).

10/66 Study: depression

Depression, anxiety, and co-occurrence of anxiety and depressive syndromes have been investigated among the 10/66 centres (Prina et al., 2011). Anxiety was measured using the GMS/AGECAT, and depression was assessed according to ICD-10 and EURO-D criteria.

The prevalence of depression according to the ICD-10 was reasonably consistent across Latin America and India (range 4.9–13.8%) but was much lower in the Chinese site. A similar pattern was also found for the distribution of anxiety (range, excluding China: 2.3–8.9%). The prevalence of co-occurring anxiety and depression ranged between 0.9% and 4.2% across sites. Having both disorders was linked to higher disability scores than having anxiety or depression alone. This has major implications for treatment outcome, which is found to be worse in individuals with comorbid anxiety and mood disorders, compared to individuals suffering from depression alone (Prina et al., 2011).

10/66 Study: summary

The 10/66 Dementia Research Group focuses on the study of dementia diagnosis among populations in LMICs. Their population-based surveys provide a unique resource for comparative descriptive research of not only prevalence and incidence, but also its effects, risk factors, costs, interventions, estimations of needs, and roles of racial mixture, micronutrient deficiency, and cardiovascular disease.

Synthesis of literature

In this section, the following studies for the epidemiology of dementia will be presented:

- Worldwide prevalence and incidence of dementia.
- Delphi consensus study.
- Meta-analysis of dementia prevalence and incidence.
- World Alzheimer Report 2015.

Worldwide prevalence and incidence of dementia

Fratiglioni et al. (1999) reviewed the prevalence and incidence data for dementia reported in the international literature from 1990 to 1998. In total, 36 prevalence (including studies with sites in: Europe, the United

Epidemiology of old age psychiatry: An overview of concepts and main studies

States, Canada, Japan, Korea, India, China, and Nigeria) and 15 incidence (including studies with sites in: Europe, the United States, China, and Taiwan) studies were identified. Worldwide dementia prevalence and incidence rates were found to increase with age. Worldwide prevalence was estimated to be 0.3–1.0 per 100 people in individuals aged 60–64 years, and 42.3–68.3 per 100 people in individuals aged 95 years and older. Incidence rates ranged from 0.8–4.0 per 1000 person-years in people aged 60–64 years and increased to 49.8–135.7 per 1000 person-years when the population was older than 95 years. Geographical variation in prevalence and incidence was low, with differences between countries largely reflecting methodological, rather than real, differences. Regarding dementia subtypes, AD was always the leading type of dementia in all continents. However, the relative proportions attributed to AD and vascular dementia seemed to differ among continents and multi-ethnic communities of Western countries. North America had the highest relative proportion of AD among all the dementing disorders (74.5%), whereas Asia had the least relative proportion of AD (46.5%). The prevalence of vascular dementia ranged from 10.0% in North America to 38.1% in Asia. Differences in diagnostic criteria and procedures might account for these inconsistencies.

Delphi consensus study

Alzheimer's Disease International convened an international group of experts to generate up-to-date evidence-based estimates for the prevalence of dementia for each world region (Ferri et al., 2005). The authors used the Delphi consensus method, which, in essence, derives quantitative estimates through the qualitative assessment of evidence where studies of widely different design and quality can be assessed. When published information is scarce, experts can make inferences using other data from comparable contexts. Although studies varied widely in quality, methodology, and dementia outcome definition, the only inclusion criterion was that the study should be population-based. They found that the seven areas with the largest number of people with dementia in 2001 were: China (5.0 million), the European Union (5.0 million), the United States (2.9 million), India (1.5 million), Japan (1.1 million), Russia (1.1 million), and Indonesia (1.0 million). They estimated that 24 million people had dementia in 2005 and that this amount would double every 20 years to 42 million by 2020 and 81 million by 2040, assuming no changes in mortality and no effective prevention strategies or curative treatments.

Meta-analysis—dementia prevalence

Prince et al. (2013) conducted a meta-analysis on the global literature on dementia prevalence published from 1980 to 2009 in 21 Global Burden of Disease regions. The search identified 147 studies (representing 135 publications), including studies from Western Europe, East Asia, the Asia Pacific High Income, North America, Latin America, South Asia, South East Asia, Australasia, the Caribbean, Central Europe, North Africa/Middle East, Western sub-Saharan Africa, Eastern Europe, and Southern

Epidemiology of old age psychiatry: An overview of concepts and main studies

sub-Saharan Africa. No eligible studies were identified for Central and Eastern sub-Saharan Africa or Central Asia. Prevalence of dementia was found to increase exponentially with age and in all regions, except North America and Asia Pacific, and men had a predicted prevalence ranging from 19% to 20% lower than women. Similar to the Fratiglioni et al. (1999) study, the estimated age-standardized prevalence of dementia in people aged ≥ 60 years varied little across regions (range between 5% and 7%), although some regions had lower (2.1% in West sub-Saharan Africa) and higher (8.5% in Latin America) estimates. Based on the figures, it was estimated that, in 2010, there were 35.6 million people with dementia worldwide, with the projected number estimated to double every 20 years to 48.1 million in 2020 and 90.3 million in 2040. These estimates are approximately 10% higher than those reported by the earlier Delphi Consensus Study described in the previous section.

Meta-analysis—dementia incidence

Jorm and Jolley (1998) conducted a meta-analysis of the age-specific incidence of all dementias, including AD and vascular dementia. The inclusion criteria were: case finding should be based on a field survey or studies of medical and social agencies, excluding purely hospital-based case register studies; age-specific incidence of dementia had to be reported for age groups spanning 10 years or less; the study had to involve a population-based sample, rather than volunteers; incidence rates had to be reported for mild or moderate dementia; and data needed to calculate the standard errors of incidence rates had to be available or accessible from the authors. The final analysis was based on data from 23 studies and showed that the incidence of both dementia and AD rise exponentially up to the age of 90 years, with no sign of levelling off, whereas the incidence for vascular dementia varied greatly. There was no sex difference in dementia incidence, but women tended to have a higher incidence of AD in very old age and men tended to have a higher incidence of vascular dementia at younger ages. East Asian countries had a lower incidence of dementia than European countries.

World Alzheimer Report 2015

The Alzheimer's Disease International's World Alzheimer Report 2015 was based on a series of updated systematic reviews conducted by an independent research group to collate and review all of the available evidence relating to the global prevalence, incidence, and costs of dementia (Alzheimer's Disease International, 2015). They reported the crude prevalence estimates of dementia in individuals aged ≥ 60 years in 2015 ranged from 4.7% in Central Europe to 8.7% in North Africa/Middle East (world estimate = 5.2%). Worldwide incidence was estimated at over 9.9 million new cases each year, with varying regional distribution: 4.9 million (49% of the total) in Asia, 2.5 million (25%) in Europe, 1.7 million (18%) in the Americas, and 0.8 million (8%) in Africa. The cost of dementia, including direct medical costs, social care costs, and costs of informal (unpaid) care, have been suggested to have increased by 35.4%

Epidemiology of old age psychiatry: An overview of concepts and main studies

from 2010 (US\$ 604 billion) to 2015 (US\$ 818 billion). The report stresses that research investment into dementia needs to be scaled up, with a focus on cure, care, treatment, prevention, and risk reduction.

Longitudinal studies

Numerous longitudinal studies on the epidemiology of depression and dementia, including its subtypes, have been undertaken in the last 50 years. We will present a selection of the main truly population-based longitudinal studies across the years to illustrate methods and findings. This cannot be comprehensive. In all of these studies, we will focus on the papers that disclosed figures for prevalence and incidence of dementia and depression, and comment on possible additional findings on those papers.

Lundby Study

The first and the longest comprehensive prospective study of an entire community, with a focus on psychiatric epidemiology, was conducted by Essen-Möller in 1947 (Essen-Möller et al., 1956). This study had a unique place in the field of not only epidemiology of old age psychiatry, but also epidemiology of psychiatry overall since it involved participants aged 15 years and over. The aim was to observe the entire population of a community in the south of Sweden, notionally called Lundby, to study individual traits and morbidity in a general population, not in patients. All but 1% of the 2550 adult inhabitants of Lundby aged 15 years and over

Epidemiology of old age psychiatry: An overview of concepts and main studies

were examined (Henderson and Jablensky, 2010). This cohort was further re-examined in 1957, 1972, and 1997. In addition to the psychiatric interview, and unlike most other surveys, information was obtained from multiple sources: face-to-face interviews, informants and community nurses, general practitioners, death registers, the Swedish psychiatric register, the national hospital inpatient register, and the local outpatient register. In 1972, the investigators were able to obtain sufficient information to reach a diagnosis on 99% of the cohort, and in 1997 on 94%.

The Lundby strategy is a marked contrast to today's large-scale surveys. Information was obtained by psychiatrists, who were free to explore the respondent's symptoms and behaviour at interview, rather than by lay interviewers who were required to complete a symptom checklist and follow a tightly scripted text from which they must not deviate.

Lundby Study: dementia

The prevalence of all-cause dementia in both sexes in the Lundby Study, according to age group, is shown in Table 4.1 (Hofman et al., 1991).

Table 4.1 Prevalence of dementia of all types in both sexes in the Lundby Study according to age group

Age group (years)	Prevalence (%)	Cases (n)	Group (n)
30-59	0.0	0	971
60-64	0.5	1	191
65-69	1.7	3	177
70-74	4.8	6	126
75-79	7.9	6	76
80-84	17.8	8	45
85-89	15.8	3	19
90-94	27.3	3	11
95-99	0.0	0	1

Epidemiology of old age psychiatry: An overview of concepts and main studies

Male- and female age-standardized first incidence rates of dementia every fifth year from 1947 to 1997 are seen in Fig. 4.1. In both males and females, a trend of decreasing dementia incidence can be observed from 1947 to 1997 (Bogren et al., 2007). The data between waves were gathered from all available sources such as registers and case notes.

Fig. 4.1

First-incidence rates of dementia in the Lundby study.

Adapted with permission from Bogren, M., et al. Lundby revisited: first incidence of mental disorders 1947-1997. *Australian and New Zealand Journal of Psychiatry*, 41 (2): 178-86. Copyright © 2007, SAGE Publications. <https://doi.org/10.1080/00048670601109964>.

This finding was unexpected and may be explained by the fact that the study ran when different principles of classification were used, possibly affecting diagnostic conclusions, or even because there was a difference in study waves regarding the number of supplementary sources of information concerning outpatient care and key informants, which was greater in 1947-1972 than in 1972-1997 (Bogren et al., 2007). An alternative explanation is that it might be a genuine cohort effect, as the incidence of dementia could have fallen due to factors such as less medical comorbidity or healthier lifestyle.

Lundby Study: depression

The median age at first onset of depression was reported to be around 35 years, and the recurrence rate was about 40%. Transition to other diagnoses was registered in 21% of the total sample, alcohol disorders in 7%, and bipolar disorder in 2%. Five per cent committed suicide, with an increased risk of suicide associated with male sex and increased

Epidemiology of old age psychiatry: An overview of concepts and main studies

depression severity. Although figures are not specific for older individuals, the Lundby Study showed that after the first onset of depression, 6% of men and 10% of women developed an organic disorder or dementia (Mattisson et al., 2007).

Lundby Study: Summary

The Lundby cohort has been followed prospectively during a period of great transition in society, which encompasses increased welfare, urbanization, and a change of societal structures, including development of public health care and education, entrance of women into the labour market, birth control, changes in family structure, lessening of the cohesive power of the family, church, and community, and changing roles of men and women. Biological and physical factors have also undergone change, including changes of lifestyle (diet and tobacco use) and availability of medical care such as new drug therapies, as well as changes in the physical environment (Bogren et al., 2007). Moreover, with an increase in life expectancy, it is possible to distinguish two different profiles for the older old and the recent old.

Iceland birth cohort

The Iceland birth cohort consisted of all Icelanders born in the years 1895, 1896, and 1897, and focused on the investigation of psychiatric diagnosis. The study was completed in four phases: the first spanning from 14 to 61 years (Helgason, 1964); the second from 61 to 75 years; the third from 75 to 81 years; and the concluding phase extending from 81 to 87 years (Magnusson, 1989). Information on the mental health of each proband was collected from several different sources. In each phase, every general practitioner in the country was interviewed in a systematic manner by a psychiatrist, asking about mental symptoms of the probands in the cohort. Next, all records from every hospital and nursing home in the country were studied and cross-checked with the data provided by general practitioners. When it was not possible to collect sufficient information to make a psychiatric diagnosis, other key informants were contacted such as relatives, local nursing staff, or neighbours. This method of data collection is referred to as the indirect method, since the information on mental and physical health did not come directly from the persons.

Diagnoses of psychiatric conditions were divided into three groups, including the dementia syndrome, affective disorders, and other mental disorders. The accuracy of the information in the initial phases of this study depended on how well the informants knew the proband. In the last phase of the study, however, an interview scheme which covered the major symptoms and signs of mental disorders in the aged population was implemented to allow validation of the indirect method.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Iceland birth cohort: dementia

The dementia syndrome was initially diagnosed using information acquired from probands and records. Individuals were categorized according to severity as either mildly or severely demented. At later study stages, the participant was interviewed using the shortened version of the GMS Schedule. This allowed psychiatric diagnoses based on the computerized program AGE CAT (Copeland et al., 1986). Comparison of dementia prevalence across methods indicated a tendency of the indirect method to over-diagnose. The average age was 87 years. Indeed, 46% of participants considered to have dementia by the indirect method did not according to AGE CAT, whereas only 3% of the probands diagnosed as not having dementia by the indirect method were diagnosed as having dementia by AGE CAT (Magnússon, 1989). The prevalence of dementia according to the indirect method was 27%, and according to AGE CAT 17%. The most disagreement was in the group of participants considered to have mild dementia.

When examining the course of mild dementia in this cohort, Magnússon and Helgason (1993) found that many cases diagnosed as mild dementia by the indirect method had no or very few cognitive symptoms when AGE CAT was applied. Almost 30% of cases of mild dementia diagnosed by the indirect method before the age of 75 years had no symptoms of dementia at the age of 81 years, and >10% continued to have mild symptoms. Similar results were found at the age of 87 years.

Iceland birth cohort: depression

The prevalence of depression according to the indirect method was 8.7%, and it was unaffected by age (Magnússon, 1989).

Iceland birth cohort: summary

The study demonstrates how prevalence can be influenced substantially by information sources. While indirect methods have their advantages (e.g. avoid retrieval problems in patient groups), within the context of psychiatric illness, reliability of diagnoses derived from indirect data is questionable. Indeed, depression and dementia were, in many cases, not known to the family doctor (Magnússon and Helgason, 1993).

Reykjavik Study (Age, Gene/Environment Susceptibility study: AGES-Reykjavik)

The Reykjavik Study started in 1967 and comprised a random sample of 30,795 participants born in 1907–1935 in Reykjavik, Iceland (Harris et al., 2007). The study was performed in six waves (1967–1969, 1970–1972, 1974–1979, 1979–1984, 1985–1991, and 1991–1996), and the study sample was divided into six groups by birth date within each month. Each group was invited to participate in specific waves of the study. One group attended at all waves, another at two, and the remaining only once. In 2002, 11,549 participants were still alive and 5764 were re-examined

Epidemiology of old age psychiatry: An overview of concepts and main studies

during 2002–2006, as part of the Age, Gene/Environment Susceptibility (AGES)-Reykjavik Study (AGES I). In this sub-study, the oldest group of the original study was not recruited. The response rate was 72%. From 2007 to 2011, there was a follow-up examination of all surviving participants who agreed to participate (AGES II). The AGES-Reykjavik Study aimed to evaluate the common mechanisms leading to diseases in neurological, cardiovascular, musculoskeletal, and metabolic systems. Participants underwent comprehensive assessments, which included a questionnaire, a clinical examination, a cognitive battery, and imaging of the brain and retina (Harris et al., 2007).

Reykjavik Study: dementia

Dementia case ascertainment followed a 3-step procedure (Qiu et al., 2010). All participants were screened using the MMSE (Folstein et al., 1975) and Digit Symbol Substitution Test (DSST) (Wechsler, 1981). Screened positives on either of the tests were administered another more complete diagnostic test battery. Those who screened positively on the Trails A and B (Reitan, 1992) or the Rey Auditory Verbal Learning Test (Rey, 1958) went for a final assessment that included a proxy interview and a neurological examination. A diagnosis of dementia and its subtypes was made by means of a consensus, including a geriatrician, a neurologist, a neuropsychologist, and a neuroradiologist. Dementia was diagnosed according to the guidelines of the DSM-IV (American Psychiatric Association, 1994). AD, according to the criteria of the NINCDS-ADRDA (McKhann et al., 1984) and vascular dementia followed the criteria of the State of California AD Diagnostic and Treatment Centers (Chui et al., 1992). Of the 3906 participants, 132 (3%) were diagnosed with dementia, including 66 with AD, 31 with vascular dementia, and 20 with both. The group also explored if microvascular damage, indicated by cerebral ‘microbleeds’ (imaging detected excess iron, possibly due to small haemorrhages) and retinal microvascular signs, was associated with cognitive impairment and dementia. People with multiple cerebral ‘microbleeds’ had lower scores on tests of processing speed and executive function, and this difference was greater if there were multiple cerebral ‘microbleeds’ in deep hemispheric or infratentorial areas. All these associations were independent of major cardiovascular factors, white matter hyperintensity, and cerebral infarcts.

Reykjavik Study: depression

Data on depressive symptoms were collected on the AGES-Reykjavik Study and included the Geriatric Depression Scale (GDS) (Yesavage, 1988), depression history, and medications. History of major depressive disorder (MDD), including age at onset and number of episodes, and MDD in the past 2 weeks were diagnosed according to DSM-IV criteria using the MINI International Neuropsychiatric Interview. A prevalence of lifetime history of MDD was reported at 4.5%; 1.5% had a current diagnosis of MDD (i.e. in the past 2 weeks) and 3.0% had a past, but no current, diagnosis (Geerlings et al., 2013). Current MDD was found to be

Epidemiology of old age psychiatry: An overview of concepts and main studies

associated with higher levels of global brain atrophy (Geerlings, 2013). The prevalence of MDD was also found to be higher in men with deficient (<30 nmol/L) versus adequate (≥ 50 nmol/L) serum vitamin D levels (3% versus 1%), but not in women (Imai et al., 2015).

Reykjavik Study: summary

This large population-based cohort has made several contributions to the understanding of risk factors for myocardial infarcts and cancers (Harris et al., 2007). Extension of the data collected as part of the AGES-Reykjavik Study will allow examination of genetic susceptibility and gene/environment interactions, as these contribute to phenotypes common in old age.

Gothenburg Study

In 1986–1987, all 85-year-old people born between 1 July 1901 and 30 June 1902 in Gothenburg, Sweden, and registered for census purposes in Gothenburg were invited to take part in a health survey. This study was conducted as part of a series of longitudinal gerontological population studies (Rinder et al., 1975). Participants from both the community and institutions were invited. Some of the later publications from this group disclose amalgamated results from this cohort and the study of women in Gothenburg, 1968–1969 (Bengtsson et al., 1973).

Gothenburg Study: dementia

A systematic subsample of 826 individuals underwent psychological and psychiatric examination comprising questions about background factors, ratings of psychiatric symptoms and signs, ratings of signs common in dementia, and tests of mental functioning. Response rate was 63% ($n = 494$). After examination, an interview with a close informant was carried out (Skoog et al., 1993). There were 147 cases of dementia, according to the DSM-III-R criteria (American Psychiatric Association, 1987), and a prevalence of 30%. Subjects with dementia were further investigated with CT scans and classified into subtypes of dementia—AD, according to the NINCDS-ADRDA classification (McKhann et al., 1984), was present in 43% of the participants; vascular dementia based on the criteria proposed by Erkinjuntti et al. (1988) was found in 47%, and dementia due to other causes was diagnosed in the remaining 9%. The 3-year mortality rate was 23% in subjects without dementia, 42% in patients with AD, and 67% in patients with vascular dementia. Individuals diagnosed as having mixed dementia were included in the vascular dementia category. The population at risk comprising 347 individuals was re-evaluated 3 years later (Aevarsson and Skoog, 1996). Of these, 188 (54%) took part in a neuropsychiatric examination at the age of 88 years. Information on 132 withdrawals (deceased and refusals) was obtained from medical records or other sources. Sufficient information was thus obtained on 320 participants (92% of the population at risk). Sixty-three (20%) developed dementia during the study period. Of these, 42 cases were diagnosed from the neuropsychiatric examination, and 21 deceased or refusals from

Epidemiology of old age psychiatry: An overview of concepts and main studies

medical records or other information. The incidence of dementia was 90/1000/year, of which the incidence of AD was 36/1000/year and vascular dementia 39/1000/year (Aevarsson and Skoog, 1996).

The group also investigated the role of blood pressure on dementia at 75, 79, and 85 years (Skoog et al., 1996) in participants free from dementia at 70 years. They found that participants who developed dementia at ages 79–85 years had higher systolic and diastolic blood pressures at 70 years of age. However, just before dementia onset, blood pressure declined and was then similar to, or lower than, that of participants without dementia. Although the sample was representative of survivors at age of 79 years, only 11 participants had dementia, and at age 85 years, 18 had dementia, which makes it difficult to extrapolate these findings. The group further investigated this relationship in a different, but larger, cohort and published similar findings (Joas et al., 2012).

Gothenburg Study: depression

The contribution of this cohort in terms of depression was based on an investigation of the relation between depression and the 3-year incidence of first ever stroke. The diagnosis of depression was made according to the DSM-III-R (American Psychiatric Association, 1987) criteria and included the categories of major depression, dysthymia, and depression not otherwise specified. The diagnoses were based on symptoms during the month preceding the examination and observed symptoms during the psychiatric examination. Of all 85-year olds, 93 had a history of stroke and 19% were diagnosed with depression. Depression at baseline [hazard ratio (HR) = 2.7; 95% CI = 1.5, 4.7] was related to an increased incidence of first ever stroke during follow-up. Depression increased the stroke risk not only among participants without dementia, but also among those with dementia. However, a stroke history at age 85 years (baseline) was not associated with clinical depression.

Gothenburg Study: summary

This study emphasises the magnitude of dementia in the very old showing that almost 10% of persons between the ages of 85 and 88 develop dementia each year. This cohort showed a high prevalence and incidence of vascular dementia with the caveat that clinically defined mixed dementias were included in the vascular dementia diagnosis. Depression was quoted as a predictor of stroke.

Cambridge City over-75s Cohort Study (CC75C)

The first cohort study especially devoted to investigating dementia from a population perspective and determining the clinico-pathological correlates of dementia was the CC75C (<http://www.cc75c.group.cam.ac.uk>). The original prevalence phase of the study is known as the Hughes Hall Project for Later Life, and the incidence survey, which was launched 2 years later, is known as the Cambridge Project for Later Life (Fleming et al., 2007). The study began in 1985. A

Epidemiology of old age psychiatry: An overview of concepts and main studies

representative sample of 2609 individuals aged 75 years and over living in Cambridge city, UK were surveyed (O'Connor et al., 1989)—approximately one-third of all residents in this age range. All people in this age group in six family practices were approached and one in three from a seventh practice. Respondent rate was 95% and 40% of the oldest old in Cambridge took part (Brayne et al., 1992), so the sample was representative of the whole population in terms of age distribution, sex, and accommodation according to the Office of Population Censuses and Surveys (OPCS).

Each survey has included a detailed cognitive assessment, including at least the MMSE (Folstein et al., 1975), usually its extended version, and, in the majority of interviews, the Cambridge Cognitive Exam (CAMCOG) (Roth et al., 1986). Sub-samples have had detailed psychiatric assessment using the CAMDEX, detailed neuropsychological assessment, informant interview, and additional tests.

A consensus diagnosis for dementia status at death was made, consistent with the DSM-IV (American Psychiatric Association, 1994) criteria, using post-mortem review of all interviews, including proxy informant data, death certificates, and retrospective informant data after death, but blinded to neuropathology findings. Dementia was rated by severity and, where possible, subtypes were identified (Brayne et al., 2009). The study is still ongoing, representing an exceptional duration for a population-based cohort, although there are now very few survivors, all aged over 100.

CC75C: dementia

The total prevalence of all grades of dementia was 10.5%. Estimates of prevalence increased with age, including: 4.1% (75–79 years), 11.3% (80–84 years), 19.1% (85–89 years), and 32.6% (90 years or over) (O'Connor et al., 1989). Annual incidence rates for dementia also increased, with age approximately doubling every 5 years: 2.3% for participants initially aged 75–79 years, 4.6% for participants aged 80–84 years, and 8.5% for participants aged 85–89 years (Paykel et al., 1994).

CC75C: depression

Using questionnaire information, diagnoses according to the DSM-III-R criteria (American Psychiatric Association, 1987) were made. In addition, the interviewing clinician rated each person for 'severity of depressive symptoms' on a 5-point scale: none, minimal, mild, moderate, and severe (Girling et al., 1995). The population's estimated prevalence of MDD, based on the DSM-III-R criteria, was 2.4% (95% CI = 0.9%, 4.0%) and was 3.0% based on the CAMDEX criteria (95% CI = 0.7%, 5.3%). Five per cent of persons diagnosed as having dementia according to the CAMDEX criteria also received a diagnosis of depression. Around one in five people with dementia were rated as mildly or moderately depressed (Girling et al., 1995).

Epidemiology of old age psychiatry: An overview of concepts and main studies

CC75C: neuropathology

Using data from the brain donation programme, neuropathological analyses on tissue from a representative sample of the older population have been undertaken. The neuropathological protocol was based on the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) method, with additional features to allow Braak staging of neurofibrillary pathology. The first 101 brains were reported by Xuereb et al. (2000), with half having developed dementia by death. The median age group was 86–90 years. This study found that tangles and neuritic plaques were highly inter-correlated. Significant, but weaker, correlations were also found between plaques and vascular amyloid, plaques and white matter pallor, tangles and vascular amyloid, and tangles and white matter pallor. Microvascular infarcts showed no relationship to any of these measures (Xuereb et al., 2000).

Results after over 200 donations had occurred have also been reported (Brayne et al., 2009). The overall burden of pathology was generally high across all participants, with most brains showing sufficiently extensive lesions to suggest a pathological classification of dementia, whether or not the donor had been clinically demented before death. However, participants with a clinical diagnosis of dementia did generally have a greater burden of pathology than those without dementia.

CC75C: summary

The main contribution for our understanding from this genuinely population-based study with substantial numbers of brains was the heterogeneity of lesions found in very old populations. Further, there was considerable overlap in the pathologies found in the demented and non-demented groups, and the pathological overlap between those diagnosed as having different subtypes of clinical dementia. This indicates that when assessing dementia during life, particularly in the older old, a focus on a single pathology has limited utility.

Framingham

Established in 1948, the Framingham study (Dawber et al., 1951) began as a longitudinal population-based cohort study of cardiovascular disease and associated risk factors, which enrolled 5209 volunteers (55% woman). Comprehensive physical examinations of the Framingham cohort have been obtained on a biennial basis. During biennial examination 14 or 15 (January 1976 through to March 1978), a dementia-free inception cohort was established. Among 2828 persons who were seen for physical examination, the response rate was 75% and complete data were available for 1085 participants aged 65 years or older who agreed to complete a brief neuropsychological screening battery (Linn et al., 1995). Starting with examination 17 (1982/1983) and on all successive biennial examinations, the MMSE was administered. Participants falling below age and education-adjusted levels were evaluated by a neurologist and a neuropsychologist to determine if dementia was present and, if so, to

Epidemiology of old age psychiatry: An overview of concepts and main studies

ascertain the dementia type. By using the criteria of Cummings and Benson (1986), dementia was considered to be present by the neurologist if the participant demonstrated a compromise in at least three areas of mental activity, including language, memory, visuospatial skills, personality or behaviour, and cognition, and if there was no disturbance in consciousness. Dementia severity was judged by criteria similar to those in the DSM-III-R (American Psychiatric Association, 1980). A neuropsychologist who was unaware of the dementia diagnosis made by the neurologist also saw the participants. If a person's performance was impaired on at least three of the seven neuropsychological tests used, they were considered to have cognitive impairment consistent with dementia. Dementia was considered present by the panel if the following three criteria were met: (1) cognitive impairment—if the neurologist found moderate or severe dementia to be present and the neuropsychologist independently confirmed the presence of cognitive impairment consistent with dementia; (2) cognitive decline—evidence that the person had definite deterioration in cognition from a pre-existing level of functioning; and (3) duration of cognitive impairment of at least 1 year (Linn et al., 1995).

Framingham: dementia

The prevalence of dementia was 30.5/1000 for men and 48.2/1000 for women and increased with advancing age. Cases of probable AD constituted 55.6% of all dementia cases. The prevalence of AD was 11.7/1000 for men and 30.1/1000 for women and also increased with advancing age. Prevalence of dementia and probable AD was greater for women than men. The female-to-male ratio of prevalence for cohort members aged 75 years and older was 1.8 for all cases of dementia and 2.8 for cases of probable AD (Bachman et al., 1992).

To determine the incidence of dementia and AD (Bachman et al., 1993), people previously free of dementia and falling below the 1-standard deviation (SD) cut-off score on screening tests were evaluated further to verify if dementia was present and, if so, the type of dementia, following the procedure described earlier. All new cases arising in this cohort over a maximum of 10 years of follow-up were ascertained. The incidence of dementia increased with age, doubling in successive 5-year age groups. Dementia incidence rose from 7.0 per 1000 per year at ages 65–69 to 118.0 per 1000 at ages 85–89 for men and women combined. The incidence of probable AD also doubled with successive quinquennia from 3.5 at ages 65–69 to 72.8 per 1000 at ages 85–89 years. Incidence of dementia and probable AD did not level off with advanced age and was not different in men and women.

Framingham: depression

In 1990, at the start of the 22nd biennial examination cycle, 1753 people from the original cohort were still alive. Of these, 1166 (67%) attended the 22nd biennial examination and, among them, 949 (81%; 604 women

Epidemiology of old age psychiatry: An overview of concepts and main studies

and 345 men) were dementia-free and were assessed for depressive symptoms. These participants were followed for up to 17 years (average follow-up 8 years) for incident dementia to examine the association between depressive symptoms at baseline and the risk of incident dementia (Saczynski et al., 2010).

During the 17-year follow-up period, 164 participants developed dementia; 136 of these cases were AD. A total of 21.6% of participants who were depressed at baseline developed dementia, compared with 16.6% of those who were not depressed. Depressed participants, defined by scores of at least 16 on the Center for Epidemiologic Studies Depression (CES-D) Scale (Radloff, 1977), had >50% increased risk for dementia (HR = 1.72; 95% CI = 1.04, 2.84) and AD (HR = 1.76; 95% CI = 1.03, 3.01). Results were similar when participants taking antidepressant medications were included. For each 10-point increase on the CES-D Scale, there was a significant increase in the risk of dementia (HR = 1.46; 95% CI = 1.18, 1.79) and AD (HR = 1.39; 95% CI = 1.11, 1.75). Results were similar when persons with possible MCI were excluded.

Framingham: summary

Another important contribution of the Framingham study to the field of dementia was the estimation of the lifetime risk of dementia. A group of 2794 participants without dementia who were 65 years or older were followed up for a maximum of 29 years (42,233 person-years). There were 400 cases of incident dementia of all types and 292 cases of incident AD. The lifetime risk of any dementia was estimated at more than 1 in 5 in women and 1 in 6 in men, and the lifetime risk of AD about 1 in 5 for women and 1 in 10 for men (Seshadri et al., 2006).

Established Populations for Epidemiologic Studies of the Elderly (EPSE)

The goals of the EPSE project were to describe and identify predictors of mortality, hospitalization, and placement in long-term care facilities and to investigate risk factors for chronic diseases and loss of functioning. The survey elicited information from persons 65 years of age and older in four different geographic locations in the United States: East Boston, New Haven, Iowa, and North Carolina. The baseline data cover demographic characteristics (age, sex, race, income, education, marital status, number of children, employment, and religion), height, weight, social and physical functioning, chronic conditions, related health problems, health habits, self-reported use of dental, hospital, and nursing home services, and depression.

In East Boston, individuals eligible for the study were identified through a total community census performed concurrently with a baseline interview in 1982. In Iowa, the sample was not truly populational since interviews were attempted with all eligible individuals enumerated using a list from the area's Agency on Aging, supplemented by additional listings from local informants. New Haven used a stratified random sample of clusters

Epidemiology of old age psychiatry: An overview of concepts and main studies

of households. The sample was stratified for three types of residence, including: public housing for the older population, private housing for the older population, and elsewhere in the community. Males were over-sampled to attempt to achieve balance in the sex distribution of the sample. In North Carolina, area sampling was used in the first stage of the design to obtain a sample of 1980 census blocks, block clusters, and enumeration districts. The sample was designed so that it would consist of at least 50% black older persons. The investigation of dementia was conducted using the sampled members of the Duke EPESE (Heyman et al., 1991), which focused on five adjacent counties, one primarily urban and the other four mostly rural, in the Piedmont area of North Carolina. The last stage of the sampling procedure consisted of selecting one older person at random from each household in which there were residents aged 65 years and older. Of 5223 persons selected for the sample, 4164 were successfully interviewed, yielding a response rate of 80%. Of these, 2259 (54%) were black and 1905 (46%) were non-black. The sampling design permitted the development of weights, which took into account age, sex, race, geographic location, the number of old people in the household, and non-response, so that it was possible to project data from the Duke EPESE sample to the same-age population of other areas.

A brief screen of cognitive function—the Short Portable Mental Status Questionnaire (SPMSQ) (Pfeiffer, 1975)—was administered at baseline, which, according to the authors, by using the adjusted scores, little race or education bias is found. The case finding procedure involved trichotomization of the SPMSQ scores, i.e. the total EPESE sample was divided into persons with scores below the cut-off for cognitive impairment, those with one point better than the cut-off, and finally, those with two points better than the cut-off. The selected participants were seen by a neurologist who administered a semi-structured interview which involved a medical and psychiatric history and a physical and neurological examination. Based on these measures, a diagnosis of dementia, and specifically of AD, was made, using the DSM-III and the NINCDS-ADRDA (McKhann et al., 1984). The severity of dementia, when present, was rated on the Clinical Dementia Rating scale, which includes information for rating the individual in six cognitive and behavioural categories: memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care (Hughes et al., 1982). The project attempted to compare the prevalence and incidence of dementia between black and all other participants.

EPESE: dementia

For the 1986 and 1987 survey, when the baseline data were collected, the estimated prevalence of dementia was 8.9% for black men, 19.9% for black women, 3.3% for white men, and 2.9% for white women. The overall estimated prevalence for blacks and whites were 16% (95% CI = 7.9, 24.1) and 3.0% (95% CI = 0, 6.9), respectively (Heyman et al., 1991). The overall prevalence of dementia among blacks was significantly higher than in whites. However, the same difference was not found in the 1989

Epidemiology of old age psychiatry: An overview of concepts and main studies

and 1990 survey where the prevalence of dementia was 7.0% (95% CI = 2.1, 11.9) for blacks and 7.2% (95% CI = 2.2, 12.2) for whites. Prevalence for black men (7.8%; 95% CI = 0.1, 15.5) exceeded that for black women (6.6%; 95% CI = 0.3, 12.9), but gender prevalence values for whites were reversed (men: 4.4%, 95% CI = 0.0, 10.3; women: 8.7%, 95% CI = 1.5, 16.0) (Fillenbaum et al., 1998).

The 3-year incidence of dementia between the two surveys 1986–87 and 1989–90 was found to be 5.8% (95% CI = 2.6, 9.0) for blacks and 6.2% (95% CI = 2.7, 9.7) for whites. Neither race nor gender differences were significant (Fillenbaum et al., 1998).

EPESE: depression

To address the influence of socio-economic variables in the association between racial differences and late-life depression, basic needs, income, and education variables controlling for sex, age, and functional status were examined (Sachs-Ericsson et al., 2005). Data for this analysis were derived from the Duke EPESE. Before adjusting for socio-economic variables, African American older people had more depressive symptoms than white older participants in the cross-sectional analyses. However, after the inclusion of socio-economic variables, the relationship was inverted, such that white Americans were significantly more likely to endorse depressive symptoms than African Americans. In the longitudinal analyses, after controlling for baseline depressive symptoms, race was unrelated to depressive symptoms 3 years later.

EPESE: summary

The study highlights the importance of race and demographic and socio-demographic factors in determining estimates of disease prevalence and incidence. These findings reinforce that there is room for improvement of chronic conditions by reducing socio-economic disparities.

Gospel Oak Study

This is a longitudinal prospective study, based on the Gospel Oak electoral ward, North London (Livingston et al., 1990a). Its main purpose was to detect those persons likely to be suffering from dementia or depression or to be impaired in performing activities of daily living. The electoral ward had an estimated population of 6136 living in 3000 households and had higher rates of most indices of deprivation than the average for England and Wales at the time.

Interviews took place in 1987. The sample consisted of all women aged over 60 years and men over 65 years who were residents of this area. All participants were interviewed using the Standard Comprehensive Assessment and Referral Evaluation (CARE) (Gurland et al., 1984). This instrument is composed of six screening scales that assess depression, organic brain syndrome, subjective memory impairment, sleep disorder, somatic symptoms, and activity limitation. The depression and dementia

Epidemiology of old age psychiatry: An overview of concepts and main studies

scales have been further refined to become depression and dementia diagnostic scales (the Dementia Diagnostic Syndrome scale) which refer to syndromes of cognitive impairment and depressed mood severe enough for further clinical intervention (Kay et al., 1964). The final sample for interview consisted of 932 participants (women over 60 years, men over 65 years) who represented 15.2% of the ward population. The response rate of available people was 87.2%.

Gospel Oak Study: dementia

On the six screening scales, 8% were identified as cases of organic brain syndrome, 27% as depressive cases, 25% with subjective memory complaints, 33% with sleep disorders, 32% with limitation in performing activities of daily living, and 24% with somatic symptoms. After refinement for identifying syndromes of cognitive impairment (the Dementia Diagnostic Syndrome scale), dementia prevalence at screening was estimated at 4.7%. However, this value increased to 7% when residents of the local authority home were included.

Eighty per cent of the 60 people initially identified by screening were further assessed using the GMS/AGECAT instrument (Copeland et al., 1986), a psychiatric interview, and neuropsychological testing (Livingston et al., 1990b). Among those participants, 43 were diagnosed as having dementia of any type, based on the psychiatric diagnosis. For the whole Gospel Oak population, the overall prevalence for dementia of any type was 6.1% (43/705). AD prevalence, according to the NINCDS/ADRDA criteria (McKhann et al., 1984), was 3.1% (22/705). Multi-infarct dementia (0.01%, 1/705), mixed dementia (0.7%, 5/705), and secondary dementia (0.7%, 5/705) were rare. In contrast, diagnosis based on the GMS/AGECAT resulted in a prevalence of organic caseness of 4% (28/705). The GMS/AGECAT was more likely to diagnose as 'organic' those participants whom the psychiatrists diagnosed as having AD. The total dementia prevalence as diagnosed by the psychiatrists was higher (6.1%) than that reported at screening (4.7%) where the prevalence was calculated according to the Dementia Diagnostic Syndrome scale.

In 1990, 502 participants were successfully re-screened using the Short CARE. Six per cent of the re-screened participants were identified as incident dementia cases, based on screening (Boothby et al., 1994), and 1.6% according to the Dementia Diagnostic Syndrome scale. However, by means of clinical diagnosis, the overall annual incidence of dementia in persons aged over 65 years was 2%.

Gospel Oak Study: depression

Depression varied according to the place of residence. A total of 17.3% (122) of the population living at home were classed as probably suffering from pervasive depression, as measured using the Depression Diagnostic Scale. Excluding those individuals who also were diagnosed as having dementia reduced the prevalence of depression to 15.9%. On the other

Epidemiology of old age psychiatry: An overview of concepts and main studies

hand, the prevalence increased to 18.5% when residents of the local authority home were included. Depression was not associated with age (Livingston et al., 1990a).

Gospel Oak Study: summary

Additional research questions within the framework of the Gospel Oak Study have focused on the association between cigarette smoking and alcohol drinking and incident cognitive impairment (Cervilla et al., 2000). Participants were asked whether they had ever smoked, and among those who smoked, currently or in the past, information was obtained on the average number of cigarettes smoked a day and on the number of years for which they had smoked. Participants were also asked about the amount of alcohol used before or after the age of 65 years. Current smokers were nearly four times more likely to be cognitively impaired than never-smokers or ex-smokers, after adjusting for baseline cognitive function, depression, occupational class, education, handicap, and alcohol consumption before and after the age of 65 years. Alcohol drinking was not a risk factor for incident cognitive impairment. The finding that current smokers, but not ex-smokers, are at higher risk of developing cognitive decline is of great public health relevance for smoking prevention and smoking cessation campaigns and policies targeting the prevention of cognitive impairment.

Cognitive Function and Ageing Study I (CFAS I)

CFAS is a multidisciplinary, multiphase, population-based study, which involved five sites with identical assessments: Cambridgeshire, Gwynedd, Newcastle, Nottingham, and Oxford. An additional site was based in Liverpool, but the sampling and interview structure were different. The study was designed to cover three main areas related to dementia and ageing, including epidemiology, neuropathology, and policy (Brayne et al., 2006). The fieldwork began in 1991 (Chadwick, 1992).

Background information on the demographics of the populations sampled was collected from the OPCS 1990–1991 census, to enable comparison with regional and national data. The population sample was drawn from the Family Health Service Authorities lists. These are registers of the general practitioners providing a near-total population enumeration in the areas chosen for study, including individuals living in institutions. Individuals aged 65 years and over were selected for participation.

Trained interviewers administered structured interviews at the respondents' homes, which included the GMS and the MMSE (Folstein et al., 1975), and basic information on residence, marital status, social class, and main occupation during working life (Elias et al., 1993); social and service contacts (Wenger, 1989); physical health and well-being, including vascular risk factors (Launer et al., 1992); activities of daily living, as measured by the Townsend Scale (Townsend, 1979); and regular medication use (prescribed and over-the-counter). CFAS I also includes a

Epidemiology of old age psychiatry: An overview of concepts and main studies

brain donation programme, with a total of 456 brains donated up to August 2004 (Matthews and Brayne, 2005).

From the five identical sites, 13,004 individuals were screened (85% response from the eligible sample). Following screening, a 20% sub-sample was selected, based on age and cognition, weighted towards the older and more cognitively frail, to complete a more in-depth interview shortly afterwards, with a repeat at 2 years. Further screening and assessment interviews with the whole sample who remained in the study were carried out (see <http://www.cfas.ac.uk> for full details on the study design) (Brayne et al., 2006).

The ALPHA Liverpool Study fits within the framework of the CFAS but started earlier than the other five centres (Saunders et al., 1993). The Liverpool Family Practitioner Committee central computerized list of general practice patients was used as a sample frame. From this list, all patients aged 65 years or over with Liverpool addresses were selected. To provide a check on the diagnosis and to enable subclassification of GMS/AGECAT organic disorder into dementia types, a sub-sample of individuals received a second-stage assessment and an informant interview conducted by psychiatrists. The informant interview consisted of the History and Aetiology Schedule (HAS), which is drawn upon by the HAS/AGECAT.

CFAS I: dementia

CFAS I has reported on the UK population prevalence and incidence of dementia, as well as extensively on cognition and MCI. In the population aged 65 years and over, the standardized (to England and Wales population estimates for 1991) dementia prevalence was estimated at 6.6% (95% CI = 5.9, 7.3). This was based on dementia defined as an AGECAT organicity rating scale of three and above. Dementia prevalence across the centres did not vary greatly, although there was some evidence of non-systematic fluctuation in individual age- and sex-specific groups.

Dementia incidence estimated between the first two waves of interviews increased with age, from 7.4 (95% CI = 3.6, 16.1) per 1000 person-years at age 65–69 years to 84.9 (95% CI = 63.0, 107.8) per 1000 person-years at age 85 years and above. The rate of increase for both sexes was marked and continued into the oldest age groups. It was estimated that approximately 180,000 new cases of dementia occur in England and Wales each year. There is no convincing evidence of variation across sites, and incidence rates did not reflect the variations in the prevalence of possible risk factors in these sites (Matthews and Brayne, 2005). CFAS has also provided profiles of cognition weighted back to the UK population, based on MMSE, extended MMSE, and CAMCOG scores [including total score and sub-domain scores of orientation, language (expression and comprehension), memory (learning, recent, remote),

Epidemiology of old age psychiatry: An overview of concepts and main studies

praxis, attention and calculation, and perception] (Huppert et al., 2005; Williams et al., 2003).

The scope and operability of 16 different terms reflecting cognitive decline intermediate to normal ageing and dementia, and quantification of their prevalence and longitudinal course of disease have also been undertaken (Matthews et al., 2008). Across the 16 definitions, prevalence estimates were found to vary substantially (range 0.1–42%). As expected, the prevalence tended to increase for those definitions that capture a broader state of impairment, including, for example, Subjective Memory Complaint (SMC) and criteria for Cognitive Impairment No Dementia (CIND), and was less frequent for more restrictive definitions, including Amnesic Mild Cognitive Impairment (A-MCI). Rates of progression to dementia also varied and tended to be low. Overall, dementia progression was highest for more broadly defined concepts and those that capture greater levels of cognitive decline, particularly in older individuals. Across definitions, at 2-year follow-up, most individuals had remained stable, reverted to normal, or developed impairment outside the intermediate range. In the neuropathological analysis, MCI was found to be associated with an increased risk of neurodegenerative and vascular pathologies (Stephan et al., 2011; Stephan et al., 2012).

In terms of risk factor analyses, CFAS has shown that a simple measure of self-rated health (SRH) was associated with a higher risk of death and functional and cognitive impairment. The associations remained after adjustment for age, gender, functional ability, and MMSE at baseline; comparing those who rated their health as excellent and good, HRs for risk of death and functional and cognitive impairment were 0.8 (95% CI = 0.8, 0.9), 0.6 (95% CI = 0.5, 0.7), and 0.7 (95% CI = 0.5, 0.9), respectively (Bond et al., 2006).

Results from the neuropathological analyses have found that multiple neuropathological features determine the overall burden of dementia, including mixed vascular and Alzheimer's lesions, together with other changes such as atrophy (Matthews et al., 2009; Neuropathology Group, 2001; Savva et al., 2009; Wharton et al., 2011). Furthermore, the relationship between the clinical manifestations of dementia and the neuropathological findings varies with age, such that there is considerable overlap in the burden of neuropathological features of AD between groups of the oldest old persons with dementia and those without dementia. Even in participants who died without dementia, the burden of Alzheimer's-type disease in the population increased with increasing age.

In the Liverpool centre, GMS interviews were obtained on 5222 (87%) of the 6035 in the study area. A total of 444 GMS/AGECAT organic cases were identified at phase 1 and a sample of these was randomly selected for re-interview at phase 2. Of the available 205 participants who were assessed by psychiatrists to verify the clinical diagnosis, dementia was diagnosed in 84% ($n = 172$) of the organic cases. At wave 2, 328 were

Epidemiology of old age psychiatry: An overview of concepts and main studies

diagnosed as cases of organic disorder (of whom 120 were from wave 1 and 208 were new cases), and 232 in wave 3 (of whom 54 were from wave 1 and 53 from wave 2, leaving 125 new cases). Comparison of the CIs for the age-specific rates by sex showed no significant sex difference for the incidence rates of undifferentiated dementia (Copeland et al., 1999).

CFAS I: depression

The age and sex prevalence of depression standardized to the 1991 population of England and Wales was 8.7% (95% CI = 7.3, 10.2). No relationship between depression prevalence and age was found. However, high deprivation, high disability, and two or more comorbid illnesses were associated with a greater prevalence of depression (McDougall et al., 2007). Some, but not all, previous neuropathology studies have found an association between depression and markers of neurodegenerative and non-AD pathology (Jellinger, 2009; Sweet et al., 2004; Thomas et al., 2001; Wilson et al., 2003). In the CFAS neuropathology resource, depression ($n = 36$ out of 153 non-demented participants at death) has been associated with subcortical Lewy bodies (Tsopelas et al., 2011). In contrast to early findings from other studies, no association was found between depression and cerebrovascular or Alzheimer's pathology, although depression was associated with neuronal loss in the hippocampus, as well as in some of the subcortical structures investigated (nucleus basalis, substantia nigra, and raphe nucleus) (Tsopelas et al., 2011). It is important to note that despite the strong statistical association with depression in the samples where subcortical Lewy bodies or neuronal loss were detected, these neuropathological features were relatively rare, and most cases of depression found in this sample were not associated with any subcortical pathology. This suggests that subcortical pathology may account for a small number of cases of late-life depression in the population.

In the ALPHA Liverpool Study, the relationship between depression and the risk of incident dementia was also investigated (Chen et al., 2008). The risk of dementia was significantly increased with level four depressive syndromes derived from the GMS/AGECAT. The multiple adjusted HR was 2.47 (95% CI = 1.25, 4.89) and 2.62 (95% CI = 1.18, 5.80) at 2- and 4-year follow-up, respectively. The effect was greater in younger participants.

CFAS I: summary

Estimates of prevalence and incidence of dementia, cognitive decline, and depression from the CFAS I represent true population estimates due to study design. This has important implications for gauging the consequence of each disease (e.g. burden of care, cost) from a true population perspective.

Cognitive Function and Ageing Study II (CFAS II)

Epidemiology of old age psychiatry: An overview of concepts and main studies

CFAS II builds on the design and infrastructure of CFAS I and consists of centres in Cambridgeshire, Newcastle, Nottingham, and CFAS Wales: Gwynedd and Swansea. Recruitment began in 2008, and the study provides data on generational and geographical differences, including people in institutions. It also provides important baseline information on older people aged 65–84 years in 2008–2011 who will reach the age of greatest frailty during the 2020s, when the peak in the number of people aged 85 years or over is expected and at a time when major therapeutic interventions for dementia could be expected to have an effect.

Both CFAS I and CFAS II had identical designs and methods, apart from a change from a two-stage design with CFAS I to a one-stage design with CFAS II. In CFAS I, the first phase was a screening process, which identified a subset of individuals who underwent diagnostic assessment. CFAS II combined the screening and assessment phases. In total, 7796 individuals (14,242 approached, 56% response) in Cambridgeshire, Newcastle, and Nottingham were interviewed at baseline (2008–2011). At 2-year follow-up, 5288 individuals were re-seen (2010–2013, 74% response).

CFAS II: dementia

CFAS II reported a UK prevalence of dementia of 6.5% ($n = 670,000$) (Matthews et al., 2013). A comparison of standardized prevalence across time showed a substantial decrease in the prevalence of dementia [odds ratio (OR) CFAS II versus CFAS I = 0.7, 95% CI = 0.6–0.9; $p = 0.003$, adjusted for age, sex, area, and deprivation status]. The overall decrease was driven by non-care settings and was not noted within people in care settings where the prevalence increased (OR = 1.7, 95% CI = 1.0–2.9; $p = 0.05$). Women had a consistently higher prevalence of dementia than men in all settings. This study provides compelling evidence that a cohort effect exists in dementia prevalence in that later-born populations have a lower risk of prevalent dementia than those born earlier in the past century in the UK.

The overall incidence of dementia was reported at 17.7 (95% CI = 15.2–20.9) per 1000 person-years (Matthews et al., 2016). When compared to the estimates of CFAS I (20.0 per 1000 person-years, 95% CI = 16.9–23.8), a reduction was observed [incidence rate ratio (IRR) = 0.8; 95% CI = 0.6–1.0; $p = 0.08$, Poisson regression, $n = 10,444$]. Gender differences were reported; the results appear to be driven by a decrease in the incidence seen in men (0.6, 95% CI = 0.4–0.9; $p = 0.007$), but not in women (1.0, 95% CI = 0.7–1.3; $p = 0.9$).

CFAS II: depression

Data on depression have been collected, but not yet analysed.

Epidemiology of old age psychiatry: An overview of concepts and main studies

CFAS II: summary

Over the last two decades, there have been major changes in the health of people aged 65 years and over, with longer life and reductions in risk factors (e.g. smoking), increases in protective factors (e.g. education), and better management of some health conditions (e.g. cardio-metabolic diseases). CFAS II has provided updated evidence for policy purposes. The study also provides an opportunity to investigate the implications of changes in morbidity and frailty on health itself, as well as the use of services and expenditure in health and social care in future.

Rotterdam Study

The Rotterdam Study is a single-centre, population-based, prospective, dynamic cohort study of individuals aged 55 years and over that started in 1990 in Ommoord, a suburb of Rotterdam. The main objective has been to investigate the prevalence and incidence of risk factors for chronic diseases in the older aged population, including cardiovascular, neurological, locomotor, and ophthalmologic diseases.

Baseline measurements were obtained between 1990 and 1993, and all participants were subsequently examined every 2–3 years. In total, 7983 (78%) persons took part, including 897 persons living in one of the six homes for older people. In 2002, another 3011 participants (55 years of age since 1990) were added to the cohort, which comprised a total of 10,994 persons. In 2006, the cohort was further expanded by 3932 persons aged 45 years and over. The total Rotterdam Study population encompasses 14,926 participants. In 1995 and 1999, random subsets of the Rotterdam Study underwent neuroimaging, and from 2005 onwards, MRI has been implemented into the core protocol of the Rotterdam Study. Up to January 2011, a total of 5886 MRI brain scans have been obtained, which include multiple scans from the same people (Ikram et al., 2011).

Regarding old age psychiatric conditions, the Rotterdam Study addresses questions about the prevalence and incidence of various types of dementia and Parkinson's disease, and also verifies the determinants of such conditions. Participants were screened for dementia using a brief cognitive test, including the MMSE and GMS. Once screened positively, participants were then seen by a physician with the CAMDEX, and those who were still suspected of dementia were examined by a neurologist, had a brain MRI, and were tested by a neuropsychologist. No interviews were done on those who screened negatively (MMSE scores 26–30).

Rotterdam Study: dementia

Of the 10,275 eligible individuals, 7528 (73%) were screened for dementia, of whom 6.3% were diagnosed as having dementia. Overall, 72% of the dementias were of Alzheimer's type, 16% were vascular dementia, 6% were Parkinson's disease dementia, and 5% were other dementias (Ott et al., 1995). At follow-up, 5571 (79%) participants were re-screened for dementia. The overall incidence was 10.7 per 1000

Epidemiology of old age psychiatry: An overview of concepts and main studies

person-years (Ott et al., 1998). Dementia subtype clinical diagnosis was determined in 98% of the cases. AD was diagnosed in 61%; mixed dementia of Alzheimer's with cerebrovascular disease was detected in 12%, vascular dementia in 14%, and other dementias in 13%.

Results from the neuroimaging data show that white matter lesions are related to impairment of subcortico-frontal functions (Breteler et al., 1994), but also that changes affecting the microstructural integrity of normal white matter before these can be visualized using conventional MRI are also associated with cognitive function (Vernooij et al., 2009b). Those changes, such as mean diffusivity and fractional anisotropy, correlate directly with the amount of myelin in the white matter and, to a lesser extent, also to axonal count. They can be measured using the diffusion tensor imaging technique in MRI.

Regarding cerebral 'microbleeds', their spatial distribution was found to follow the known topographic distribution of amyloid angiopathy implicated in AD (Vernooij et al., 2009a). They were present in one in five persons aged ≥ 60 years and in over one in three persons aged ≥ 80 years (Poels et al., 2010; Vernooij et al., 2008). Furthermore, the presence of these numerous 'microbleeds', especially in a strictly lobar location, was associated with worse performance on cognitive tests, even after adjustment for vascular risk factors and other imaging markers of small vessel disease (Ikram et al., 2011). These results suggest an independent role for 'microbleed'-associated vasculopathy in cognitive impairment.

Rotterdam Study: depression

Depressive disorders were assessed by a 2-step procedure that included completion of the Dutch version of the original CES-D Scale, and for those who screened positive for depressive symptoms, a clinical psychiatric evaluation was undertaken. A strong relationship was observed between severe coronary and aortic calcifications and depressive disorders (OR = 3.89, 95% CI = 1.55, 9.77; and OR = 2.00, 95% CI = 1.02, 3.96, respectively). Although the analysis cannot establish a causal role of atherosclerosis, due to the cross-sectional nature of the study, it provides evidence that a generalized atherosclerotic process is associated with late-life depression (Tiemeier et al., 2004).

Rotterdam Study: summary

The Rotterdam Study has extensive information from a wide variety of sources, such as biological and MRI-based data, that can be used to help untangle the association between health and health-related risk factors and poor mental health. The high prevalence with MRI scans has helped with understanding the association between white matter lesions and cognitive impairment.

Vantaa 85+

Epidemiology of old age psychiatry: An overview of concepts and main studies

The Vantaa 85+ study is a prospective population-based study, which was established in 1991 (Polvikoski et al., 1995). The study population included all individuals who were born before 1 April 1906 and were aged 85 years or over, living in the city of Vantaa in Southern Finland ($n = 601$). Clinical examination was possible on 553 (92%) participants, and a neuropathological examination on 304 (51%). A neurologist and a trained public health nurse performed the clinical evaluations, which included a structured general and neurological examination. Data were systematically collected on health, health-related behaviour, and medication. Cognitive function, depression, and functional abilities were also assessed. Survivors were re-examined in 1994, 1996, 1999, and 2001. The entire study population is now deceased.

Dementia was diagnosed using the DSM-III-R criteria, AD using the NINCDS-ADRDA criteria, and vascular dementia using the NINDS-AIREN criteria. Initial blood samples for DNA analysis were obtained from 550 of the 553 persons examined.

Vantaa 85+: dementia

AD was clinically diagnosed in 16% of the Vantaa 85+ cohort. In contrast, the prevalence of AD was 33% (Polvikoski et al., 2001) when defined neuropathologically according to the CERAD protocol (Mirra et al., 1991). Forty-one (55%) of the 74 individuals with neuropathological AD were either in the no-dementia group or had dementia non-Alzheimer's type clinically defined (Polvikoski et al., 2001). The incidence of dementia was 8.1 per 100 person-years (Ahtiluoto et al., 2010).

In this study, the authors also investigated the relation of diabetes to dementia, AD, and vascular dementia, based on the fact that population-based longitudinal studies have shown controversial findings regarding diabetes as an independent risk factor for dementia. When the prevalence of dementia was split among those with and without diabetes, no association was found between dementia and diabetes after adjusting for sex, age, education, cardiovascular conditions, and apolipoprotein E (APOE) $\epsilon 4$ allele frequency. However, the incidence of clinically defined dementia in participants free of dementia at baseline ($n = 355$) was almost twice as high in patients with diabetes (12.1 person-years, 95% CI = 8.5, 17.2) than non-diabetic (7.2 person-years, 95% CI = 5.7, 9.0) individuals, even after adjustments for age, sex, education, and APOE $\epsilon 4$ status (Ahtiluoto et al., 2010). One possible explanation for the difference between the findings for prevalence and incidence is that the dementia duration was shorter in diabetic, compared to non-diabetic, participants, probably due to the diabetes-related increase in mortality.

Regarding the neuropathological findings, the proportion of individuals with β -amyloid and neurofibrillary tangles was lower in diabetic, compared to non-diabetic, individuals. In contrast, the proportion of participants with cerebral infarctions was significantly higher in diabetic,

Epidemiology of old age psychiatry: An overview of concepts and main studies

compared to non-diabetic persons, even after adjustments for age at death, gender, education, APOE, and dementia status.

Vantaa 85+: depression

Depressive symptoms were investigated using the Zung Depression Status Inventory (DSI) (Zung, 1972), which is a 20-item semi-structured, interviewer-rated depression instrument, with scores ranging from 25 to 100. Higher scores indicate more depressive symptoms. In the general population aged 85+ years, there was a very low prevalence of depression (1.1% for clear-cut clinical depression, and 4.1% for minimal to mild depression). Among participants with dementia, vascular dementia was significantly more common in individuals with higher depression scores (40 points or more on the Zung DSI). There was no association between Zung DSI scores and dementia severity.

Vantaa 85+: summary

The Vantaa 85+ study is one of the few autopsy-controlled, prospective, and population-based studies available on the prevalence of dementia in the very old population.

Personnes âgées QUID (PAQUID)

Paquid was the first large French epidemiological study on dementia. It is an interdisciplinary study designed to investigate cerebral and functional ageing. Residents living in two administrative areas of South-Western France (2797 in Gironde and 1504 in Dordogne) were randomly chosen from the electoral lists. A cohort of 3777 participants aged 65 years or over was interviewed. This cohort was complemented by a random sample of 380 institutionalized persons (Letenneur et al., 1993a).

Trained psychologists administered a standardized questionnaire at home. Baseline variables included socio-demographic factors, living conditions and habits, subjective health measures, dependence in activities of daily living (ADL) (Katz et al., 1970) and Instrumental Activities of Daily Living (IADL) (Lawton and Brody, 1969), and the Rosow and Breslow scale (Rosow and Breslau, 1966). Depressive symptomatology was also assessed. Intellectual functioning was examined through an extensive test battery that included an evaluation of global mental status, visual memory, verbal memory, verbal fluency, visuospatial attention, and simple logical reasoning.

After the psychometric evaluation, the psychologists completed systematically a standardized questionnaire, allowing determination of the DSM-III criteria for dementia. Patients who met the DSM-III criteria for dementia were seen by a neurologist who applied the NINCDS-ADRDA criteria to indicate the aetiology of the deterioration. Persons were re-evaluated following the same procedure as used for the baseline screening at 1, 3, and 5 years after the initial visit in Gironde, and 3 and 5 years after the initial visit in Dordogne. However, to improve the

Epidemiology of old age psychiatry: An overview of concepts and main studies

sensitivity of the detection of incident cases, respondents were selected for the neurological examination if they met the criteria for DSM-III-R dementia or if they had experienced a cognitive decline of >2 points on the MMSE.

PAQUID: dementia

Of the 5554 contacted subjects, 3777 (68%) agreed to participate in the study. The overall prevalence of dementia was estimated, based on the Gironde data, and was 4.3%. No difference was found between men and women (Letenneur et al., 1993b). Risk factor analysis found a greater risk for AD in people with fewer years of formal education. The overall incidence of dementia and AD was estimated at 1.59/100 person-years and 1.17/100 person-years, respectively. The incidence of AD was higher in women than in men after 80 years of age, whereas the incidence was higher in men before the age of 80 years. This different progression of the incidence according to sex was not found when other dementias were analysed (Letenneur et al., 1999). Numerous risk factors for dementia have been identified, with examples including a decreased risk in participants with lower psychosocio-economic precariousness, who remain/become active, and who have higher levels of engagement in social, physical, or intellectual pursuits (Dartigues et al., 2013; Foubert-Samier et al., 2014; Marioni et al., 2015; Ouvrard et al., 2017).

PAQUID: depression

To estimate the predictive relationship between depressive symptoms and incident dementia, Fuhrer et al. (2003) investigated 16,373 person-years of observation. The baseline prevalence of depressive symptomatology was 12.9% for men and 14.7% for women. The OR for the age-adjusted association between elevated depressive symptoms and onset of dementia was 2.0 (95% CI = 1.4, 2.8). However, after adjusting for gender, education, and cognition, the risk was reduced to 1.3 (95% CI = 0.8, 2.0), but these associations were significantly different between men and women. Men who had high depressive symptoms were more than three times as likely (OR = 3.5, 95% CI = 1.9, 6.5) than men with low depressive symptoms to develop incident dementia. This effect was not replicated for women. A possible explanation for this finding could be due to sex differences in vascular disease. It was found that the risk of dementia for men with hypertension who were depressed was 50% higher than for normotensive depressed men.

PAQUID: summary

PAQUID is an interdisciplinary study on cerebral and functional ageing, made up of a cohort of 3777 community residents living in two administrative areas of South-Western France. It has one of the longest follow-ups (i.e. 20 years). The epidemiological basis of the research programme is focused on the incidence, natural history, and risk factors of dementia.

Epidemiology of old age psychiatry: An overview of concepts and main studies

Italian Longitudinal Study of Ageing (ILSA)

ILSA is a population-based, longitudinal study aimed at determining the health status of people aged 65–84 years (Maggi et al., 1994). Common chronic conditions were investigated, along with potential risk and protective factors. ILSA was also designed to assess age-associated physical and mental functional changes. A random sample of 5632 people, stratified by age and sex using an equal allocation strategy, was gathered from the demographic lists of the registry office of eight municipalities including: Genoa, Segrate (Milan), Selvazzano-Rubano (Padua), Impruneta (Florence), Fermo (Ascoli Piceno), Napoli, Casamassima (Bari), and Catania. Baseline examination started in March 1992. Case identification for all conditions was based on a two-phase procedure, consisting of a screening phase, administered by lay interviewers, and, for those who screened positive, a clinical assessment run by specialists according to the condition. The final diagnosis of dementia was made according to the DSM-III-R criteria, for AD according to the NINCDS-ADRDA criteria, and for vascular dementia and other dementias according to the ICD-10. From the total population sampled, 5462 were eligible, 84% took part in the home interview, and 64% participated in the clinical examination (The Italian Longitudinal Study on Aging Working Group, 1997).

ILSA: dementia

Among the 3497 persons included in the baseline wave, the prevalence of dementia was 7.2% for women and 5.3% for men (The Italian Longitudinal Study on Aging Working Group, 1997). The follow-up phase was conducted on 2498 individuals free of dementia who were reassessed after a mean period of 3.8 years. The incidence rate of overall dementia was 12.5 per 1000 person-years (Di Carlo et al., 2002).

ILSA: depression

Depressive symptoms were investigated using the Italian version of the 30-item GDS (Yesavage et al., 1982). Further investigation sought to determine the possible impact of depressive symptoms on the rate of progression to dementia in individuals diagnosed with MCI (Panza et al., 2008). Of the 2963 participants, 139 prevalent patients with MCI were diagnosed at baseline. During the 3.5-year follow-up, 14 patients with MCI progressed to dementia, of whom nine had a GDS score of over 10. The association between depressive symptoms and the rate of progression to dementia in MCI was not significant [relative risk (RR) = 1.42, 95% CI = 0.48, 4.23].

ILSA: summary

This cohort has produced results on the prevalence of not only neuropsychological conditions such as dementia, but also general medical disorders such as myocardial infarction, angina, arrhythmia, congestive heart failure, peripheral arterial disease, hypertension, diabetes, stroke,

Epidemiology of old age psychiatry: An overview of concepts and main studies

parkinsonism, and disability. These data are of great importance for planning of health services, to evaluate the real needs for assistance and to study those factors that determine the transition from independence to loss of autonomy.

The Three-City Study (3C)

The main objective of the 3C Study is to estimate the risk of dementia attributable to vascular diseases or vascular risk factors and to provide data for modelling the expected impact of vascular risk reduction on the incidence and prevalence of dementia (<http://www.three-city-study.com/>). Other objectives are to study the incidence and risk factors of stroke, to provide data on the incidence and risk factors of coronary diseases, and to analyse temporal trends in the incidence and prevalence of incapacities and loss of autonomy (Alperovitch et al., 2002). Recruitment was undertaken based on the electoral registries of three French cities (Bordeaux, Dijon, and Montpellier) and included individuals aged 65 years and over between 1999 and 2011. The acceptance rate was 37% (9693) of the selected people who could be contacted.

Data were collected during face-to-face interviews using standardized questionnaires. Baseline work-up included extensive assessment of vascular risk factors, including blood pressure measurements, ultrasound examination of the carotid arteries, measurement of biological parameters such as blood glucose, urea and electrolytes, and lipids, cognitive functioning, and a clinical diagnosis of dementia. Cerebral MRI examinations were also performed in a sub-sample of 3442 persons aged between 65 and 79 years. Participants have been re-examined, on average, every 2 years. The third wave of follow-up examinations started in 2006 and was completed in 2012.

Dementia was diagnosed using a three-step procedure (3C Study Group, 2003). Firstly, screening was based on a thorough neuropsychological examination by trained psychologists. From the initial cohort of 9693 participants, seven had to be excluded as they were aged <65 years. Secondly, participants who were suspected of having dementia on the basis of their neuropsychological performance were examined by a neurologist. Four per cent of the participants refused to take part in the medical interview. Finally, all suspected dementia cases were analysed by a common independent committee of neurologists according to the DSM-IV criteria. The committee reviewed by teleconference all potential cases of dementia of the three study centres to obtain a consensus on the diagnosis and aetiology, based on all existing information. With regard to the different subtypes of dementia, AD was diagnosed according to the NINCDS-ADRDA criteria, and vascular dementia based on the history of vascular disease, the Hachinski score (Hachinski, 1994), and MRI whenever possible (Raffaitin et al., 2009). To date, the baseline vascular risk has been investigated and the prevalence of vascular disease at baseline explored (3C Study Group, 2003).

Epidemiology of old age psychiatry: An overview of concepts and main studies

3C: dementia

The baseline prevalence of dementia was 2.2% (3C Study Group, 2003). During 4 years of follow-up, 0.84 incident dementia cases per 100 person-years (95% CI = 0.72, 0.95) were validated (Raffaitin et al., 2009). The authors investigated the relationship between incident dementia and metabolic syndrome, defined according to the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) criteria (Grundey et al., 2005). Metabolic syndrome was present in 15.8% of the study participants, and its presence increased the risk of incident vascular dementia, but not AD, over 4 years (Raffaitin et al., 2009). High triglyceride level was the only component of metabolic syndrome that was significantly associated with the incidence of all-cause (HR = 1.45, 95% CI = 1.05, 2.00) and vascular (HR = 2.27, 95% CI = 1.16, 4.42) dementia. Diabetes, but not impaired fasting glycaemia, was significantly associated with all-cause (HR = 1.58, 95% CI = 1.05, 2.38) and vascular (HR = 2.53, 95% CI = 1.15, 5.66) dementia. It is worth highlighting that one of the challenges in studies which use all the available information to diagnose subtypes of dementia is that it is difficult to avoid the circular process of diagnosis of vascular dementia, which might result in over-emphasizing the strength of relationships.

3C: depression

The relationship between metabolic syndrome and depression was also investigated. Both metabolic syndrome and depressive symptoms increased during old age (Akbaraly et al., 2011). Over the 4-year follow-up, 827 (18.6%) new cases of depression, measured using the CES-D Scale (Radloff, 1977), were observed. Participants with metabolic syndrome were more likely to develop depressive symptoms (OR = 1.73, 95% CI = 1.02, 2.95), compared to participants without metabolic syndrome, even after adjusting for socio-demographic characteristics, smoking, alcohol consumption, and health status factors such as treatment, cognitive deficit, disability, body mass index, and self-reported history of cardiovascular disease at baseline. However, this association was not significant within the older age groups (70–75, 75–80, and 80–91 years). Regarding the specific components of metabolic syndrome, low high-density lipoprotein (HDL) cholesterol was associated with increased odds of new-onset depressive symptoms in those aged 65–69 years. These results suggest that onset of late-life depression (age above 70 years) does not share the same aetiology and risk factors as onset of depressive symptoms in middle-aged and ‘young’ old people. However, the results could also be due to different response rates or bioresources at different ages.

3C: summary

This is a population-based study which focuses on the investigation of the association between vascular health, cerebrovascular disease, and risk of cognitive decline and dementias. New data collected from the third wave

Epidemiology of old age psychiatry: An overview of concepts and main studies

of follow-up has been important for investigating the long-term impact of vascular disease and its risk factors on cognitive health.

Epidemiological Clinicopathological Studies in Europe (EClipSE)

EClipSE harmonizes the neuropathological and longitudinal clinical data of brain donors from three population-based, prospective, longitudinal studies of ageing in Europe that included a brain donation programme: the CFAS (baseline 1989–1993), the CC75C (baseline 1985), and the Vantaa 85+ (baseline 1991) studies (EClipSE Collaborative Members, 2009) (<http://www.eclipsestudy.eu>). The project was created to address the lack of statistical power within individual studies for specific analyses assessing relationships between data collected during life and neuropathology at death. All three studies interviewed participants at regular intervals, including information on socio-demographic details and health status, in addition to cognitive function, including dementia diagnosis. Neuropathological parameters include neocortical and hippocampal neuritic plaques, diffuse plaques, tangles, cerebral amyloid angiopathy and atrophy, lacunes, infarcts, white matter pallor, Braak stage, and brain weight. This study is the largest data set of its type in the world, with brain donor sample sizes of 241 (CC75C), 304 (Vantaa 85+), and 548 (CFAS).

EClipSE: dementia

The potential protective role of education for dementia was explored within the EClipSE study (Brayne et al., 2010). Almost all older people have some pathology in their brain at death but have not necessarily died with dementia. The relationship between education and brain pathology at death was investigated, testing the hypothesis that greater exposure to education reduces the risk of dementia through either protection from pathology or compensatory mechanism (EClipSE Collaborative Members et al., 2010). Education during earlier life was recorded in number of years; incident dementia was detected through follow-up interviews, complemented by all the available sources of information such as retrospective informant interviews, death certificate data, and linked health/social records after death. Dementia-related neuropathologies were assessed, based on the CERAD protocol (Mirra et al., 1991). Eight hundred and seventy-two brain donors were included, of whom 56% were diagnosed as having dementia at death. The main findings in this study were that longer years in education were associated with decreased dementia risk at death (OR = 0.89, 95% CI = 0.83, 0.94). Moreover, education did not protect individuals from developing neurodegenerative and vascular neuropathology by the time they died, but it did appear to mitigate the impact of pathology on the clinical expression of dementia before death. In other words, for a specific pathological burden, those participants who remained in education for longer, earlier in life, were at reduced dementia risk in older age. These results support the ‘brain reserve hypothesis’ (Stern, 2002; Valenzuela, 2008) where greater exposure to education reduces the risk of clinical dementia by

Epidemiology of old age psychiatry: An overview of concepts and main studies

compensating for the pathological burden later in life, rather than being protective against the accumulation of pathology.

Geographical and cross-cultural differences such as education should be taken into account when interpreting the study results. During the early mid-twentieth century, the educational systems differed considerably between the UK (CFAS and CC75C) and Finland (Vantaa 85+). Participants from CFAS and CC75C completed an average of 9 years of formal education, while participants from the Vantaa 85+ study completed approximately 4 years. However, even after controlling the analysis regarding education and dementia for study site differences, age, and sex, the results remained strongly associated.

EClipSE also investigated the significance of rarer and 'disregarded' pathologies, such as Pick bodies, severe neuronal loss, gliosis, and granulovacuolar degeneration, along with brainstem plaques, tangles, neuronal loss, gliosis, pigmentary incontinence, and Lewy bodies, in relation to dementia in the population. A total of 627 individuals with clinical dementia were assessed. All pathologies were associated with dementia when controlling for plaques and tangles, except Hirano bodies, granulovacuolar degeneration, and brainstem plaques, which shows that dementia in old age is associated with a broad range of pathological and anatomical substrates (Keage et al., 2012).

EClipSE: depression

Depression has not yet been studied within the EClipSE data resource.

EClipSE: summary

The EClipSE study represents a unique resource of neuropathological and longitudinal clinical data of brain donors in Europe. Data from three studies were combined: CFAS in England and Wales, CC75C in England, and the Vantaa 85+ study in Finland. The finding that education can mitigate the impact of pathology on the clinical expression of dementia, combined with an understanding of life course factors, supports investments in health and education in early life.

Newcastle 85+ Study

The focus of the Newcastle 85+ Study is the oldest old. The main aim is to examine health trajectories and outcomes as the cohort ages and their associations with underlying biological, medical, and social factors. All individuals born in 1921 who were permanently registered with a participating general practice in Newcastle upon Tyne or North Tyneside primary care trusts in the UK were sampled (Collerton et al., 2007). Of the 1470 people eligible to participate, 1042 participated, with three having health assessment only, 188 having general practice record review only, and 851 having both (Collerton et al., 2009). Participants were re-seen at 18 (phase 1), 36 (phase 2), and 60 (phase 3) months. Since

Epidemiology of old age psychiatry: An overview of concepts and main studies

September 2016, the study has been undertaking a 10-year follow-up (phase 4).

For most diseases, prevalence was determined on the basis of a review of data from general practice records alone. The targeted common old age chronic diseases include: hypertension, ischaemic heart disease, cerebrovascular disease, peripheral vascular disease, heart failure, atrial flutter or fibrillation, arthritis, osteoporosis, chronic obstructive pulmonary disease or asthma, diabetes, hypothyroidism, hyperthyroidism, cancer diagnosed within the past 5 years, eye disease, dementia, Parkinson's disease, and renal impairment.

Newcastle 85+ Study: dementia

Screening for dementia was based on the standardized MMSE score (sMMSE). Using the sMMSE score, moderate or severe cognitive impairment was found in 12.5% (105/840) of participants, of whom 53% (56/105) had no diagnosis of dementia in their general practice records. Therefore, the prevalence of undiagnosed cognitive impairment was estimated at 7%.

Newcastle 85+ Study: depression

Depression was assessed using the GDS. Similar results were disclosed for depression as for dementia; 8.4% of the participants (65/772) had a GDS score suggestive of severe depression, of whom 82% (53/65) had no diagnosis recorded in their general practice records in the previous year.

Newcastle 85+ Study: summary

Overall, this large cohort of 85-year olds showed good levels of both self-rated health and functional ability, despite significant levels of disease and impairment. Hypertension, ischaemic heart disease, atrial fibrillation, depression, and dementia may, however, be underdiagnosed among this age group.

Conclusion

There is a continuous need for further epidemiological research in old age psychiatry as the world population is ageing. Neuropsychiatric conditions, such as depression and dementia, cognitive impairment, and behavioural and functional decline, place a considerable onus on health, social, and economic systems. Of particular importance is the potentially large impact on resources and care worldwide. Indeed, the cost of dementia is significant, not only in terms of personal cost, but also on societal resources. As highlighted in this chapter, many large population-based cohort studies have been undertaken in the ageing population, worldwide and in Europe, in order to better identify patterns of disease and disease risk factors.

Epidemiology of old age psychiatry: An overview of concepts and main studies

There is, however, no standardized approach to the diagnosis of dementia, cognitive dysfunction, and depression. As a result, estimates of disease prevalence and incidence that have been reported across studies may vary, not due to true differences, but as a result of methodology. Reported estimates could also vary across studies as a result of differences in the presence of risk and protective factors across individuals and as a result of cultural variation. Such variability is important to identify, especially for the development of preventative strategies (such as those linked to modifiable factors such as diet, educational exposure, and health-related comorbidity). Furthermore, the type of information collected and the method of assessment are variable across the studies. For example, some studies report cardiovascular disease comorbidity (self-reported or objectively measured), brain-related changes (determined through neuroimaging), psychiatric-related comorbidity (e.g. behavioural and psychological symptoms of dementia), blood-based biomarkers (including nutritional and genetic risk markers), or neuropathology. No single study has included all the measures required to completely map the full spectrum of risk/protective factors and the determinants of disease progression. Summarizing the results across all studies suggests that with the age demographic transition, the impact of dementia and age-related conditions is, and will continue to be, considerable. Better methodology for extracting and weighting data across studies will be important for future synthesis of cross-study analysis and for informing the design of new cohort studies focused on the life course of ageing populations.

Acknowledgements

The authors thank Dr Hannah Keage for generously giving her time to provide expert input into the revision of this chapter.

Neuropathology

Chapter: Neuropathology

Author(s): Johannes Attems and Kurt A. Jellinger

DOI: 10.1093/med/9780198807292.003.0005

Introduction

This chapter mainly describes the neuropathological lesions of age-associated neurodegenerative diseases and their related pathological classifications to assist the reader in interpreting neuropathological reports. It is beyond the scope of this chapter to provide a comprehensive review of the neuropathology of all neurodegenerative diseases. Cerebrovascular disease, which is common and strongly age-associated, is covered and the chapter also reviews the increasing evidence on cerebral multimorbidity, i.e. the presence of multiple pathologies in post-mortem brains. It is now recognized that multimorbidity in the aged brain is the rule, while pure pathologies are the exception (Jellinger and Attems, 2015; Rahimi and Kovacs, 2014). Finally, we give a view on new and currently emerging neuropathological methods that should more accurately reflect the burden of pathology seen in post-mortem brains.

Neurodegeneration: general considerations

Neurodegenerative diseases are characterized by progressive neuronal dysfunction, with consecutive loss of specific populations of neurons that frequently involve distinct anatomically related systems (Jellinger, 2010). Thus, selective neuronal vulnerability is a characteristic feature of neurodegenerative diseases. It should be emphasized that diseases with known vascular, toxic, metabolic, infectious, or immunologically determined causes are, by definition, not classified as (primary) neurodegenerative diseases. The clinical presentation of neurodegenerative diseases depends on the system or region affected by the disease, rather than on the molecular nature of the characteristic neuropathological lesion per se, e.g. severe neuronal loss in the substantia nigra will clinically present as parkinsonism, irrespective of the associated neuropathological lesion, which potentially could be aggregates of α -synuclein (Lewy bodies), hyperphosphorylated tau (neurofibrillary tangles), cerebrovascular lesions, or other pathologies. Admittedly, the most likely neuropathological lesion associated with clinical parkinsonism is α -synuclein deposition in the substantia nigra, in which case the neuropathological diagnosis would be Lewy body disease with brainstem preponderance, i.e. Parkinson's disease (PD) (Dickson, 2018, Jellinger, 2014). On the other hand, in patients with advanced Alzheimer's disease (AD), the substantia nigra is often affected by tau pathology, resulting in clinical parkinsonism (Attems et al., 2007), and vascular lesions in the basal ganglia, thalamus, and substantia nigra are well recognized as causing vascular parkinsonism, which is a rare form of parkinsonism (Dickson, 2018).

What are the causes and mechanisms of neuronal dysfunction and cell death in neurodegeneration? Apoptosis, or 'programmed cell death', is an attractive mechanism to explain selective neuronal vulnerability (Dickson, 2011), while the term necrosis refers to the morphological changes that take place in a living organism in response to a noxious stimulus that causes cell death. In the CNS, necrosis is commonly observed after trauma, infection, and infarction, conditions that, by definition, do not fall into the category of neurodegeneration.

Apoptosis, on the other hand, is regulated by extrinsic (receptor-mediated) or intrinsic (mitochondria-mediated) pathways that, via the activation of caspases, lead to degradation of both DNA and cytoskeletal proteins. In several neurodegenerative diseases, damage resulting from reactive oxygen species has been identified as a major cytopathological feature, and cells that fail to compensate for oxidative stress enter apoptosis, suggesting that oxidative stress plays an important role in neurodegeneration (Jellinger, 2006; Jellinger, 2010). However, apoptosis leads to cell death within hours, while neurodegenerative diseases typically have a course of years, possibly due to an increased compensatory cellular response to neurodegeneration in living organisms. In addition, failure in the maintenance of mitochondria has been

Neuropathology

suggested to play a role in neurodegeneration (Karbowski and Neutzner, 2012).

While the respective roles of apoptosis, oxidative stress, and mitochondria in neurodegeneration remain unclear, aggregation of misfolded proteins (that might be neurotoxic) is a well-described and unifying feature of neurodegeneration. Various proteins, e.g. amyloid- β (A β) and tau, lose their native structure and form fibrils rich in β -sheets that accumulate intra- or extracellularly (Jellinger, 2010). Indeed, the nature of the respective misfolded protein, in conjunction with the topographical localization of the affected regions, is the basis for the classification of neurodegenerative diseases (Table 5.1).

Table 5.1 Major protein aggregates in neurodegenerative diseases.

Disease	Protein aggregate	Characteristic form	Localization
Alzheimer's disease	tau (3R, 4R)	NFT, NT	Neuronal cell bodies (NFT) and processes (NT)
	A β (1-40, 1-42)	A β plaque	Extracellular
	A β (1-40, 1-42) and tau (3R, 4R)	NP	A β , extracellular; tau, neuronal processes
Lewy body diseases			
<i>Parkinson's disease</i>	α -synuclein	LB, LN	Neuronal cell bodies (LB) and processes (LN)
<i>Dementia with Lewy bodies</i>	α -synuclein	LB, LN	Neuronal cell bodies (LB) and processes (LN)
Multiple system atrophy	α -synuclein	GCI	Cytoplasm of glial cells

Neuropathology

Frontotemporal lobar degeneration			
<i>Pick's disease</i>	tau (3R)	Pick bodies	Neuronal cell bodies
<i>Corticobasal degeneration</i>	tau (4R)	Astrocytic plaque	Distal segments of astrocytes
<i>Progressive supranuclear palsy</i>	tau (4R)	Globose NFT	Neuronal cell bodies
	tau (4R)	Tufted astrocyte	Astrocytic cell bodies
<i>Agyrophilic grain disease</i>	tau (4R)	Grains	Neuronal processes (dendrites)
<i>Neurofibrillary tangle dominant dementia</i>	tau (3R, 4R)	NFT, NT	Neuronal cell bodies (NFT) and processes (NT)
<i>FTLD-TDP</i>	TDP-43	NCI (NII)	Neuronal cytoplasm (and nuclei)
<i>FTLD-UPS</i>	Ubiquitin	NCI (NII)	Neuronal cytoplasm (and nuclei)
<i>FTLD-FUS</i>	FUS protein	NCI (NII)	Neuronal cytoplasm (and nuclei)
<i>FTLD-ni</i>	none known	n.a.	n.a.

3R, 3-repeat tau; 4R, 4-repeat tau; NFT, neurofibrillary tangle; NT, neuropil thread; LB, Lewy body; LN, Lewy neurite; NCI, neuronal cytoplasmic inclusion; NII, neuronal intranuclear inclusions.

For various forms of FTLD, see main text.

Despite considerable advances in our understanding of some pathomechanisms that ultimately lead to sporadic age-associated neurodegeneration, the exact causes for protein accumulation await

further elucidation and are likely to be multifactorial. However, in hereditary neurodegenerative diseases, the mechanisms that cause accumulation of misfolded proteins are, in most cases, reasonably well understood, thereby providing helpful information to further our understanding of patho-mechanisms in sporadic neurodegeneration; for example, in trisomy 21 (Down's syndrome), an increased expression of the amyloid precursor protein (APP) that is encoded on chromosome 21 leads to an increased production of A β , with consequent formation of A β plaques. However, another possibility for the increased production of A β in both sporadic and hereditary (e.g. mutations in presenilin genes 1 and 2) neurodegenerative diseases and ageing might be an increased activity of β - and γ -secretase, which leads to an increased formation of A β oligomers (for more details on amyloid processing, see Alzheimer's disease, p. 79).

On the other hand, a decrease in protein degradation and/or elimination out of the brain may cause protein accumulation and aggregation; cellular protein degradation and clearance are mediated via both the ubiquitin-proteasome system (UPS; ubiquitin pathway) and the autophagy-lysosomal pathway (ALP). Failure of UPS and ALP might be caused by increasing amounts of proteins that overwhelm these systems and/or malfunction of the systems themselves, both probably resulting in protein misfolding and aggregation (Jellinger, 2010). Similarly, reduced elimination out of the brain could lead to accumulation of the respective protein; in the CNS, solutes are mainly transported out of the brain via drainage along the perivascular pathway, and impairment of the perivascular pathway has been suggested to result in A β accumulation (Weller et al., 2009).

It is generally assumed that misfolded proteins exert neurotoxicity, but the underlying mechanisms are poorly understood. Misfolded proteins form soluble oligomers that aggregate into insoluble structures, and by using appropriate histochemical techniques and immunohistochemical antibodies, these insoluble structures can be seen on microscopic examination. However, it is not clear if the soluble oligomers and/or the insoluble, microscopically visible aggregates are the neurotoxic species. This has important implications with respect to the interpretation of neuropathological findings regarding disease mechanisms, as neuropathology detects insoluble aggregated proteins, but not the soluble oligomers. It has indeed been suggested that the formation of insoluble aggregates represents a protective mechanism, insofar as neurotoxic oligomers are 'trapped' in their aggregated form and thereby lose their neurotoxic property. Alternatively, the accumulation and aggregation of proteins might primarily be the result of synaptic and/or cellular damage, rather than the cause for cell death (Jellinger, 2010).

It was believed previously that protein aggregate formation is an entirely cell-autonomous process occurring independently in many cells. However, it is now thought that a prion-like mechanism is responsible for the spread of misfolded proteins (e.g. tau and α -synuclein) throughout the

brain (Goedert et al., 2014). This does not imply that age-associated neurodegenerative diseases are prion diseases, as the latter are characterized by an infective agent, i.e. the prion protein (see Prion diseases, p. 89). Such prion-like mechanisms rather implies that a limited number of neurons initially develop misfolded proteins which can then induce misfolding of the corresponding physiological protein in neighbouring neurons. This has huge therapeutic implications, as novel strategies aiming to prevent prion-like spread are currently being developed.

In most age-associated neurodegenerative diseases, the amount of pathology is crucial for the development of clinical symptoms. In particular, AD pathology is frequently present to a limited extent in the brain of many people without dementia (Jack et al., 2014; Jellinger and Attems, 2012; Mufson et al., 2016). It is therefore still a matter of discussion whether age-associated neurodegenerative diseases are a pure consequence of ageing, rather than a distinct disease, or if age is an important risk factor but would not inevitably lead to the development of full-blown disease with overt clinical symptoms, even in individuals aged over 100 years.

Neurodegeneration per se usually does not lead to fatal brain lesions that would cause the death of a patient but naturally can be considered as a severe underlying disease that predisposes individuals to acquire potentially fatal diseases. Bronchopneumonia most frequently represents the immediate cause of death in AD (approximately 50%), while in patients with vascular dementia (VaD), cardiovascular disease has been shown to be the immediate cause of death in approximately 50% (Attems et al., 2005b).

Alzheimer's disease

AD is the most frequent neurodegenerative disease, accounting for 50–80% of dementias. Both prevalence and incidence increase with age; in 65- to 69-year olds, the prevalence is 1%, doubling with each subsequent 5-year increment. Above the age of 85 years, prevalence rates range from 20% to 50%. Therefore, increasing age is the most important risk factor for AD (see Chapter 30 for details and other risk factors).

The neuropathological diagnosis of AD is based on the semi-quantitative and topographical assessment of A β plaques, neurofibrillary tangles/neuropil threads (NFTs/NTs), and neuritic plaques (NPs). However, additional neuropathological lesions, such as cerebral amyloid angiopathy (CAA) and granulovacuolar degeneration (GVD), are typically present, but assessment of those lesions is not required for stating a neuropathological diagnosis, according to current diagnostic criteria. The loss of neurons (Gomez-Isla et al., 1996) and synapses (Terry et al., 1991) in AD has been shown to be more directly related to the severity of the cognitive deficit. Using quantitative methods in human brain tissue of AD and controls, the correlation between neuronal loss, NFTs, and cell death

Neuropathology

markers has been studied recently and the findings suggest that caspases and changes in macroautophagy play a role early in the disease (Theofilas et al., 2018).

Neuropathology of AD

On gross examination, post-mortem brains of AD patients often appear relatively normal, without striking pathological changes, and reduction in brain weight may be minimal. However, if present, the characteristic atrophy in AD involves the entorhinal cortex, hippocampus, amygdala, and olfactory bulb, as well as the inferior temporal, superior frontal, and middle frontal gyri (Fig. 5.1). In all of these areas, tau pathology predominates and atrophy in AD is not associated with the burden of A β plaques (Josephs et al., 2008). Cerebral atrophy leads to enlargement of the ventricles (i.e. *hydrocephalus internus e vacuo*) and the cortical ribbon may be thin. The substantia nigra is well pigmented, while the locus caeruleus might be pale and the cerebellum is normal.

Fig. 5.1

Comparison between formalin-fixed brain slices of the left hemispheres (level of posterior hippocampus) of an aged nondemented individual (A) and an AD patient (B). Note the marked atrophy (thinning of the gyri and deepening of the sulci) in B, in particular hippocampal atrophy (arrow in B) with widening of the inferior horn of the second ventricle (asterisk in B).

In AD, neuronal loss has been described, in particular in the nucleus basalis of Meynert, the amygdala, the olfactory bulb with the olfactory nucleus, the locus caeruleus, and the serotonergic raphe nuclei. Another important feature of AD is synaptic loss and there is strong evidence that synapses play a major pathophysiological role in AD (Duyckaerts et al., 2009). Band-like spongiosis and reactive astrogliosis may be present in AD. Despite the fact that the aforementioned lesions are of

pathophysiological importance for AD (neuronal and synaptic loss) or frequent findings (spongiosis), they are not used for neuropathological diagnostic purposes, which rely on the assessment of NFTs/NTs and A β plaques, including NPs.

Neurofibrillary tangles and neuropil threads

NFTs and NTs are aggregates of hyperphosphorylated microtubule-associated protein (MAP) tau. MAP tau is particularly abundant in axons, and its physiological function is primarily to stabilize microtubules. Six isoforms of MAP tau exist in the human brain and, based on the number of C-terminal microtubule-binding repeat motifs, 3-repeat (3R) and 4-repeat (4R) isoforms can be distinguished (Mandelkow and Mandelkow, 2012). In the dephosphorylated state, MAP tau binds to microtubules, while phosphorylation leads to detachment from microtubules. Under physiological conditions, MAP tau is in a dynamic equilibrium, on and off the microtubules, but under pathological conditions (neurodegeneration), MAP tau is hyperphosphorylated, resulting in the disintegration of microtubules and the aggregation of insoluble filaments/fibrils composed of hyperphosphorylated MAP tau (Ballatore et al., 2007). NFTs/NTs are composed of aggregates of hyperphosphorylated MAP tau, while so-called pre-tangles represent non-aggregated hyperphosphorylated or abnormally phosphorylated MAP tau and are considered to be precursors of NFTs/NTs. Importantly, the extent of NFTs/NTs in the neocortex has been shown to correlate with cognitive deficits (Nelson et al., 2012).

Using appropriate immunohistochemical antibodies (e.g. AT8), both NFTs and NTs can be visualized for histological assessment (Fig. 5.2). Of note, in AD, both 3R and 4R tau isoforms are present, while some tauopathies are characterized by the exclusive presence of either 3R or 4R tau (for details, see Frontotemporal lobar degenerations (including tauopathies, p. 86). NFTs are located in neuronal cell bodies, and NTs in axons and dendrites, with the latter appearing in immunohistochemically stained sections as immunopositive threads in the neuropil (i.e. area of unmyelinated axons, dendrites, and glial cell processes, practically the area between cell bodies). It has been suggested that the amount of NTs, rather than NFTs, should be assessed for diagnostic purposes (Alafuzoff et al., 2008). NFTs and NTs are predominately found in the hippocampus, the entorhinal cortex, and layers III and VI of the isocortex. However, NFTs and NTs are also present in the olfactory bulb and subcortical nuclei, in particular the locus caeruleus, in early preclinical stages of AD (Attems et al., 2012; Braak et al., 2011).

Fig. 5.2

In AD, high amounts of neurofibrillary tangles and neuropil threads are seen in the hippocampus (A), among other regions (see main text). Arrows in B mark a neuronal cell body that comprises a neurofibrillary tangle, while ovals encircle some of the many neuropil threads in neuronal processes that are seen in this photomicrograph. CA1, CA2, and CA4 hippocampal *cornu ammonis* (Ammon's horn) sectors 1, 2, and 3, respectively; GR, granule cell layer of the dentate gyrus. Immunohistochemistry with antibody against hyperphosphorylated tau AT8.

Scale bars: A, 50 μm ; B, 10 μm .

It is generally assumed that in AD, NFTs and NTs primarily manifest in transentorhinal and entorhinal cortices and then gradually spread towards the hippocampus and isocortex (Braak and Braak, 1991), and this pattern is the basis for the diagnostic Braak stages (see Neuropathological diagnostic criteria for AD, p. 82). However, pre-tangle material (i.e. hyperphosphorylated, but non-aggregated, tau) was found in the locus caeruleus in the majority of individuals under 30 years of age who were devoid of cortical tau pathology, suggesting that tau pathology begins in the locus caeruleus, rather than the transentorhinal cortex (Braak et al., 2011), but this is controversial (Attems et al., 2012).

Amyloid- β plaques

A β peptides (4 kDa) are generated by β - and γ -secretase cleavage of the transmembranous APP and comprise peptides terminating at carboxyl terminus 40 (A β_{40}) and 42 (A β_{42}). Cerebral A β depositions are a hallmark of AD, but in the majority of clinicopathological correlative studies, cerebral A β load does not correlate with clinical dementia (Nelson et al., 2012). Nevertheless, most therapeutic approaches against AD target A β . This is mainly due to the so-called amyloid cascade hypothesis that postulates that an increase in A β is the trigger for a series of events that ultimately lead to the formation of NFTs/NTs (Hardy and Selkoe, 2002). The observation that mutations in genes that lead to an increase in A β (APP, presenilins) cause familial AD with tau pathology (NFTs/NTs), while mutations that lead to tau pathology cause familial tauopathies without A β , argues in favour of the 'amyloid cascade hypothesis'. However, several observations suggest that the 'amyloid hypothesis' might not apply for sporadic, age-associated AD; in the early stages of AD, A β is mainly present in neocortical areas, while tau pathology is seen in the

transentorhinal cortex, and it is not clear how A β influences tau at this distance. Furthermore, a large autopsy study analysing the prevalence of A β and tau pathology, as a function of age, demonstrated that tau pathology precedes A β (Tsartsalis et al., 2017). Also, APP transgenic mice develop abundant A β , but no tau pathology (Duyckaerts et al., 2009). However, the frequent co-occurrence of A β and tau, as well as the finding that the highest NT Braak stages V/VI (see Neuropathological diagnostic criteria for AD, p. 82) are never seen in the absence of A β , strongly suggests a mutual interaction between A β and tau (Spires-Jones et al., 2017). Although both A β and tau have been extensively studied with regard to their separate mode of toxicity, their possible interactions and synergistic effects in AD, linking A β and tau, are currently being investigated (Ittner and Gotz, 2010; Spires-Jones et al., 2017).

While A β ₄₀ constitutes the majority of cerebral A β (over 95%), A β ₄₂ is more aggregatable and hence believed to initiate the formation of oligomers, fibrils, and plaques (Masters and Beyreuther, 2011). A β aggregates extracellularly and, using appropriate antibodies (e.g. 4G8 antibody), various morphological forms of A β aggregates can be detected (Fig. 5.3). The main parenchymal A β deposits are diffuse or focal. Diffuse A β deposits are usually large (up to several 100 μ m) and show ill-defined borders; they are referred to as 'lake-like', 'fleecy', and 'subpial band-like'. A β plaques, on the other hand, are focal A β deposits; 'mature', 'classical', and 'neuritic' plaques can be distinguished.

Fig. 5.3

A β depositions in the neocortex (A–C) show different morphology: subpial band-like A β (arrows in A1), fleecy A β (arrowheads in B), and A β plaques (C). Immunohistochemistry with A β antibody 4G8.

Scale bars: A, 500 μ m; B, 20 μ m; C, 50 μ m.

It should be emphasized that NPs contain—in addition to A β aggregates—hyperphosphorylated tau in dystrophic neurites (Fig. 5.4). NPs are strongly associated with AD, while other forms of parenchymal A β

deposits are frequently seen to a considerable extent in post-mortem brains of individuals without dementia (Jellinger and Attems, 2012) and, as mentioned earlier, their density does not correlate with clinical dementia (Duyckaerts and Dickson, 2011). However, it has been suggested that the most advanced spread of A β —Thal A β phases 4 and 5—is correlated with clinical dementia (see Neuropathological diagnostic criteria for AD, p. 82). According to recent *in vivo* ^{18}F -AV-1451 PET imaging and post-mortem studies, tau pathology is related in a degeneration-specific manner to cognitive impairment in AD, which is weakly related to amyloid burden, but, in part, mediated by grey matter volume (Bejanin et al., 2017).

Fig. 5.4

Neuritic plaques are a neuropathological hallmark lesion of AD and represent A β plaques that contain tau in distended neuronal processes (i.e. dystrophic neurites). A–C are photomicrographs from adjacent histological sections. A, Gallyas silver stain visualizes both aggregated A β and tau and is therefore ideal to detect neuritic plaques (ring in A1, neuritic plaque; arrow in A2, dystrophic neurite; arrowhead in A2, neurofibrillary tangle). On the other hand, the combined use of tau (B, antibody AT8) and A β (C, antibody 4G8) immunohistochemistry on adjacent sections is also useful to detect neuritic plaques, as tau immunopositivity shows a plaque-like pattern (ring in B) and A β immunostaining confirms the presence of A β plaques (C).

Scale bars: A, B, and C, 200 μm .

Additional lesions in AD

Although the neuropathological diagnosis of AD solely relies on the assessment of both A β and tau pathology, a variety of additional neuropathological lesions are usually present. Indeed, the presence of multiple pathologies in the brain of older people with and without dementia is not an exceptional finding, and this is addressed in detail in

Cerebral multimorbidity, p. 91. However, there are some additional pathologies that are particularly frequent in AD; among those are CAA, cerebrovascular lesions, hippocampal sclerosis, transactivation-responsive DNA-binding protein 43 (TDP-43) pathology, and GVD. Although GVD may be present in diseases other than AD, it is regarded as a primarily AD-related phenomenon and therefore is described in the next section, while TDP-43 pathology in AD is described in Cerebral multimorbidity, p. 91 and other additional pathologies in their own respective sections.

Granulovacuolar degeneration

The term GVD describes vacuolar changes in the cytoplasm of neurons of the medial temporal lobe, in particular in pyramidal neurons of the hippocampus, often in association with NFTs, but they have also been described in other regions (e.g. neocortex, amygdala). GVD has been reported to be more frequent in AD, compared to controls, and may be present in tauopathies (e.g. Pick's disease, progressive supranuclear palsy). GVD first develops in neurons of the CA1/CA2 hippocampal subfield and then expands in a predictable sequence into other brain regions, allowing for the distinction in five different stages (Thal et al., 2011). Importantly, these stages are related to AD pathology, pointing towards a role of GVD in AD pathogenesis.

White matter lesions in AD

White matter lesions (WMLs) histologically encompass structural damage of the cerebral white matter as a result of white matter rarefaction, are visualized as white matter hyperintensities (WMHs) on *pre-* and *post-mortem* T2-weighted MRI, and have been associated with a wide range of cognitive deficits (McAleese et al., 2016). The pathogenesis of WMHs is generally thought to be associated with small vessel disease (SVD), but recent studies have suggested a multifactorial aetiology of WMHs, inclusive of SVD-related ischaemia, but also degenerative axonal loss secondary to cortical AD pathology (McAleese et al., 2017b). Indeed, it appears that in neurodegenerative diseases, such as AD, WMHs, in particular in the parietal lobe, are likely to be primarily associated with cortical tau pathology, and hence WMHs on MRI images from individuals with dementia should be considered to represent a surrogate marker for severe cortical tau pathology, thus supporting a clinical diagnosis of AD, rather than suggesting the presence of significant vascular disease.

Neuropathological diagnostic criteria for AD

With the progression of the disease, the major neuropathological lesions of AD progress stepwise, following a hierarchical pattern:

1. Braak neurofibrillary stages describe the progression of NFTs/NTs from the transentorhinal and entorhinal areas (stages I and II) to the hippocampus (stage III), the temporal cortex (stage IV), and finally other neocortical areas, of which the occipital cortex (stages V and

VI) is used for staging purposes (Braak and Braak, 1991; Braak et al., 2006).

2. Thal A β phases describe the progression of parenchymal A β depositions; in phase 1, the isocortex is involved, the hippocampus and entorhinal cortex in phase 2, the striatum and diencephalic nuclei in phase 3, the brainstem nuclei in phase 4, and finally the cerebellum and additional brainstem nuclei in phase 5; phases 4 and 5 are suggested to be correlated with clinical dementia (Thal et al., 2002b).

Several criteria for the neuropathological diagnosis of AD are in use:

- Age-adjusted criteria of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) are based on the semi-quantitative assessment of NPs (sparse, moderate, frequent) in the middle frontal gyrus, superior/middle temporal gyri, and inferior parietal lobule (Mirra et al., 1993).
- The National Institute of Aging Nancy and Ronald Reagan Institute (NIA-RI) criteria give the probability that a clinical dementia has been caused by AD and are based on both CERAD criteria and Braak neurofibrillary stages, i.e. CERAD neg. and Braak neg.—no probability; CERAD A and Braak I/II—low probability; CERAD B and Braak III/IV—medium probability; and CERAD C and Braak V/VI—high probability (Hyman, 1998).
- The most commonly used criteria are the NIA-Alzheimer's Association guidelines that combine Thal A β phases, Braak neurofibrillary stages, and the CERAD criteria (Montine et al., 2012). According to these guidelines, a neuropathological report should state the A β plaque score (Thal et al., 2002b), Braak neurofibrillary stage (Braak et al., 2006), and CERAD NP score (Mirra et al., 1993), which yield a combined 'ABC score' (Montine et al., 2012). This ABC (amyloid, Braak, CERAD) score should be stated, regardless of clinical history, to reflect the amount of 'Alzheimer's disease neuropathologic change'. Table 5.2 illustrates how each A, B, and C score is determined and transformed to state the level of AD neuropathological change on a four-tiered scale: 'not', 'low', 'intermediate', and 'high'.

Neuropathology

Table 5.2 ABC criteria for the diagnosis of Alzheimer's disease-related pathology.

Level of AD neuropathologic change						
<i>Thal phase for Aβ plaques</i>	A	B			C	CERAD
		0 or 1	2	3		
0	0	Not	Not	Not	0	neg
1 or 2	1	Low	Low	Low	0 or 1	neg or A
1 or 2	1	Low	Intermediate	Intermediate	2 or 3	B or C
3	2	Low	Intermediate	Intermediate	any C	neg or A to C
4 or 5	3	Low	Intermediate	Intermediate	0 or 1	neg or A
4 or 5	3	Low	Intermediate	High	2 or 3	B or C
		<i>Braak 0-II</i>	<i>Braak III-IV</i>	<i>Braak V-VI</i>		

The level of Alzheimer's disease (AD) neuropathologic change is determined by assessing A, B, and C scores. A scores are related to Thal phase for Aβ plaques (first column), B scores to neuritic Braak stages (bottom row), and C scores to CERAD stages (last column).

Cerebral amyloid angiopathy

CAA is defined as the deposition of congophilic material (i.e. positive staining with the Congo red dye) in cerebral leptomeningeal and intracortical arteries, arterioles, capillaries, and, rarely, veins. CAA is also referred to as congophilic amyloid angiopathy (Attems et al., 2011). CAA occurs in both hereditary or familial and sporadic forms. While the amyloid in sporadic, age-associated forms is predominately composed of A β , the nature of amyloid depositions in hereditary forms is determined by the respective underlying mutation (e.g. A-Bri and cystatin C in BRI2 and cystatin C gene mutations, respectively). Sporadic CAA is frequently, but not invariably, present in AD and is often observed in older individuals without AD (Attems and Jellinger, 2014). CAA is considered a risk factor for non-traumatic intracerebral lobar haemorrhage (ICH) in the elderly and is present in 5–20% of all cases with ICH (Pezzini et al., 2009), but in large autopsy cohorts, the prevalence of ICH in CAA cases was approximately 5%, being similar to cases without CAA (Attems et al., 2008). CAA may cause microbleeds (Greenberg et al., 2009) and, in moderate to severe stages, has been shown to be an independent risk factor for cognitive impairment (Matthews et al., 2009).

Histopathology of CAA

A β is initially deposited in the outer parts of the vessel wall, but with increasing severity, all layers of the vessel wall show A β depositions, accompanied by a loss of smooth muscle cells. In very severe stages of CAA, the vascular architecture is disrupted, but endothelial cells are usually preserved (Fig. 5.5).

Fig. 5.5

Cerebral amyloid angiopathy (CAA) presents as A β depositions in the walls of meningeal (arrows in A) and cortical (arrowheads in A) arteries, while capillary CAA refers to A β depositions in the walls of capillaries (arrowheads in B). CAA may be the cause for nontraumatic intracerebral haemorrhage (ICH). Photomicrograph C shows an ICH (left upper part) in a patient with CAA; insets in C show photomicrographs of sections of the same block stained with anti-A β antibody 4G8, demonstrating CAA in regions adjacent to the ICH, thereby suggesting that CAA might have been the cause for ICH in this case. A and B and insets in C, 4G8 immunohistochemistry; C, H/E.

Scale bars: A and C, 500 μ m; B, 50 μ m.

CAA may frequently show a patchy distribution and primarily affects leptomeningeal and cortical vessels of neocortical regions. The occipital lobe has been reported to be the site that is both most frequently and severely affected by CAA, followed by either frontal, temporal, or parietal lobes (Attems et al., 2005a).

A β depositions in the walls of capillaries are referred to as capillary CAA (capCAA) and usually present as strong staining lining capillary walls in sections stained with appropriate A β antibodies. The presence of capCAA distinguishes two types of CAA—CAA-type 1 is characterized by the presence of capCAA and may show additional A β depositions in non-capillary blood vessels, whereas in CAA-type 2, A β depositions are restricted to leptomeningeal and cortical arteries, arterioles, and, rarely, veins without capillary involvement (Thal et al., 2002a). Of note, the frequency of the APOE ϵ 4 allele in CAA-type 1 is more than four times higher than in CAA-type 2 (Thal et al., 2002a). It has been shown recently that the presence of capCAA identifies a subtype of sporadic AD that is defined by characteristic neuropathological features and genotype-specific associations (Thal et al., 2010). Pericapillary A β deposits are predominately composed of A β ₄₂ and are clustered in the glia limitans around capillaries and represent another type of capillary involvement (Attems and Jellinger, 2004).

As of today, no standardized neuropathological consensus criteria for the scoring of CAA have been established, but several methods have been published and are usually used to describe the severity of CAA in post-mortem brains (Attems et al., 2011; Love et al., 2014).

Primary age-related tauopathy

NT pathology is not exclusively found in association with A β deposition, as evidenced by the disease primary age-related tauopathy (PART). PART is characterized by the presence of tau pathology in the form of NFTs and NTs without (definite PART) or with only limited (possible PART) parenchymal A β depositions up to Thal A β phase 2 (Crary et al., 2014). In addition, any other primary tauopathy has to be excluded. PART is frequent in old age (up to 40%) and is likely to represent the neuropathological correlate of a clinical condition termed ‘suspected non-AD pathophysiology’ (SNAP), which refers to individuals with temporal lobe atrophy on MRI and high CSF tau, but no evidence for cerebral A β depositions (Jack, 2014). SNAP is usually seen in cognitively normal elderly but may also be present in mildly impaired individuals. While the neuroanatomical progression of NFTs/NTs in PART follows AD-associated NFT Braak stages, the latter do not exceed stage IV in PART and NFT Braak stages V/VI are indeed only seen in the presence of A β pathology.

The relationship between PART and AD has been controversial; PART does not differ from AD-associated tau pathology, and one can argue that it actually represents an early stage of AD. However, the occurrence of ‘definite PART’ in many aged individuals clearly indicates that A β is not

necessary for the development of tau pathology, while high Braak stages V/VI, as seen in full-blown symptomatic AD, do not occur in the absence of A β . PART may therefore be considered as a distinct pathology, which is one of the prerequisites for the development of AD, but does not inevitably lead to AD (Jellinger et al., 2015). PART with clinical features of cognitive impairment may also be termed neurofibrillary tangle dominant dementia (NFTD). NFTD is characterized by the presence of NFTs/NTs that contain both 3R and 4R tau, while A β pathology is, in 80% of cases, completely absent or present to a very limited degree. Importantly, in NFTD, tau pathology is mostly confined to allocortical regions, corresponding to neurofibrillary Braak stage III, and rarely mild isocortical involvement is seen. NFTD accounts for 5–7% of late-onset dementias and differs from AD by a later onset (80 years), a shorter duration (5 years), less severe cognitive impairment, and almost absence of the *APOE ϵ 4* genotype (Jellinger and Attems, 2007a). Recent studies showed the absence of soluble A β with the tau gene *MAPT H1* haplotype, classifying it as a specific tauopathy independent of amyloid (Santa-Maria et al., 2012).

Hippocampal sclerosis

Hippocampal sclerosis (HS) is defined as severe astrogliosis and neuronal loss in the CA1 region of the hippocampus, where neurons are particularly vulnerable to hypoxia, and in the subiculum. HS occurs in up to 26% of older individuals, frequently as an additional finding in AD, and is often accompanied by multiple small infarcts in other brain regions and/or leukoencephalopathy (Jellinger, 2007a). It has been shown that patients with HS are older than those without HS and had more coronary artery disease, suggesting that related occult hypoxic-ischaemic episodes may represent pathogenic factors. On the other hand, TDP-43 pathology was detected in up to 70% of cases with HS, and approximately 50% of frontotemporal lobar degeneration-TDP (see FTLT with TDP-43 pathology, p. 88) cases show HS (Amador-Ortiz et al., 2007). In an autopsy study, TDP-43 pathology was seen in 18% of cases with HS, and in 42% of cases with concomitant AD pathology (Rauramaa et al., 2011). However, a causal link between HS and TDP-43 has not been demonstrated and their frequent co-occurrence might rather reflect a mere coincidence of two relatively common pathologies (Davidson et al., 2011). It has been suggested that HS may incorporate different subtypes: HS with advanced age (HS-ageing), with seizures (HS-SZ), with tauopathies (HS-tau), with non-tauopathy frontotemporal dementia (HS-FTD), and with cerebrovascular diseases (HS-CVD); HS-ageing is an important, but under-appreciated, brain disease of ageing (Nelson et al., 2013).

Ageing-related tau astrogliopathy

Ageing-related tau astrogliopathy (ARTAG) refers to pathological accumulation of tau in astrocytes, which show a thorn-shaped morphology, and may often be seen in clusters in grey and white matter, frequently surrounding blood vessels (Kovacs et al., 2016). ARTAG occurs

mainly, but not exclusively, in individuals over 60 years of age and has not yet been associated with a distinct clinical phenotype. Nevertheless, ARTAG is a frequent incidental finding in post-mortem brains, and its role in the spectrum of age-associated neurodegeneration is currently under investigation.

Lewy body diseases

Lewy body diseases (LBD) comprise PD, dementia with Lewy bodies (DLB), and Parkinson's disease dementia (PDD) (McKeith et al., 2017). In large autopsy series of patients with ante-mortem diagnosis of parkinsonism, the most common finding was DLB (77–84%), but only 34.8–44.7% were idiopathic PD (Dickson, 2018; Jellinger, 2007b). The characteristic neuropathological lesions of LBDs are Lewy bodies (LBs) in neuronal somata and Lewy neurites (LNs) in nerve cell processes. LBs and LNs are composed of α -synuclein aggregates. α -synuclein is a 140-amino acid residue protein that is a member of a family of proteins that include β - and γ -synucleins with unknown physiological function(s). α -synuclein is a lipid-binding protein (Goedert, 2001) located at presynaptic terminals in proximity to synaptic vesicles, and it has been suggested that its physiological function involves the modulation of synaptic transmission and neuronal plasticity (Waxman and Giasson, 2009). In addition, α -synuclein might be a chaperone protein, an inhibitor of phospholipase D2, and an active participant in oxidative stress production, as well as being both neuroprotective and neurotoxic (Spillantini, 2011). Under pathological conditions, phosphorylation of α -synuclein is enhanced (at serine 129), and its aggregates are the main component of LBs and LNs that may, in addition, contain ubiquitin and α -B-crystallin, among other proteins (Kalia and Kalia, 2015).

LBs occur in two types (Fig. 5.6): (1) classical LBs are spherical cytoplasmic inclusions, 8–30 μ m in diameter, with a hyaline eosinophilic core, concentric lamellar bands, and a narrow, pale-stained halo, that are predominately seen in pigmented neurons of the substantia nigra, locus caeruleus, and dorsal motor nucleus of the vagus nerve; and (2) cortical LBs are eosinophilic, rounded, angular, or reniform structures without a halo, which are seen in iso- and allocortical areas. Of note, while classical LBs can be easily detected on routine haematoxylin and eosin (H/E)-stained sections, cortical LBs are not readily detected, and immunohistochemistry for α -synuclein should be used to detect cortical LBs and LNs, the latter appearing as thin, immunopositive threads in the neuropil (Jellinger, 2014).

Fig. 5.6

Classical Lewy bodies in the substantia nigra (arrows in A and B) show a hyaline eosinophilic core and a narrow pale stained halo (B shows two Lewy bodies in one pigmented neuron). Degenerating pigmented neurons lose melanin (pigment incontinence) that may be incorporated by macrophages (C). On H/E sections, cortical Lewy bodies are rounded eosinophilic inclusions (D) in neuronal cell bodies that are readily detected with α -synuclein immunohistochemistry (E, arrowhead in E1) that also stains Lewy neurites as thread- and dot-like structures in the neuropil (E). A–D, H/E; E, α -synuclein immunohistochemistry.

Scale bars: A, 50 μ m; B–D, 20 μ m; E, 200 μ m.

Parkinson's disease

PD is one of the most frequent neurodegenerative movement disorders, with a mean age of onset of between 55 and 65 years. The prevalence in the general population is estimated at 0.3%, but this increases with increasing age to 3% in those over 65 years. The four cardinal clinical features are tremor at rest, rigidity, akinesia (or bradykinesia), and postural instability (TRAP), often associated with gait disturbances and falls (Jankovic, 2008). However, PD can present with a variety of additional clinical features, and various clinical subtypes have been described and the neuropathology underlying clinical variability in α -synucleinopathies (e.g. PD) has been described (Halliday et al., 2011).

On macroscopic examination, the most remarkable feature of PD is pallor of the substantia nigra and often the locus caeruleus. Histologically, abundant LBs and LNs are predominately present in subcortical nuclei, e.g. substantia nigra, locus caeruleus, and dorsal motor nucleus of the vagal nerve. In particular, the substantia nigra pars compacta shows severe depletion of pigmented/melanized (45–66%) and dopaminergic (60–88%) neurons, particularly in an area projecting to the striatum (ventrolateral tier). Importantly, PD may present as a multiorgan disease, with α -synuclein pathology involving the central, autonomic, and peripheral nervous systems, but also extraneuronal organs, e.g. the adrenal glands (Jellinger, 2014).

Dementia with Lewy bodies and Parkinson's disease dementia

The distinction between DLB and PDD is primarily based on clinical data; in PDD, the onset of extrapyramidal symptoms should precede dementia by 1 year. Neuropathologically, a significantly more severe A β plaque load in the striatum of DLB than in PDD patients has been observed (Halliday et al., 2011; Jellinger and Attems, 2006). However, on neuropathological post-mortem examination, clinical PDD usually shows the same neuropathological hallmark features as DLB, but A β and tau loads are less severe than in DLB (Jellinger, 2018a). Cognitive deficits in PD patients without dementia are related to age and A β status but are not associated with measurable AD (Winer et al., 2017).

DLB is the second most common age-associated neurodegenerative dementia, accounting for up to 26% of dementias in specialized referral centres (Ince, 2011). The clinical symptoms of DLB are dementia associated with core neuropsychiatric features of fluctuating cognitive function, visual hallucinations, and, in up to 75% cases, mild parkinsonism (McKeith et al., 2017). For a more detailed description of clinical findings in DLB, see Chapter 32.

Macroscopically, brains of DLB patients may appear normal or show diffuse cerebral atrophy that is indistinguishable from AD. The pigmentation of the substantia nigra varies from normal to pale, and the locus caeruleus is usually depigmented. Histologically, DLB is characterized by abundant LBs and LNs in the neocortex, in particular the cingulate gyrus and the limbic system, including the entorhinal cortex and hippocampus. Similar to AD, additional pathologies are usually present in DLB (Z. Walker et al., 2015) and these are discussed in Cerebral multimorbidity, p. 82.

Neuropathological diagnostic criteria for Lewy body disease

Several neuropathological staging systems for LBD are in use:

1. Braak stages for α -synuclein-related pathology postulate that nuclei in the medulla oblongata (e.g. dorsal motor nucleus of the vagus nerve) become initially affected (stage 1) and pathology spreads gradually to the pons (locus caeruleus, stage 2), midbrain (substantia nigra, stage 3), and entorhinal cortex and hippocampus (stage 4), and finally reaches the neocortex (stages 5 and 6) (Braak et al., 2003). Using this classification, PD would reach stage 3, while DLB should at least show stage 4.
2. The Newcastle-McKeith criteria for LBD (McKeith et al., 2005) distinguish between brainstem-predominant (PD), limbic (transitional; DLB), and diffuse neocortical (DLB) types. These criteria differ from Braak stages insofar as they do not strictly postulate a stepwise progression of α -synuclein pathology from the medulla oblongata to the pons, midbrain, limbic areas, and neocortex, and cases might show severe neocortical α -synuclein pathology, with only minimal involvement of brainstem regions.

Therefore, this staging system questions the validity of the system proposed by Braak and colleagues (Braak et al., 2003).

3. Leverenz and colleagues (Leverenz et al., 2008) modified the Newcastle–McKeith criteria by adding an amygdala-predominant type that may completely lack α -synuclein pathology in regions other than the amygdala. This amygdala-predominant type frequently co-occurs with severe AD (e.g. in 24% of otherwise pure AD cases) (Uchikado et al., 2006).

Multiple system atrophy

Multiple system atrophy (MSA) is a sporadic, adult-onset, and fatal neurodegenerative disease, characterized clinically by parkinsonism, cerebellar ataxia, autonomic dysfunction, and corticospinal signs. MSA primarily involves striatonigral and olivopontocerebellar structures (Jellinger and Wenning, 2016). On macroscopic examination, considerable atrophy of the cerebellum and pontine base is frequently observed and the atrophic putamen shows dark discoloration. The substantia nigra and locus caeruleus are depigmented. The characteristic neuropathological lesions of MSA are oligodendroglial α -synuclein cytoplasmic inclusions known as glial cytoplasmic inclusions (GCIs or Papp-Lantos inclusions) that are associated with myelin depletion. α -synuclein also accumulates in oligodendroglial nuclei, as well as in the cytoplasm and nuclei of neurons (Valera and Masliah, 2017) (Fig. 5.7). MSA is currently classified as an oligodendroglioneuronal synucleinopathy with multisystem neurodegeneration (Jellinger, 2018b)

Fig. 5.7

In multiple system atrophy (MSA), aggregates of α -synuclein termed Papp-Lantos inclusions or glial cytoplasmic inclusions (arrows in B and C) are frequent in the oligodendroglia. Photomicrographs are taken from sections of the external capsule. A and B, α -synuclein immunohistochemistry; C, H/E.

Scale bars: A, 500 μ m; B and C, 20 μ m.

Frontotemporal lobar degenerations (including tauopathies)

Frontotemporal lobar degenerations (FTLDs), the third or fourth most frequent cause of dementia, are a heterogeneous group of neurodegenerative diseases that usually show a frontotemporal-pronounced cerebral atrophy (Lashley et al., 2015). Microscopically, they

are characterized by cellular inclusion bodies that are composed of either tau or TDP-43 or a protein encoded by the fused in sarcoma gene (FUS) and/or ubiquitin or neurofilament or a basophilic substance (basophilic inclusion bodies). According to the predominant protein aggregates, the subtypes described in the following sections can be distinguished, but there are cases with overlapping pathology (Mann and Snowden, 2017). A recent review demonstrated their genetic pleiotropy, indicating that sporadic FTLT is a polygenetic disorder (Ferrari et al., 2017). It should be mentioned that FTLT-tau are frequently listed in the group of tauopathies that additionally include diseases that are not characterized by atrophy of frontal and/or temporal lesions such as parkinsonism–dementia complex of Guam and post-encephalic parkinsonism.

FTLT-tau

Pick's disease

Pick's disease (PiD), although a well-known eponym, is a rare cause of frontotemporal dementia (<5% of FTLT cases), with behavioural abnormalities or with non-fluent progressive aphasia as the most common clinical presentation. Both sexes are equally affected, with an average age of onset at approximately 60 years and a disease duration of 8–10 years (Munoz et al., 2011). At post-mortem examination, the characteristic macroscopic feature is severe, circumscribed atrophy of the frontal, temporal, and sometimes parietal lobes, while the motor and sensory cortices, posterior two-thirds of the superior temporal gyrus, and occipital cortex are preserved. The brainstem and cerebellum show no macroscopic abnormalities. Histologically, the macroscopically atrophic areas, as well as the deep grey matter and the brainstem, in particular the monoaminergic nuclei, show neuronal loss and gliosis, which also affects the atrophic subcortical white matter. Pick bodies—the neuropathological hallmark lesion of PiD—are large argyrophilic, neuronal, cytoplasmic, round inclusions, predominately composed of 3R tau. Pick bodies are frequent in hippocampal pyramidal neurons of the CA1 sector, while CA2–4 and subiculum are less frequently involved. In other cortical areas, Pick bodies may occur less evenly distributed, but in large clusters (Irwin et al., 2016). Ballooned neurons, similar to the ones seen in corticobasal degeneration (CBD), may be present, as well as tau-immunoreactive glial lesions that, interestingly, are predominately composed of 4R tau (Zhukareva et al., 2002).

Corticobasal degeneration

The clinical symptoms in CBD are highly variable, the most characteristic being the corticobasal syndrome with asymmetrical akinetic-rigid parkinsonism and cortical signs, including apraxia, dystonia, and myoclonus. However, some autopsy series indicate that—although being characteristic—the corticobasal syndrome may not be the most common clinical presentation of CBD, as frontal-type dementia has been reported to be more frequent. No epidemiological data are available for the

prevalence and incidence of CBD, but its incidence has been estimated to be <1 per 100,000 people per year. CBD is a disease of middle to late age, with no gender predisposition and age being the only known risk factor (Dickson et al., 2011). Reflecting the broad spectrum of possible clinical presentations, the neuropathological findings in CBD are highly variable (Lee et al., 2011). However, the classical presentation shows asymmetrical atrophy of cortical gyri that is most marked in superior frontal and parietal parasagittal regions. Among other macroscopic features, a red-brown discoloration may be seen in the globus pallidus and the substantia nigra shows loss of neuromelanin pigment, while the locus caeruleus appears normal. The characteristic neuropathological finding of CBD is the accumulation of 4R tau in the neuropil and astrocytes in the cortex, white matter, basal ganglia, thalamus, and brainstem. 4R tau may also be present in neurons, but the neuropathological hallmark lesion is the astrocytic plaque, which is not seen in other diseases. The early prominence of the astrocytic plaques suggests that CBD begins as an astrogliaopathy, while neuronal lesions represent the predominant lesion type in advanced disease (Ling et al., 2016). The astrocytic plaque represents 4R tau accumulation in distal segments of astrocytes, while the cell body is free of accumulation. This morphology is reminiscent of an NP, but no A β accumulation is present in astrocytic plaques. Astrocytic plaques predominately occur in the cortex but can also be present in other regions such as the caudate and putamen. Swollen cortical neurons that are termed ballooned neurons are another neuropathological hallmark of CBD.

Progressive supranuclear palsy

Symmetrical, akinetic-rigid parkinsonism with severe postural instability and supranuclear ophthalmoplegia are the typical clinical symptoms of progressive supranuclear palsy (PSP) (Steele–Richardson–Olszewski syndrome) (Höglinger et al., 2017), but less frequent atypical presentations, such as asymmetrical clinical syndromes (e.g. corticobasal syndrome), may be seen (Ling et al., 2016). In the UK, the prevalence of PSP is estimated at approximately 5 per 100,000, with the mean age at onset ranging from 66 to 69 years (Nath et al., 2001), while it is 10 per 100,000 in Japan (Yoshida et al., 2017). The basal ganglia, subthalamic nucleus, and substantia nigra are primarily affected, and usually pathology in the cerebellar dentate nucleus is severe and associated with profound atrophy of the superior cerebellar peduncle. The characteristic neuronal lesion is the globose NFT that is composed of 4R and occurs in the brainstem nuclei and the nucleus basalis of Meynert, while in other regions, NFTs may be flame-shaped. Immunohistochemistry for 4R tau also labels tuft-shaped astrocytes (tufted astrocytes), which are the most characteristic glial lesion in PSP (Yokoyama et al., 2016). In addition, 4R-positive NTs are seen in the grey and white matter of both cortical and subcortical regions. The severity and distribution of tau pathology vary in the different subtypes of PSP (PSP-parkinsonism/PSP-P, Richardson's

syndrome, and atypical forms), causing a broad spectrum of clinical phenotypes (Respondek et al., 2017).

Argyrophilic grain disease

Argyrophilic grain disease (AGD) has a mean age of onset of approximately 80 years, with males and females affected equally. AGD is the most common sporadic tauopathy and is observed in up to 5% of late-onset dementia cases (Saito et al., 2002). However, AGD is a frequent finding in other neurodegenerative diseases and has been reported to be present in varying severity in up to 26% of AD cases (Fujino et al., 2005). Macroscopically, the brain appears relatively normal, with mild frontotemporal cortical atrophy, but severe atrophy of the ambient gyrus was described in late stages of the disease (Saito et al., 2002). In AGD, 4R tau aggregates occur in dendrites and present as comma- or grain-shaped structures in the neuropil of the medial temporal lobe, in particular in the hippocampal Ammon's horn sector CA1 and prosubiculum. In addition, 4R tau is present in oligodendroglia, referred to as coiled bodies, that may be present in other tauopathies, but in AGD, they are a consistent finding in the white matter. AGD differs from other tauopathies by lacking tau acetylation (Grinberg et al., 2013).

FTLD with TDP-43 pathology

FTLD with TDP-43 pathology (FTLD-TDP) may underlie any of the three major clinical variants of the frontotemporal dementia syndrome, behavioural variant, progressive non-fluent aphasia, and semantic dementia (Alafuzoff et al., 2015). It has been shown that neuropathologically, FTLD-TDP is present in 50% of cases with clinical frontotemporal dementia syndrome (Neumann et al., 2006), with 20–40% being associated with a positive family history with various disease-causing mutations. The mean age of onset of FTLD-TDP is approximately 60 years (33–89 years), with a mean disease duration of 8 years (2–18 years). FTLD-TDP can be categorized into four distinct histopathological patterns of TDP-43 pathology (types A to D), with an additional rapidly progressive subtype 'E' (Lee et al., 2017). Neuropathologically, FTLD-TDPs are characterized by neuronal cytoplasmic inclusions (NCIs) that consist of phosphorylated TDP-43. TDP-43 is involved in regulating transcription and alternative splicing (Alafuzoff et al., 2015); physiologically, TDP-43 is present in the nucleus, but under pathological conditions, such as FTLD-TDP, it is usually located in the cytoplasm (TDP-43 NCIs in spinal motor neurons are a characteristic feature of ALS). Macroscopically, cerebral atrophy is variable, but frontal and temporal lobes are most frequently affected, sometimes with asymmetrical distribution. In addition to unspecific features of neurodegeneration, TDP-43-positive NCIs and dystrophic neurites (DNs) are usually seen in the frontotemporal neocortex and granule cell layer of the dentate gyrus (Mackenzie et al., 2010) (Fig. 5.8). Neuronal intranuclear inclusions (NIIs) may also be present and, depending on the amount and distribution of NCIs and DNs, as well as on the presence of

NIIs, four neuropathological subtypes (types A, B, C, and D) of FTLD-TDP have been described (Lee et al., 2017; Mackenzie et al., 2011; Yousef et al., 2017).

Fig. 5.8

TDP-43 positive neuronal cytoplasmic inclusions (NCI, arrow in A1 and B) and thread-like structures (arrowhead in A1) are the characteristic neuropathological lesion for FTLD-TDP-43 and motor neuron disease (amyotrophic lateral sclerosis) but may be present as an unspecific feature in a variety of other diseases, including AD. Of note, under physiological conditions TDP-43 is present in neuronal nuclei (ring in B). Immunohistochemistry with antibody against (nonphosphorylated) TDP-43.

Scale bars: A, 100 μ m; B, 20 μ m.

FTLD-UPS

Ubiquitin-positive inclusions are the characteristic lesion of FTLD-UPS (ubiquitin-proteasome system). It now appears that most cases of sporadic FTLD-UPS have FUS-immunoreactive pathology, but the term FTLD-UPS is still appropriate for a familial form of FTLD—familial FTLD linked to chromosome 3 (FTD-3). Brains show frontotemporal atrophy, cortical microvacuolation, neuronal loss, and astrogliosis. The remaining neurons show enlarged vacuoles (Lashley et al., 2015).

FTLD-FUS

FTLD-FUS are characterized by abnormal accumulation of a nuclear DNA/RNA-binding protein, encoded by the fused in sarcoma (*FUS*) gene, as the most prominent pathology and include atypical FTLD with ubiquitinated inclusions (aFTLD-U), neuronal intermediate filament inclusion disease (NIFID), and basophilic inclusion body disease (BIBD) (Mackenzie et al., 2010). A more detailed description of FTLD-FUS is beyond the scope of this chapter. For a review, see Mackenzie and Neumann, 2017.

FTLD with no inclusions

The term FTLD-no inclusions (FTLD-ni) is used for FTLD cases that lack any histochemically and immunohistochemically detectable inclusions but otherwise show clinical features of dementia and non-specific neuropathological changes (e.g. atrophy, neuronal loss). This type has previously been referred to as 'dementia lacking distinctive

histopathology' (DLDH), but it is suggested that FTL D-ni replaces the term DLDH, as the latter suggests that pathological lesions are completely absent (Mackenzie et al., 2009).

Perry syndrome

Perry syndrome (PS) is a rare atypical parkinsonism, with depression, apathy, weight loss, and central hypoventilation, caused by mutations in the dynactin p150^{glued} (*DCTN1*) gene, with TDP-43 inclusions as the defining morphological feature. PS has NCIs, DNIs, and frequent perivascular astrocytic inclusions (PVIs) and spheroids, which are different from other TDP-43 proteinopathies (ALS, FTL D with or without motor neuron disease) and HS (Mishima et al., 2017). Pallidonigral TDP-43 proteinopathy is the underlying pathological process (Dickson, 2018).

Huntington's disease

Huntington's disease (HD) is an autosomal dominant hereditary disease. HD belongs to the family of trinucleotide repeat diseases that are caused by expansions of pre-existing tandem repeat sequences, with each of the diseases (e.g. myotonic dystrophy type 2, spinocerebellar ataxia) affecting different genes. There is recent evidence suggesting that HD is a new member of the family of tauopathies, but this awaits further confirmation (Gratuzi et al., 2016). The gene for HD (*huntingtin* or HTT) is located on the short arm of chromosome 4 (4p16.3), and the mutation consists of an expanded repetition of the cytosine-adenine-guanine (CAG) trinucleotide. HD equally affects men and women; age at diagnosis is, on average, 40 years, and the symptomatic prevalence ranges from 5 to 10 per 100,000, with global variations in its prevalence (Baig et al., 2016; Rawlins et al., 2016). The prodromal period of HD commonly includes neuropsychiatric symptoms, such as depression and psychosis, as well as motor features (subtle involuntary movements and oculomotor dysfunction), and these may be present for many years before the diagnosis in attenuated form. Typical symptoms of the disease include chorea and mental dysfunction, leading to dementia. The neuropathology of HD shows a multisystem degeneration which, apart from the striatum, affects the neo- and allocortex, thalamus, pallidum, brainstem, and cerebellum, sharing similarities with polyglutamine spinocerebellar ataxias (Rüb et al., 2016). The brain in end-stage HD shows severe reduction in weight (900–1000 g), mainly due to profound atrophy of the caudate nucleus and putamen, but the cerebral cortex, hippocampus, thalamus, and white matter are also affected. Microscopically, the basal ganglia show severe neuronal loss and gliosis, and on microscopic examination, huntingtin or ubiquitin-positive protein accumulations are frequently seen in cellular processes (neurites) and, to a lesser degree, as nuclear inclusion bodies. A rating scale of five grades (0–4) designating the order of severity of neuropathological involvement correlates closely with the extent of clinical disability (Rüb et al., 2016; Singh-Bains et al., 2016; Vonsattel et al., 1985). HD-like (HDL) 2 is an autosomal dominant disorder with adult

onset that shows very similar neuropathological features, suggesting overlapping pathogenesis (Govert and Schneider, 2013, Rudnicki et al., 2008).

Prion diseases

Prion diseases that are also known as transmissible spongiform encephalopathies (TSEs) are caused by a potentially infectious agent and thereby differ from other neurodegenerative diseases. The infectious agent is the prion protein (PrP) that essentially consists of PrP^{Sc} which presents as aggregates of an abnormally folded β -sheet-rich isoform of a normal cellular protein of largely unknown function (possible role in myelin maintenance), termed PrP^C (Aguzzi and Heikenwalder, 2006). Prion diseases occur in humans and animals. Human prion diseases encompass sporadic [sporadic Creutzfeldt-Jakob disease (sCJD) and fatal sporadic insomnia], inherited (familial CJD, Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia), and infectious forms (iatrogenic CJD, variant CJD (vCJD), and Kuru). Of note, as vCJD predominately occurred in the UK, the country with the highest incidence of bovine spongiform encephalopathy (BSE), a bovine prion disease, exposure to prion proteins due to past consumption has been suggested to cause vCJD in humans. It is assumed that PrP^{Sc} is capable of inducing conformational conversion of PrP^C into PrP^{Sc}, thereby leading to a spread of aggregated PrP^{Sc} in the CNS.

The most common form of prion disease in humans is sCJD, accounting for 85% of all CJD cases. No cause for sCJD has been identified, and the typical clinical picture is rapidly progressive dementia with ataxia and myoclonus. The incidence of sCJD is between 1 and 2 cases per million per year, and the mean age of onset is 65 years. On macroscopic examination, the brain may appear normal, but usually some degree of atrophy is present. Histologically, sCJD is characterized by a triad of spongiform change, neuronal loss, and astrocytic, as well as microglial, gliosis. Spongiform change presents as diffuse or focal small, round or oval vacuoles in the cerebral cortex (whole thickness or deep layers), subcortical grey matter (almost constantly in the head of the caudate nucleus), and cerebellar molecular layer. In addition, PrP immunohistochemistry should be used to confirm the diagnosis. A consensus classification of human prion disease subtypes allows reliable identification of molecular subtypes (Barron et al., 2016). While most cases of prion disease are idiopathic and acquire the disease through an identified source of infection, about 10–15% of patients are affected by a genetic form and carry either a point mutation or an insertion of octapeptide repeats in the *PrP* gene—such as Gerstmann-Straussler-Scheinker syndrome or fatal familial insomnia (Honda et al., 2017).

Vascular dementia

VaD, or vascular cognitive impairment, can be defined as acquired cognitive impairment caused by cerebrovascular disease. Due to the high variability of morphological findings and multifactorial pathogenesis of VaD, no generally accepted morphologic scheme for staging cerebrovascular lesions and no validated neuropathological criteria for VaD have been established (Jellinger, 2013). Therefore, many aspects of VaD, such as prevalence, morphology, and pathogenesis, are a matter of ongoing discussions. The recently established 'Vascular Cognitive Impairment Neuropathology Guidelines' (VCING) are based on the assessment of occipital CAA, arteriolosclerosis in the occipital white matter, and infarcts. This assessment allows to state the likelihood (low, <50%; moderate, 50–80%; high, >80%) that cerebrovascular disease contributed to cognitive impairment (Skrobot et al., 2016). VaD has, however, been suggested to be the cause for dementia in approximately 10% of cases. Clearly, cerebrovascular lesions can cause neuronal loss and—depending on the topographical localization—this process may lead to dementia (Iadecola, 2013; Jellinger, 2016; Thal et al., 2012).

The morphological substrates for VaD are extensive, and only a brief and incomplete description can be provided here (for comprehensive reviews, see Grinberg and Thal, 2010 and McAleese et al., 2016).

Two types of vessel disorders can potentially cause VaD:

1. Atherosclerosis is a very common vessel disorder in the older person, frequently affecting large to medium-sized arteries of the entire cardiovascular system. In the cranium, it often affects the circle of Willis, and an important extracranial site—with respect to the development of cerebrovascular lesions—is the carotid arteries, in particular at the level of the carotid bifurcation. Atherosclerosis is initiated by thickening of the tunica intima (i.e. the innermost layer of a blood vessel), with subsequent accumulation of blood-derived lipids. This process is followed by splitting of the internal elastic lamina, and finally cholesterol accumulation leads to the manifestation of atherosclerotic plaques that can calcify. Atherosclerosis causes narrowing of the arteries' lumina, thereby reducing the blood supply for the supported region, but this is frequently compensated by a shift in blood flow towards collateral arteries (e.g. vertebral arteries for the internal carotid arteries). On the other hand, rupture of atherosclerotic plaques often leads to thrombosis that results in either occlusion of the lumen or thromboembolism. Depending on the size of the embolus, thromboembolism may cause lesions that range from 'silent infarcts' to large cerebral infarcts with overt clinical symptoms.
2. Small vessel disease refers to pathological changes that affect small arteries and arterioles (Fig. 5.9). Small arteries may show morphological changes that are similar to atherosclerotic changes (i.e. microatheroma) and are termed 'small vessel arteriosclerosis/

atherosclerosis'. 'Lipohyalinosis' is used for asymmetric fibrosis/hyalinosis, while concentric hyaline thickening with lumen stenosis is termed 'arteriosclerosis'. The latter is particularly common in the white matter and the main cause for white and deep grey matter lesions, respectively.

Fig. 5.9

Small vessel disease is a frequent cause of white matter (WM) lesions. (A) Normal vessel and white matter; note the slight perivascular space that is regarded as an artifact; (B) mildly enlarged perivascular spaces; (C) considerable enlargement of the perivascular space accompanied by moderate demyelination of the WM (pallor in myelin staining); (D) severe WM lesions with enlarged perivascular spaces, WM pallor, and tissue loss; (E) normal artery; (F) artery with mild fibrosis; (G) artery with moderate fibrosis; (H) severe arteriolar fibrosis with acellular concentric thickening of the vessel wall (usually associated with hypertension). A-D, Luxol Fast Blue histochemistry (myelin stain); E-H, H/E.

Scale bars: A and G, 50 μ m; B, C, D, and H, 100 μ m; E and F, 20 μ m.

Reproduced courtesy of Kirsty McAleese.

White matter lesions (leukoaraiosis) are increasingly detected by modern neuroimaging methods (on MRI, such lesions are present in most older people), frequently clinically asymptomatic, and in most cases related to small vessel disease of the white matter. The associated neuropathological findings include demyelination, axonal loss, and lacunar infarcts (usually small), most frequently in the frontal, parietal, and occipital white matter. Using special stains (e.g. Luxol fast blue), demyelination is indicated by a pallor in staining intensity, and arterioles in these areas may show concentric thickening of the vessel wall and perivascular spaces that are filled with macrophages (of note, small perivascular spaces alone are not an indicator of small vessel disease but are an artefact caused by tissue processing; Fig. 5.9). Lacunes are cavities measuring 5–10 mm in diameter that are caused by either old (lacunar) infarcts or, less frequently, haemorrhages. In addition to the

Neuropathology

white matter, they occur in the basal ganglia (deep grey matter lesions) and, if severe, are the morphologic substrate of the so-called status lacunaris or *état criblé*.

Ischaemic brain infarcts are caused by insufficient blood supply frequently due to thromboembolism. After 6–12 hours, the neurons show signs of acute ischaemic cell injury (e.g. eosinophilic cytoplasm and shrunken nucleus), and between 24 and 48 hours, neutrophils appear that are replaced by macrophages after 48 hours. Ten days after the infarction, the area is liquefied, resulting in the formation of a cavity (third week) that becomes intersected by vascular and connective tissue strands and surrounded by gliosis (scarring; Fig. 5.10). Haemorrhagic brain infarcts are characterized by secondary blood influx into the infarcted territory, and microinfarcts refer to infarcts below 5 mm in diameter (for lacunar infarcts, see earlier).

Fig. 5.10

Old cystic infarct in the right frontal lobe in the territory of the middle cerebral artery (A; B, frontal plane).

Scale bars: A, 50 mm; B, 20 mm.

Cerebral haemorrhages are larger than 10 mm in diameter. Causes for non-traumatic intracerebral haemorrhage include aneurysms of cerebral arteries, coagulation disorders, atherosclerosis, hypertension with small vessel disease, and CAA. Recently, cerebral microbleeds (i.e. haemorrhage not visible to the naked eye) have gained wider attention, as MRI detects small signal voids, indicating perivascular accumulation of haemosiderin/haemosiderin-laden macrophages that are presumed to reflect old cerebral microbleeds. Cerebral microbleeds are associated with CAA and, according to MRI studies, are frequent in older people (e.g. 23.5%) (Vernooij et al., 2008). However, microbleeds are rarely seen at neuropathological post-mortem examination and their true incidence is therefore controversial.

It is beyond the scope of this chapter to provide a comprehensive review of the many possible ways to classify cerebrovascular pathology, and several articles are suggested for further reading (Gorelick et al., 2011; Kalaria, 2016; McAleese et al., 2016). As an example, a brief outline of the classification of VaD, according to the underlying disease, is provided here.

1. Large vessel disease: atherosclerosis of extra- or intracranial arteries may cause thromboembolism or hypoperfusion that leads to single or multiple infarctions in the cerebral regions that receive blood supply by the respective artery. Cognitive impairment might result from smaller infarcts that are strategically placed, affecting functionally important brain areas and neuronal circuits ('strategic' infarct dementia syndrome).
2. Small vessel disease: small vessel disease affects small arteries and arterioles and includes arteriosclerosis/atherosclerosis, arteriolosclerosis, and lipohyalinosis. Small vessel disease may cause ischaemic white matter damage and lacunar infarcts in the basal ganglia, both of which may present a morphological correlate for VaD.
3. Hypoxic damage: this is caused by cerebral hypoperfusion and may lead to ischaemic-anoxic damage and HS (see Hippocampal sclerosis, p. 84).

Cerebral multimorbidity

It is becoming increasingly clear that the ageing brain is characterized by the presence of multiple pathologies, rather than the characteristic neuropathological lesions of one single neurodegenerative disease only. Of particular importance is the frequent presence of other pathologies in the aged brain that coexist with AD, e.g. cerebrovascular disease, LB pathology, AGD, TDP-43 pathology, and HS (Jellinger and Attems, 2015).

As already outlined, neurodegenerative diseases are neuropathologically characterized by the presence of discrete lesions in a specific topographical pattern. However, data from many different autopsy studies point towards the presence of additional lesions in otherwise well-characterized cases, which fulfil the criteria for a single distinct disorder (Jellinger and Attems, 2007b; Jellinger and Attems, 2010; Kovacs et al., 2008; Rahimi and Kovacs, 2014) (Fig. 5.11):

Fig. 5.11

Multiple pathologies in brains of older demented patients. Full arrows point towards the characteristic neuropathology of the respective disease, while dotted arrows point towards neuropathological lesions that are frequently seen in addition to the main pathological hallmark lesions. Approximate percentages are encircled.

AD, Alzheimer's disease; LBD, Lewy body diseases; FTLD-TDP, frontotemporal lobar degeneration with TDP-43 pathology; VaD, vascular dementia.

In AD that is characterized by A β and tau pathology, LBs are seen in up to 43% (Uchikado et al., 2006) (AD with amygdala LBs is considered a distinct form of α -synucleinopathy) and severe cerebrovascular lesions in up to 20% of cases, respectively (Jellinger and Attems, 2007b). TDP-43 pathology following a distinct hierarchical spreading pattern (which is different from FTLD-TDP) is seen in up to 70% of AD cases and, if severe, has a strong independent effect on cognition, memory loss, and medial temporal lobe atrophy (Josephs et al., 2014; McAleese et al., 2017a). Of note, such TDP-43 pathology is also present in LBD (33%) and cognitively unimpaired elderly controls (18%), suggesting that the prevalence of this type of TDP-43 pathology increases with advancing age (McAleese et al., 2017a).

In LBD that is characterized by α -synuclein pathology, A β pathology was identified in 95%, considerable tau pathology (Braak stages V/VI) in 55%, and various degrees of cerebrovascular pathology in 75% of cases (Jellinger and Attems, 2008). In another large clinicopathological cohort of over 200 DLB/PDD cases, 26% had additional low, 21% intermediate, and 30% high AD neuropathologic changes, respectively (Irwin et al., 2017). The latter group, showing neocortical LBD, together with high AD neuropathologic changes, can be classified as mixed dementia, since the amount of each LB and AD pathology would be sufficient to cause clinical dementia (L. Walker et al., 2015).

Pure VaD without additional lesions is rare, and frequently additional, often limited, AD pathology is present. However, since 50–85% of post-mortem brains from individuals (with and without dementia) who die over 80 years of age show appreciable cerebrovascular lesions, a particular problem is the impact of cerebrovascular disease on cognition, especially in relation to AD pathology (Kapasi et al., 2017).

The high prevalence of multiple pathologies in the brains of aged individuals could reflect the simultaneous presence of one single distinct neurodegenerative disease and age-related changes that are not directly associated with the primary neurodegenerative disease; for example, the high prevalence of cerebrovascular lesions in AD brains of individuals aged 80+ years probably mirrors the prevalence of age-associated vascular diseases in the aged per se, rather than suggesting causal relationships between AD and cerebrovascular lesions. The burdens of vascular and AD-type lesions are indeed considered to be independent of each other and are consistent with an additive (or even synergistic) effect of both types of lesions on cognitive impairment. The thresholds for vascular and degenerative lesions in distinguishing 'pure' VaD or AD from mixed cases have been critically discussed (Gold et al., 2007). AD pathology alone more frequently accounts for dementia than both microscopic and macroscopic infarcts, and in advanced stages of AD, concomitant small vascular lesions do not significantly influence the overall state and progression of cognitive decline; hence, the severity and extent of AD pathology seem to overwhelm the effects of cerebrovascular disease (Jellinger, 2007a). However, this does not preclude the possibility that cerebrovascular lesions exert an influence on AD pathology itself and it has been suggested that cerebrovascular lesions in AD lower the threshold for overt clinical dementia, i.e. less AD pathology is needed to cause clinical symptoms, if additional cerebrovascular pathology is present (Kapasi et al., 2017).

Another example of the simultaneous presence of a distinct neurodegenerative disease and age-associated change would be limited AD pathology (e.g. Braak stage III and A β -plaques) in DLB; here, AD pathology could be regarded as age-associated change that manifests independently of DLB. Similarly to the presumed impact of cerebrovascular lesions in AD, α -synuclein pathology in DLB might be aggravated by age-associated AD pathology.

Co-occurrence of abnormal depositions of tau, α -synuclein, and/or A β suggests an interaction between these misfolded proteins in the human brain, and such an interaction is supported by studies in animal models. *In vitro* studies demonstrated synergistic fibrillization of tau and α -synuclein (Giasson et al., 2003), and data from studies on transgenic (tg) mice indeed suggest a mutual interaction of A β , tau, and α -synuclein pathologies; Clinton and colleagues crossed 3 $\times$ tg mice that develop both A β plaques and tau pathology with mice that express the A53T mutation in α -synuclein (M83-h) (Clinton et al., 2010). At 12 months of age, these so-called DLB-AD mice had significantly higher detergent-soluble and

insoluble A β ₄₀, detergent-insoluble A β ₄₂, and insoluble tau levels than 3 $\times$ tg mice, respectively. Moreover, detergent-insoluble α -synuclein as well as detergent soluble α -synuclein phosphorylated at serine 129 levels were significantly higher in DLB-AD mice, compared to M83-h mice. Taken together, these results suggest that A β , tau, and α -synuclein interact *in vivo* to promote the aggregation and accumulation of each other.

Recent studies suggest similar interactions in human brains; for example, in DLB cases, cerebral α -synuclein scores increased with increasing AD pathology (Irwin et al., 2017) and in PDD and PD cases, a significant correlation between LB scores and NFT Braak stages was found (Compta et al., 2011). These findings suggest: (1) a synergistic or triggering effect between tau, α -synuclein, and A β pathologies (Spires-Jones et al., 2017), as increasing levels of AD pathology may induce a higher burden of α -synuclein pathology, and vice versa (Guo et al., 2013); (2) an overlap in the pathology between various proteinopathies; and (3) the cognitive decline and related symptoms in LBDs may not always be solely a consequence of α -synuclein-induced neurodegeneration, but also due to additional AD-related pathologies, and hence mixed pathologies may contribute to the clinical symptoms (Colom-Cadena et al., 2017; Howlett et al., 2015; Irwin et al., 2017; Kapasi et al., 2017; Spires-Jones et al., 2017; Z. Walker et al., 2015). On the other hand, the considerable overlap between tau and α -synuclein pathologies could be explained by a mechanistic linkage between tauopathies and synucleinopathies (Jellinger, 2018a).

In summary, keeping in mind that prevalence rates of A β , tau, α -synuclein, TDP-43, and cerebrovascular pathologies all increase with advancing age (Spires-Jones et al., 2017), it is no surprise that, for example, a considerable proportion of AD patients will show additional α -synuclein and/or TDP-43 and/or cerebrovascular pathologies; otherwise AD, as such, would be protective against other age-associated cerebral pathologies, which, quite clearly, is not the case. On the contrary, it rather seems that different pathologies aggravate each other, and hence future patient stratification should be based on the actual pathologies present in the brain, rather than on distinct diseases (e.g. AD, DLB, etc.). The latter approach introduces a considerable bias into all types of clinical studies, as it assumes that clinical cohorts are homogenous with regard to their underlying pathology, while they are actually highly heterogenous due to the high prevalence of cerebral multimorbidity in old age.

Future directions in neuropathological assessment

Currently, neuropathological assessment is based on semi-quantitative scoring, usually on a four-tiered scale, e.g. 0, absent; 1, mild; 2, moderate; 3, severe. Frequently, the criteria for scoring one of those categories have been standardized. While semi-quantitative assessment allows for the statement of routine diagnoses, it provides only a rough estimation of the amount of pathology present. For example, Walker and

colleagues found that the area covered by immunopositivity for the AT8 antibody (tau) in cases that were assigned the score 'severe' may differ by nearly 50% between cases (Walker et al., 2017). In the 90+ study, a prospective, longitudinal, population-based study of ageing and dementia, the area covered by A β immunopositivity in selected neocortical regions significantly correlated with the presence of clinical dementia (Robinson et al., 2011); of note, in most studies, the extent of neocortical A β immunopositivity, as assessed by semi-quantitative scoring, did not correlate with the presence of clinical dementia. It is likely that new clinicopathological phenotypes could be identified by routinely assessing the amount of pathology in a more quantitative way. Indeed, in quantitatively assessing tau pathology in a large cohort ($n = 889$) of neuropathologically diagnosed AD cases, hippocampal sparing and limbic-predominant subtypes of AD were found, which differed from typical AD in clinical presentation, age at onset, disease duration, and rate of cognitive decline (Murray et al., 2011). Given that quantitative assessment of tau pathology alone in AD cases points towards new clinicopathological phenotypes, we believe that a more accurate, quantitative assessment of various neuropathological lesions is necessary to further elucidate possible mutual relationships between pathologies, as well as their combined influence on the clinical picture (Walker et al., 2017). A deeper knowledge of underlying pathologies in age-associated neurodegeneration and cerebrovascular disorders is paramount to identify suitable targets for new therapeutic approaches.

Introduction

Recent years have witnessed an increasing understanding of the molecular and cellular underpinnings of Alzheimer's disease (AD) (Winblad et al., 2016). The complex pathophysiology of AD involves a series of interconnected pathophysiological pathways, including—extracellular accumulation of the 42-amino acid-long amyloid beta (A β 1–42) peptide into oligomers, fibrils, and plaques as well as the accumulation of intraneuronal neurofibrillary tangles—and downstream processes such as widespread neuroinflammation (Heneka et al., 2015). These events ultimately induce neurodegeneration and synaptic dysfunction with disruption of physiological neural connectivity (Spire-Jones and Hyman, 2014). Hence, several molecular alterations take place in the AD brain, including, but not restricted to, the following: (1) alterations in amyloid precursor protein (APP) and tau protein homeostasis (O'Brien and Wong, 2011); (2) mitochondrial dysfunction; (3)

Biomarkers for Alzheimer's disease

increased oxidative stress (Verri et al., 2012); (4) lipid dishomeostasis (Giannopoulos et al., 2014); and (5) membrane and cell trafficking dysregulation (Di Paolo and Kim, 2011). These molecular pathways are linked with each other and with (epi)genetic factors; thus, a systems biology approach to explore different molecular networks is needed to fully untangle the pathogenesis and pathophysiology of AD (Kaddurah-Daouk et al., 2013; Noorbakhsh et al., 2009).

Different research criteria, integrating the use of biomarkers of AD pathophysiology, have been introduced for the diagnosis of AD: the International Working Group (IWG)-1 (Dubois et al., 2010), IWG-2 (Dubois et al., 2014), and the National Institute of Aging and Alzheimer's Association (NIA-AA) criteria (Albert et al., 2011). These criteria facilitate the identification of early stages of AD including the definition of mild cognitive impairment (MCI) and provide guidance on how to interpret biomarker alterations (Visser et al., 2012).

The IWG criteria use the term 'prodromal AD' for the diagnosis of AD and were intended to serve as research criteria. The IWG-1 criteria require episodic memory impairment and at least one abnormal AD biomarker; this can be either (1) a topographical marker (evidence of medial temporal lobe atrophy on structural MRI or parieto-temporal hypoperfusion on ^{18}F -fluorodeoxyglucose-positron emission tomography [^{18}F -FDG-PET]) or (2) a pathophysiological marker (decreased CSF concentrations of A β 1-42, increased CSF concentrations of tau protein, or increased amyloid PET uptake) (Dubois et al., 2007, 2010).

The IWG-2 criteria include cognitive impairment in any cognitive domain and either (1) reduced CSF A β 1-42 concentrations, along with increased CSF tau, or (2) increased amyloid PET uptake (Dubois et al., 2014). Two subcategories are defined by the IWG-2 criteria: typical prodromal AD (if impairment on a memory test is observed) and atypical prodromal AD (if only impairment on a non-memory test is observed).

The NIA-AA criteria use the definition 'MCI due to AD' and were proposed for both clinical and research uses. They require: (1) the presence of cognitive impairment in any cognitive domain and either (2) abnormal amyloid markers (reduced CSF A β 1-42 concentrations or increased amyloid PET uptake) or (3) neuronal injury markers (evidence of medial temporal lobe atrophy on structural MRI, increased CSF tau concentrations, or parieto-temporal hypoperfusion on ^{18}F -FDG-PET).

Substantial disagreements exist between these sets of criteria with reference to staging, nomenclature, and interpretations of biomarker findings. Moreover, in spite of the importance of associating biomarkers with clinical findings, a purely biomarker-based classification scheme is expected to have the widest approval if it is totally independent of any clinically definite diagnostic model, given the lack of consensus on competing definitions (Jack et al., 2016). In this respect, the recently introduced 'A/T/N' scheme is increasingly gaining support. This is a

Biomarkers for Alzheimer's disease

dissection model including three binary (positive/negative) categories of biomarkers, based on the nature of the underlying pathophysiology that each biomarker measures: 'A' indicating brain overaccumulation of A β (CSF A β 1-42 or amyloid-PET); 'T' indicating tau hyperphosphorylation (CSF p-tau or tau-PET); and 'N' indicating a quantitative or topographic biomarker of neurodegeneration or neuronal injury (CSF t-tau, ¹⁸F-FDG-PET, or structural MRI). Since each individual score is represented in an 'A $\pm$ /T $\pm$ /N $\pm$ ' arrangement, eight different profiles (combinations) can be generated. This stratification model is agnostic to the hypothesized temporal ordering of AD pathophysiology (i.e. that amyloid precedes tau which, in turn, precedes neural loss). Since it does not require any disease labels, it cannot be considered a diagnostic classification; rather, it is a descriptive approach facilitating the categorization of multi-domain biomarker findings (Jack et al., 2016).

Role of biomarkers in the diagnosis and treatment of Alzheimer's disease

A biomarker is defined as a 'characteristic that is measured as an indicator of normal biological processes, pathogenic processes, or response to an exposure or intervention, including therapeutic interventions. A biomarker is not an assessment of how an individual feels, functions, or survives' (FDA-NIH Biomarker Working Group, 2016). Biomarkers have achieved a crucial role in drug development in all therapeutic areas. Thanks to progress in clarifying pathophysiological mechanisms at a molecular level, as well as in diagnostics and pharmacogenomics, biomarkers have been designated as tools to facilitate all phases of drug discovery and development programmes (Hampel and Lista, 2013). For example, they can be used in clinical trials to support proof of mechanism and increase diagnostic accuracy for AD, thus improving individuals' enrolment (Blennow et al., 2014). Moreover, biomarkers can potentially support patient stratification to achieve better clinical response, can be used to monitor the progression of disease and response to therapy, can identify prognostic molecular signatures, and can underpin diagnostic assays (Blennow et al., 2014). Consequently, biomarkers are integrated in research and development strategies to identify novel candidate drugs, from discovery to regulatory authorization (Hampel et al., 2010a; Vellas et al., 2013). Starting from these premises (Lista et al., 2015a), biomarkers are commonly organized in several categories: (1) target engagement biomarkers, testing hypothesized interaction of a candidate drug with its molecular target; (2) mechanism of action biomarkers, assessing downstream biochemical effects; (3) outcome biomarkers, assessing efficacy and safety; (4) safety biomarkers, more specifically assessing and predicting tolerability and side effects; and (5) theragnostic biomarkers, supporting therapeutic choices through the prediction of both the most appropriate therapy (or response to therapy) for an individual and the most accurate dose. Thus, theragnostic biomarkers are needed to optimize drug efficacy and diminish toxicity (Hampel and Lista, 2013). They are assumed to have a key position across

Biomarkers for Alzheimer's disease

the different phases of AD drug development, from early clinical to late registration trials (Blennow et al., 2014).

Recently, a novel integrated partnership model has been introduced for advancing the field of AD biomarkers from discovery to clinic implementation (O'Bryant et al., 2017). The Food and Drug Administration (FDA)/NIH Biomarker Working Group (FDA-NIH Biomarker Working Group, 2016) released the Biomarkers, EndpointS, and other Tools (BEST) Resource to provide definitions for several terms and concepts, especially analytical validation, candidate surrogate end point, clinical benefit, and the term biomarker itself. In this framework, the biomarker categories recommended are: susceptibility/risk, diagnostic, monitoring, prognostic, predictive, pharmacodynamic/response, and safety. Unfortunately, such distinctions are problematic to implement in AD. For example, amyloid positivity might be designated as a diagnostic or predictive biomarker, or both. However, the distinction between different categories of biomarker are argued to be important in treatment and prevention strategies targeted to individuals' characteristics (FDA-NIH Biomarker Working Group, 2016).

Directions for Alzheimer's disease biomarker research

Substantial progress in discovery, development, and validation of AD-related biomarkers has ushered in a novel era of multimodal investigations, integrating modalities, and different biological fluids (Hempel et al., 2012, 2014; Lista et al., 2015b). Candidate biomarkers have been developed from neurogenetics (Bertram and Hampel, 2011; Hampel and Lista, 2012; Zetsche et al., 2010), from neurochemistry via biological fluids such as blood (plasma/serum) (Henriksen et al., 2014; O'Bryant et al., 2015; Snyder et al., 2014) and CSF (Blennow et al., 2010; Ghidoni et al., 2011), and from structural/functional/metabolic neuroimaging (Chiesa et al., 2017; Ewers et al., 2011; Teipel et al., 2013). The longitudinal dynamics and predictive performances of this multimodal approach have not yet been fully established in terms of sensitivity, specificity, or predictive power (Lista and Emanuele, 2011; Lista et al., 2014). Furthermore, more input from regulatory agencies and industry stakeholders has been recommended (Broich et al., 2011; Hampel et al., 2010a).

Established cerebrospinal fluid biomarkers for Alzheimer's disease

Abnormal CSF concentrations of A β 1-42 peptide, total tau (t-tau), and hyperphosphorylated tau (at the threonine site 181; p-tau181) proteins are considered pathophysiological markers of amyloid pathology, cortical axonal degeneration, and neurofibrillary tangle pathology, respectively. These have been validated as core biomarkers of AD pathophysiology (Frank et al., 2003; Hampel et al., 2008). Several studies have demonstrated that these core biomarkers differentiate AD patients from healthy controls, as well as from patients with other neurodegenerative diseases, including Parkinson's disease and frontotemporal dementia

Biomarkers for Alzheimer's disease

(Blennow et al., 2010). Moreover, these three biomarkers distinguish people with MCI due to AD from those with MCI due to non-AD causes, with positive and negative predictive values of above 90% (Hansson et al., 2006; Visser et al., 2009), as well as showing dynamic alterations during preclinical disease stages (Fagan et al., 2014).

The potential diagnostic utility of CSF A β 1-42, t-tau, and p-tau underpins ongoing efforts to standardize biomarker measurements into clinical routine tests where different methodologies are calibrated across clinical settings with high precision. Standardization initiatives include the Global Biomarkers Standardization Consortium (GBSC), Materials and Methods Working Groups (http://www.alz.org/research/funding/global_biomarker_CSF_materials.asp) within the Alzheimer's Association (AA), and the International Federation of Clinical Chemistry and Laboratory Medicine Working Group for CSF Proteins (IFCC-WG-CSF) (<http://www.ifcc.org/ifcc-scientific-division/sd-working-groups/csf-proteins-wg-csf/>). The main aims are to standardize both pre-analytical and laboratory procedures and to harmonize levels between assay formats (Carrillo et al., 2013). Between-laboratory and longitudinal variations are supervised, following the Alzheimer's Association Quality Control Program for CSF biomarkers (Mattsson et al., 2011, 2012). These efforts have encouraged biotech companies to validate upgraded versions of assays and develop CSF biomarker assays on fully automated laboratory analysers. It is thereby hoped that these activities will establish uniform and globally recognized cut-off values for AD CSF biomarkers.

Shifting the focus to developing blood-based biomarkers for Alzheimer's disease

While CSF A β 1-42, t-tau, and p-tau are the most extensively validated biomarkers for the diagnosis of AD, their measurement requires lumbar puncture, which is an invasive procedure potentially associated with adverse effects (e.g. post-procedural headache) and patient discomfort (de Almeida et al., 2011). Although such shortcomings are uncommon in experienced memory clinics (Zetterberg et al., 2010), CSF sampling remains unpopular with clinicians and the public, also due to the necessity of a day-hospital setting. Imaging biomarkers present at least a potential alternative. Such investigations are based on the use of specific radiolabelled ligands capable of binding to fibrillar A β deposits in the brain such as Pittsburgh Compound B (PiB) (Herholz and Ebmeier, 2011). Positron emission tomography with PiB (PiB-PET) has been used to monitor the variations over time in cerebral A β plaque burden, and a significant positive association has been found between PiB binding and histological A β plaque load measured in post-mortem studies (Ikonomovic et al., 2008). Unfortunately, a major limitation of PiB-PET lies in the fact that PiB is labelled with the ¹¹C isotope, which is characterized by an extremely short half-life (approximately 20 minutes). PiB-PET imaging and other more recent radiotracers are therefore costly, time-consuming,

Biomarkers for Alzheimer's disease

and unsuitable for routine clinical practice (Klunk and Mathis, 2008; Hampel et al., 2018b).

Because the use of CSF and imaging biomarkers of AD remains chiefly limited to academic research and specialist clinical centres, recent research efforts have focused on identifying and validating potential blood-based biomarkers (Lista et al., 2013b). Importantly, blood collection through venepuncture is less invasive than lumbar puncture. In addition, blood-brain barrier (BBB) disruption, which occurs throughout AD course, may increase the bidirectional exchange of proteins between blood and the CSF (Zipser et al., 2007), potentially providing stage- or endophenotype-specific diagnostic information. Blood-based biomarkers have the potential to be routinely performed both in a primary care setting and in the community, and repeated blood sampling is feasible, even in elderly and frail patients (Thambisetty and Lovestone, 2010). Blood-based AD biomarkers are therefore of increasing interest because of their potential to provide a largely accessible, non-invasive, inexpensive, and easy-to-implement means of supporting diagnosis, treatment stratification, and outcome monitoring (Lista et al., 2013b).

A number of different biomolecules (e.g. proteins, nucleic acids, lipids, and other metabolic products) can be quantified in serum, plasma, or blood cellular compartments (i.e. red blood cells, leucocytes, and platelets). Owing to the diversity of blood-based biological sources of AD biomarkers, they encompass a broad spectrum of different protein concentrations, protein isoforms, and post-translational modifications, as well as numerous metabolic products (e.g. lipids and carbohydrates) and nucleic acids (Thambisetty and Lovestone, 2010). In this regard, microRNAs (miRNA) (a class of non-coding 22-nucleotide-long RNA molecules involved in post-transcriptional modulation of protein expression) (Ha and Kim, 2014) have been recently explored. A few studies have shown that miRNAs can differentiate between AD patients, MCI individuals, and cognitively healthy controls with modest accuracy; however, there are limitations in methodological heterogeneity and miRNA heterogeneity, and there is a need for standardization and validation (Wu et al., 2016). Recently, plasma neurally derived exosomes have been suggested as candidate biomarkers of early AD pathomechanistic alterations (Fiandaca et al., 2015; Goetzl et al., 2015, 2018). It has been reported that: (1) proteins contained in plasma neurally derived exosomes originate predominantly from cellular structures, in contrast with proteins in the CSF and the fluid phase of blood; and (2) protein profiles in plasma neurally derived exosomes in steady-state conditions are thought to reflect those in CNS neurons. For instance, in the case of brain A β accumulation, there is an excellent correlation between levels of brain A β accumulation, assessed through both amyloid PET scans and plasma neurally derived exosomes.

Because of its complexity and multiple interactions with different tissues and organs, blood represents an ideal biological matrix to investigate a large spectrum of molecular networks and pathophysiological

Biomarkers for Alzheimer's disease

mechanisms (Issaq, Xiao and Veenstra 2007). However, distinct from the CSF and other body fluids, it must be considered a multifaceted tissue (Thambisetty and Lovestone, 2010).

Neuroproteomics for biomarker discovery

Blood (plasma/serum) has been undoubtedly the most important subject of proteomic studies in the last 15–20 years. The proteome of an organism, as the complement of its genome, is very dynamic and is subject to variations according to cell nature and functional state. Alterations in protein composition are observed in bodily fluids, including blood, and reproduce direct modifications resulting from pathophysiological processes and external stimuli (Apweiler et al., 2009). Proteomics allows the system-wide description of all the proteins in an organism, based on sequence, localization, abundance, post-translational modifications, and biomolecular interactions (Beck et al., 2011). Because of the complexity of the cellular proteome and the low abundance of many physiologically relevant proteins, proteomics presents challenges. As the molecular alterations characterizing the AD brain are all interconnected, a comprehensive exploratory systemic approach is essential to elucidate the pathogenesis and pathophysiology of AD at a complex network level (Kaddurah-Daouk et al., 2013; Noorbakhsh et al., 2009). In this regard, a clear depiction of the significance and role of proteomics in AD pathophysiology is of key relevance.

Use of neuroproteomics and systems biology to understand Alzheimer's disease pathophysiology

As with other neurodegenerative diseases, AD is not limited to the CNS but should be considered as a complex multisystem disease (Lausted et al., 2014). Besides cognitive decline, AD patients may show systemic manifestations (Morris et al., 2014) which can only, in part, be explained by the continuing functional and behavioural impairment associated with neurodegeneration (Rivière et al., 2002). In this respect, the complex and multifaceted manifestations of AD are not limited to the neurological domain, and a systems approach is needed to explore this neurodegenerative disease (Lausted et al., 2014). Moreover, AD is per se a heterogeneous disease in terms of genetic susceptibility, neuropathological underpinnings, and clinical features (e.g. age at onset, severity and type of behavioural and clinical symptoms) (Hampel et al., 2012). Traditionally, the molecular bases of AD pathophysiology have been explored using an a priori approach based on biological candidates informed by current pathogenetic hypotheses.

However, this reductionist approach has failed to capture the complexity of the disease and has not resulted in major therapeutic advances. To circumvent this issue, the unbiased exploratory paradigm of *systems biology*—also referred to as network biology or integrative biology (Castrillo et al., 2018)—has been proposed. This new integrative interdisciplinary framework is chiefly based on the use of multimodal

Biomarkers for Alzheimer's disease

high-throughput technological platforms that enable complex networks of biological pathways to be examined simultaneously; the approach can be applied at different system levels, from subcellular compartments to the entire organism (Lista et al., 2016). The key prerequisite to systems biology is an 'all-inclusive' examination and validation of biological data, followed by a thorough statistical analysis, from which new, unbiased pathophysiological hypotheses may stem (Castrillo et al., 2018), based on high-throughput laboratory methods that allow the simultaneous study of a large number of 'omics' markers. Of these, proteomics has been used increasingly in AD.

Proteomics can be defined as a large-scale approach to analyse the identities, quantities, structures, dynamics, and functions of proteins in biological samples (Shevchenko et al., 2015). Besides informing new pathophysiological hypotheses, proteomics biomarkers have been shown to have both diagnostic and prognostic significance (Marko-Varga and Fehniger, 2004). Neuroproteomics is a specific subfield aimed at the molecular and phenotypic analysis of proteins in the CNS and/or CNS-related diseases (Kim et al., 2004), and clinical neuroproteomics seeks to clarify potential diagnostic, prognostic, and monitoring implications (Shevchenko et al., 2015). In 2001, the Human Proteome Organization (HUPO, available at <http://www.hupo.org/>) was launched, with the broad goal of promoting proteomics and its applications in basic research and the clinical field through international cooperation and research collaborations. Under the patronage of HUPO, the HUPO Brain Proteome Project (HUPO BPP, available at <http://www.hbpp.org/>) has been specifically established, with the goal of discovering diagnostic and prognostic biomarkers associated with neurodegeneration and CNS ageing. The ultimate purpose of this initiative is to obtain a better understanding of these conditions and to open new avenues for the development of innovative biomarkers and molecular drug targets.

Overview of the technologies needed for neuroproteomic examination

A major challenge faced by neuroproteomics is the high degree of complexity and heterogeneity of the CNS, which is expressed at both cellular and subcellular levels. This issue may be partially overcome by an optimized and standardized pre-analytical phase, which is a key prerequisite for the identification of clinically useful biomarkers in biological fluids such as blood (plasma/serum). The field of biomarker discovery in neuroproteomics consists of the identification and characterization of proteins and peptides, as well as the detection of significant alterations in their relative/absolute amount/concentration across different pathological conditions (Lista et al., 2017).

Over the last three decades, several technological platforms have been developed to apply the principles of neuroproteomics in biological samples collected from patients with different neurodegenerative diseases (for a detailed methodological review, see Shevchenko et al., 2015). Specifically, currently proteomic approaches are based on the

following sequence: separation, enzymatic digestion (frequently coupled with isotopic labelling), and mass spectrometric analysis (Aebersold and Mann, 2003). In this regard, mass spectrometry is considered the gold standard for the systematic analysis of proteins—from their identification and quantification to the characterization of post-translational modifications and protein-protein interactions. Apart from identification, a protein may truly serve as a candidate biomarker only when it shows specific quantitative or qualitative variations in a specific disease state, as compared with healthy controls (Hampel et al., 2012); in this respect, quantitative neuroproteomics is a research field that aims to quantify the relative and absolute abundance of proteins in two or more conditions (e.g. CNS disease conditions versus apparently healthy individuals or patients undergoing a specific treatment for a CNS disease versus placebo arm). High-throughput platforms and novel high-performance mass spectrometers are currently providing new impetus for this promising research field, and laboratories with up-to-date spectrometry facilities are technically able to characterize, identify, and quantify hundreds of proteins on a daily basis with high accuracy (Castrillo et al., 2018; Lista et al., 2017). An interesting example of ground-breaking technology in the field is the enzyme-linked immuno-mass spectrometric assay (ELIMSA), which combines the sensitivity of mass spectrometry with the high specificity and enzymatic amplification of conventional enzyme-linked immunosorbent assay (ELISA). The key idea of ELIMSA is that the reporter enzymes—horseradish peroxidase or alkaline phosphatase—yield small molecular products that are easily ionizable, making them measurable by ultra-sensitive mass spectrometry and allowing precise quantification of small molecules present at picomolar (10⁻¹² mol) to femtomolar (10⁻¹⁵ mol) levels. This potentially allows measurement over most of the known range of human protein concentrations (Florentinus-Mefailoski and Marshall, 2016; Florentinus-Mefailoski et al., 2014).

It should be emphasized that one of the central benefits of employing proteomics to explore AD and other neurodegenerative diseases is the simultaneous characterization and quantification of hundreds, or even thousands, of proteins (Mann et al., 2013). Basically, proteomic approaches can be divided into explorative and targeted methods. The former makes use of technological platforms with clinical samples to identify specific biomarkers and, consequently, typical pathophysiological molecular signatures that can help fully elucidate the mechanisms responsible for disease progression. The latter is centred on scrutinizing one protein (and its altered forms) or a precise group of proteins. In this context, proteomic methods, coupled with immunopurification and immunoprecipitation protocols, are recurrently used (Brinkmalm et al., 2015).

Biomarkers for Alzheimer's disease

The 'multiplex' approach era

Given that the use of individual blood biomarkers has been unsuccessful in defining disease pathophysiology, progression, or diagnosis, a holistic approach is required to elucidate a molecular profile for AD diagnosis. It is therefore critical to understand links between single biomarkers, rather than the outdated approach of studying concentrations of individual candidate biomarkers one at a time. Several analyses have generated sets of biomarkers to differentiate between healthy individuals and AD patients, and assessed a large panel of proteins/peptides in various combinations to yield elevated sensitivity and specificity (Gupta et al., 2013).

Monitoring complex and multifactorial diseases, including AD, involves a large number of analytes, so that optimized treatment strategies are developed (Tighe et al., 2015). Accordingly, integrating novel biomarkers into 'multiplex' immunoassay platforms allows the simultaneous identification and measurement of multiple analytes in a single patient sample. This reduces assay costs, sample volume, and time taken, while simultaneously allowing monitoring of disease progression and outcome prediction, including adverse drug reactions (Tighe et al., 2015). In addition, thanks to the advent of proteomics, multiplex immunoassays can efficiently manage the large amount of data generated, thus accelerating precision medicine and personalized therapies through molecular signatures and biomarker profiles (Hampel et al., 2017, 2018a, b). These, in turn, enable increased diagnostic resolution between strictly associated disease phenotypes, and improved disease monitoring and treatment (Tighe et al., 2015).

At present, several high-content protein microarrays for comparative profiling are commercially available. Nevertheless, only a relatively low number has been certified for *in vitro* diagnostics (IVD) applications. Furthermore, although the capacities of the multiplexing systems are supposed to be elevated, commercially available platforms are only able to utilize a fraction of this potential and seldom handle >20 single analytes (Bastarache et al., 2014; Chowdhury et al., 2009). Notably, suitable algorithms and statistical tools need to be developed and constantly upgraded for managing the massive amount of data generated (millions of assay results per day). It seems likely that currently employed singleplex assays will disappear, in favour of multiplexing immunoassay-based alternatives that offer advantages in terms of assay costs and time. Furthermore, multiplexing provides more complete analysis for performing differential diagnoses and monitoring of therapeutic interventions (Tighe et al., 2015).

Blood (plasma/serum) biomarkers for Alzheimer's disease

Biomarkers for Alzheimer's disease

Blood-based markers of amyloid pathophysiology

Several efforts have been focused on discovering and developing diagnostic biomarkers for AD in peripheral blood (Lista et al., 2013b; Snyder et al., 2014).

It is well documented that cerebral A β enters the peripheral circulation through the BBB. Several molecular transporters—including, for instance, the receptor for advanced glycation end products (RAGE) and the low-density lipoprotein receptor-related protein (LRP)—regulate the rate of efflux from the CNS into the plasma. It is well acknowledged that the peripheral (i.e. blood) concentration of A β peptides reflects the brain deposition of A β in both healthy and pathophysiological conditions (Roberts et al., 2014).

The dynamics of plasma have a time-dependent fashion similar to that of the CSF; indeed, longitudinal studies have reported that plasma A β alterations show a peak during the early stages of AD and a plateau, or even a slight decrease, during disease progression (Mayeux et al., 2003).

A β monomers are the most investigated surrogate markers of AD-related brain A β accumulation in blood (plasma/serum), both as cell-bound and as cell-free circulating molecules. However, the extent to which blood A β concentrations accurately reflect the occurrence of extracellular aggregation and accumulation of A β is not yet fully elucidated (Wang et al., 2017). Studies aimed at comparing the diagnostic performance of plasma A β with other measures of brain A β deposition have increasingly been implemented to identify individuals at risk of AD, for which a non-invasive, accessible, and less expensive investigation might be more suitable, especially in contexts-of-use involving large-scale populations and several time series.

To date, only one meta-analysis has been carried out to determine whether plasma A β concentrations may predict the development of dementia (either of AD *spectrum* or not) and MCI. Koyama and colleagues (2012) identified 13 studies exploring the accuracy (combination of sensitivity and specificity) of plasma A β_{1-42} and A β_{1-42} /A β_{1-40} ratio in predicting dementia, including AD and cognitive decline (Koyama et al., 2012). The authors showed that a reduction in plasma A β_{1-42} /A β_{1-40} ratio is strongly associated with an overall higher risk ratio for developing AD. Thus, besides a robust biological rationale, plasma A β_{1-42} /A β_{1-40} (in some cases A β_{1-40} /A β_{1-42}) ratio has been reported to have a relevant clinical significance as a reliable predictor of A β cerebral deposition (Koyama et al., 2012). Indeed, in the last 5 years, many studies have shown a good diagnostic accuracy of plasma A β_{1-42} , and even more so A β_{1-42} /A β_{1-40} , with a widely accepted overlap in sensitivity and specificity between the CSF and plasma A β markers and between the latter and A β PET imaging (Janelidze et al., 2016; Ovod et al., 2017; Teunissen et al., 2018).

Biomarkers for Alzheimer's disease

In particular, a growing body of analyses has assessed the strength of the association between plasma A β and A β PET imaging (rather than the CSF) using both a dichotomized status (positivity or negativity to A β) and quantitative measures such as the standardized uptake value ratio (SUVR). Interestingly, Nakamura and colleagues reported that the A β_{1-40} /A β_{1-42} ratio presented an accuracy of approximately 90% when using A β PET imaging as a gold standard in two pooled cohorts (either combined or alone) of cognitively normal, prodromal, and dementia-stage AD participants (Nakamura et al., 2018). In a study conducted in the Australian Imaging, Biomarker and Lifestyle (AIBL) Flagship Study cohort, Fandos and colleagues (2017) showed that the total protein A β_{1-42} /A β_{1-40} ratio reached 81% positive predictive value for high cortical A β burden (Fandos et al., 2017). Further longitudinal studies are needed since, although the overall scenario is encouraging, a substantial amount of the literature is controversial. As a result, standardization of plasma A β peptides both for clinical and pharmacological use, e.g. for clinical trial outcome measures, has not yet achieved a definitive approval, and international consensus is still missing on normal cut-off values for plasma (and even CSF) A β peptides. Despite scientific agreement on A β as a biofluid surrogate marker of cerebral pathophysiological mechanisms, the current lack of thresholds prevents plasma A β from attaining a definitive standardization for clinical practice and pharmacological trials.

Discrepancies emerging from plasma studies are the same as for the CSF and might be attributable to the high degree of between-site and intra-site variability, as well as to analytical and methodological differences such as the assay utilized and its detection limit. Furthermore, most of the investigations lack a reliable healthy control group, since the main inclusion and exclusion criteria are represented by clinical measures, and not by biological signatures of AD, such as imaging evidence of brain A β accumulation. In addition, several clinical and demographic confounding factors are not considered—namely, participants' age and sex, medical comorbidities and concomitant drugs, lifestyle (i.e. diet, physical activity, and sleep-wake cycle), and habits (i.e. caffeine, tobacco, and alcohol intake).

Whether plasma A β can be a predictor of cognitive decline, including AD, needs to be better investigated. For instance, plasma A β concentrations reported from the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort exhibited a very low correspondence to clinical state (Toledo et al., 2011). However, it is important to highlight that such findings may not be related per se to the assessment of plasma A β since the overall pathophysiological brain A β accumulation and its progress over time have not been identified yet as direct and unequivocal predictors of future cognitive decline and disease progression.

Besides the most investigated A β monomeric species (A β_{1-42} and A β_{1-40}), other A β monomers are potentially useful. Interestingly, the A β_{1-17} monomer has exhibited a good predictive value for brain A β deposition. Thus, A β_{1-17} is a promising candidate as a diagnostic biomarker of AD. In

Biomarkers for Alzheimer's disease

one study, the ratio of free to cell-bound $A\beta_{1-17}$ in blood distinguished between healthy controls and people with MCI or mild AD, with high rates of diagnostic performance (Perez-Grijalba et al., 2015). Other novel $A\beta$ isoforms are of potential usefulness as target engagement biomarkers and for monitoring the biochemical effect of an experimental treatment. For instance, in a clinical trial of the γ -secretase inhibitor semagacestat (LY450139), an increase in CSF concentrations of short $A\beta$ isoforms was found, showing a dose-dependent fashion. In the same study, there was no significant effect on plasma $A\beta$ or CSF $A\beta_{1-42}$ or $A\beta_{1-40}$ (Portelius et al., 2010). Several platforms have been developed to assess blood (plasma) $A\beta$ concentrations. In this regard, Araclon Biotech Ltd (Zaragoza, Spain) developed two ELISA sandwich colorimetric tests to assess plasma $A\beta_{1-42}$ and $A\beta_{1-40}$, in order to measure—directly and indirectly (i.e. through calculation)—biomarkers related to an increased probability to develop prodromal AD (Perez-Grijalba et al., 2013, 2016). Other ELISA-based immunoassays and novel methodologies are under development. An emergent methodology is represented by immunoprecipitation-mass spectrometry that was used in a recent analysis by Nakamura and colleagues (Nakamura et al., 2018).

This significant heterogeneity highlights the need for further longitudinal investigations aimed at assessing whether plasma $A\beta$ may be introduced into clinical practice as a biomarker (perhaps even preclinical) of $A\beta$ pathophysiology. Of note, the different analytic approaches have different costs in terms of devices, operator expertise, and data-processing time.

The biological mechanisms underlying the dynamic changes of $A\beta$ metabolism arise from a complex cross-talk among neurons, immune cells, BBB components, and peripheral tissue. Indeed, it has already been shown that $A\beta$ metabolism undergoes significant physiological changes over time, i.e. both in ageing and diseases (Wang et al., 2017). Thus, another key point along the road to standardization of plasma $A\beta$ for clinical practice and pharmacological trials will be to accomplish a full understanding of the dynamics regulating $A\beta$ metabolism at a system level: rates of active transportation across the BBB and glymphatic systems, brain outflow kinetics, and rates of vascular, immune, and peripheral tissue turnover (i.e. liver and kidney). This will provide researchers with a minimally invasive, simple, and versatile blood test, useful for stratification of risk for preventive interventions and biological screening for clinical trial protocol inclusion, as well as routine diagnostic, and potentially even prognostic, work-up.

β -site amyloid precursor protein-cleaving enzyme 1

The APP cleaving enzyme—called β -site APP-cleaving enzyme 1 (BACE1)—is an aspartyl protease playing a key role in modulating $A\beta$ processing. It cleaves APP in its ectodomain, generating the amino-(N) terminus of $A\beta$ and the membrane-bound carboxyl-terminal fragment C99 from which γ -secretase will generate neurotoxic $A\beta$ monomers and oligomers. BACE1 is assumed to have a pivotal role in regulating presynaptic activities.

Biomarkers for Alzheimer's disease

Besides leading to the production of toxic A β fragments, BACE1 overexpression (potentially even blockade) may result in dystrophic axonal neurites, with subsequent loss of plasticity. Thus, BACE1 is a key candidate drug target for AD, even during the preclinical stages. BACE1 inhibitors have been reported to have therapeutic and disease-modifying effects in AD animal models, by slowing down progressive cerebral A β deposition (Hampel and Shen, 2009). However, despite a strong rationale, clinical drug development trials targeting BACE1 in humans have failed to accomplish primary end points. A possible explanation could be the current lack of fluid biomarkers for target engagement (expression and activity of the enzyme). Data on CSF BACE1 concentrations in early stages of AD are becoming increasingly robust, as previously reviewed (Hampel and Shen, 2009; Hampel et al., 2010b).

Since BACE1 potentially appears to be an excellent biomarker for several contexts-of-use, as it directly reflects a pathophysiological process, its validation in plasma would represent a unique possibility to peripherally access AD. So far, one study has investigated the role of peripheral BACE1 expression and activity in healthy controls, people with MCI (either converters or non-converters to subsequent AD), and patients with AD (Shen et al., 2018). The authors found that MCI converters and AD patients had significantly higher BACE1 activity and expression, compared to healthy controls and MCI non-converters, with a gradient towards AD. Compared with healthy controls, BACE1 activity was increased in MCI non-converters, MCI converters, and AD patients. A sex effect on BACE1 activity was also observed since women exhibited higher activity and expression, compared to men, in MCI non-converters, MCI converters, and AD patients. These data are in line with those from AD post-mortem analyses (Nyarko et al., 2018) and should be considered in upcoming studies on this marker.

Longitudinal investigations, including larger sample size and time series, are required to assess whether increased plasma BACE1 concentrations and activity are a predictive surrogate outcome of cognitive impairment and neurodegeneration in asymptomatic individuals at risk of AD. This, in turn, will allow the depiction of different longitudinal molecular trajectories.

Tau protein

Tau is a microtubule-associated protein essential for the whole cellular cytoskeletal stabilization. N-terminal truncation and hyperphosphorylation of tau has a detrimental effect on the physiological activity of the protein, as well as on neuronal homeostasis. Consequently, the progressive accumulation of aberrant phosphorylated strains leads to widespread deposition of neurofibrillary tangles and threads (i.e. neurofibrillary pathology), which cause loss of dendritic spine density and, ultimately, neuronal cell death (Braak and Del Tredici, 2015). Current diagnostic research criteria for AD include CSF t-tau and hyperphosphorylated tau at Thr181 site (p-tau₁₈₁) as established markers

Biomarkers for Alzheimer's disease

reflecting neurodegeneration and neurofibrillary pathology, respectively (Dubois et al., 2014).

A novel ultra-sensitive assay for tau protein in peripheral blood has recently been developed based on digital array technology and consisting of previously validated digital standard ELISAs transferred onto the single molecule array Simoa™ platform. This methodology significantly improves analytical sensitivity and allows for the ultra-sensitive (sub-femtomolar range) and accurate detection of tau in plasma (Zetterberg et al., 2013). Of note, no assay has been currently validated for the plasma measurement of hyperphosphorylated tau strains. Thus, given that peripheral assessment of a surrogate marker of neurofibrillary pathology (i.e. neurofibrillary tangles) is not possible, 'peripheral' screening, diagnosis, and risk stratification of AD-related pathophysiological mechanisms remain limited to brain A β accumulation.

Zetterberg and colleagues (2013) were the first to assess plasma t-tau concentrations in a pooled cohort of clinically identified healthy control, MCI, and AD participants, and they reported higher concentrations of plasma t-tau in AD, compared to controls and MCI (Zetterberg et al., 2013). Notably, participants with MCI converting at follow-up did not show significant differences in terms of t-tau values, when compared with non-converter MCI patients and healthy controls, raising the question of whether plasma t-tau is appropriate as an AD diagnostic/prognostic indicator.

Mattsson and colleagues cross-sectionally scrutinized the diagnostic value of plasma t-tau within the ADNI and BioFinder cohorts and found, in the former cohort, more elevated plasma t-tau concentrations in AD dementia patients, compared to healthy controls and MCI patients. They also found, in the ADNI cohort, that higher plasma t-tau concentrations were associated with worse cognition, lower CSF A β ₁₋₄₂, higher brain atrophy, and higher brain hypometabolism. In addition, in the BioFinder cohort, all individuals showed a weak association between plasma t-tau concentrations and AD CSF core biomarkers, including CSF t-tau and p-tau₁₈₁. Therefore, despite group-level differences, the data did not substantiate plasma t-tau as an AD diagnostic biomarker but suggested its potential role as a predictor of neurodegeneration and clinical worsening (Mattsson et al., 2016).

A recent population-based cohort study explored the utility of plasma t-tau as a prognostic marker for cognitive decline and dementia without reaching a firm conclusion. Elevated plasma t-tau concentrations were associated with the degree of cognitive impairment; however, in line with previous studies, the results showed heterogeneity according to clinical status (healthy controls, MCI, AD) and duration of clinical follow-up (Mielke et al., 2017).

Biomarkers for Alzheimer's disease

In a recent multimodal study, Deters and colleagues reported, in a pooled cohort of healthy controls and people with MCI and AD, that plasma t-tau correlated with the rate of overall and regional grey matter density, irrespective of the clinical condition, thus confirming that plasma t-tau may reflect brain neuronal loss, regardless of upstream pathophysiological processes (Deters et al., 2017). Indeed traumatic brain injury, Creutzfeldt-Jakob disease, stroke, and other neurodegenerative disorders (non-AD) show different patterns of increased plasma t-tau concentrations (according to the pathophysiological process underlying the disease), when compared with the healthy condition (Zetterberg, 2017).

In summary, plasma t-tau concentrations are significantly increased only in the late prodromal or dementia stage of AD, thus substantially restricting the utility of this marker for diagnostic purposes during the preclinical stages. However, some studies have shown a correlation between plasma t-tau and neurodegeneration markers, thus suggesting to further explore whether plasma t-tau may serve as a prognostic indicator. On the flip side, many studies have indicated there is no significant correlation between plasma t-tau and CSF t-tau—an established biomarker of AD-related neurodegeneration. This suggests that peripheral metabolism of t-tau may undergo changes that are irrespective of the CNS processing and clearance of the protein, limiting the potential of plasma t-tau as a marker of AD.

Regarding p-tau₁₈₁, a semi-sensitive assay for tau hyperphosphorylated at Thr181 (similar to the most employed CSF test) with electrochemiluminescence detection has been developed (Mielke et al., 2018). Using this assay, plasma p-tau₁₈₁ concentration was higher in AD dementia patients than in controls, and moreover, plasma p-tau₁₈₁ concentration was associated with global SUVRs of both Aβ- and tau-PET. A very recent post-mortem study (Park et al., 2019) demonstrated that plasma tau-related biomarkers (both total t-tau and p-tau₁₈₁) are significantly correlated with brain tauopathy (i.e. tau Braak stages) and predict tau-PET status (either positive or negative).

Blood-based molecular profiles for Alzheimer's disease

Various studies have investigated the existence of a definitive molecular profile, i.e. a specific set of blood (plasma/serum) proteins/peptides of diagnostic usefulness for AD. Some relevant examples are summarized here.

- One of the most significant analyses was performed by Ray and colleagues (2007), who exploited protein array technology (cytokine antibody arrays) to scrutinize 120 secreted cell-signalling proteins in plasma samples of AD patients and controls without dementia. Notably, a set of 18 signalling plasma proteins was able to discriminate AD from control individuals, with nearly 90% accuracy, and identified MCI individuals converting to AD within 2 years, with 81% accuracy

(Ray et al., 2007). Biological examination of the 18 selected plasma proteins indicated: (1) a global decrease in the number of factors related to haematopoiesis and inflammation; and (2) deficiencies associated with neuroprotection, neurotrophism, phagocytosis, and energy homeostasis. The 18 analytes were represented by cytokines, chemokines, and growth factors, all belonging to a molecular network by which cells communicate each other. This was referred to as the 'cellular communicome'. Proteome Sciences plc developed a quantitative mass spectrometry-based assay to define a panel of nine candidate plasma proteins (O'Brien et al., 2008). Interestingly, Soares and colleagues (2009) verified the reproducibility of a subset of the original set of 18 markers previously characterized by Ray and colleagues (2007) using the Luminex xMAP® technology (Luminex Corporation, Austin, TX, USA) (Ray et al., 2007). The diagnostic accuracy using the subset was 61%. However, a subsequent multivariate analysis of an 89-analyte panel provided a diagnostic accuracy of 70%, suggesting a potentially useful plasma-based AD molecular signature as a screening tool (Soares et al., 2009).

- O'Bryant and colleagues (2010) established an algorithm based on a set of 30 serum proteins, generating a risk score with 80% sensitivity and 91% specificity for detecting AD (O'Bryant et al., 2010). This group of proteins—encompassing several inflammatory and vascular markers—showed an elevated level of diagnostic accuracy in AD, similar to that of CSF studies; moreover, this algorithm correlated with neuropsychological test performance when tested in combination with clinical and demographic data (O'Bryant et al., 2011).

- Another blood-based biomarker panel, based on multivariate data analysis, discovered three biomarkers—cortisol, von Willebrand factor, and oxidized low-density lipoprotein antibodies—that differentiated early AD patients from cognitively healthy controls, with over 80% accuracy (Laske et al., 2011).

- A gel-based proteomics approach performed in a cohort of AD, MCI, and cognitively normal individuals indicated a set of five analytes involved in complement activation and coagulation—component C3, component C3a, complement factor-I, γ -fibrinogen, and α -1-microglobulin—that, in conjunction with age and sex, accounted for >35% of variance of whole brain volume in AD patients (Thambisetty et al., 2011).

- An analysis from the Biomarkers Consortium Alzheimer's Disease Plasma Proteomics Project assessed a set of plasma analytes via a multi-analyte profile (MAP) panel (Human Discovery MAP version 1.0; Myriad RBM, Austin, TX, USA) and the Luminex® 100™ system (Luminex Corporation, Austin, TX, USA). This panel of plasma proteins showed some overlap with the CSF and an association with the *APOE* ϵ 4 allele. Specifically, increased concentrations of eotaxin 3, pancreatic polypeptide, and N-terminal protein B-type brain natriuretic peptide were reported in AD patients and MCI individuals, thus corroborating similar alterations found in CSF samples in AD and MCI. Increased

Biomarkers for Alzheimer's disease

concentrations of tenascin C and decreased concentrations of immunoglobulin M (IgM) and apolipoprotein E (APOE) were also detected (Soares et al., 2012).

- A multivariate analysis of 146 plasma analytes in a cohort of AD patients, MCI individuals, and cognitively normal older individuals from the ADNI database indicated four different molecular signatures discriminating AD from controls (sensitivity and specificity between 74% and 85%). The four molecular profiles shared five biomarkers: apolipoprotein A-II, APOE, serum glutamic oxaloacetic transaminase, α -1-microglobulin, and brain natriuretic peptide. However, none of the analytes predicted progression from MCI to AD during a 12- and 24-month follow-up (Llano et al., 2013).
- A list of 21 blood proteomics-based analyses of AD was revised and led to 163 candidate analytes. Interestingly, four biomarkers linked to AD-related phenotypes were consistently found in five independent cohorts: α -1-antitrypsin, α -2-macroglobulin, APOE, and complement C3. A large-scale replication study selecting 94 plasma analytes out of the 163 candidates was performed in 677 participants from the AddNeuroMed (ANM) and the Alzheimer's Research UK/Maudsley BRC Dementia Case Registry at King's Health Partners (ARUK/DCR) cohorts using the SOMAscan[®] Proteomic Assay (SomaLogic Inc., Boulder, CO, USA). Nine out of the 94 candidates were associated with AD-related phenotypes and showed sufficiently satisfactory replication to be included in additional analyses. This finding indicates that AD pathophysiology influences the blood proteome with a certain degree of consistency (Kiddle et al., 2014).
- An analysis conducted in three multicentre cohorts of AD patients, MCI individuals, and cognitively healthy older people used the Luminex xMAP[®] technology (Luminex Corporation, Austin, TX, USA) to validate a prior set of plasma biomarkers associated with AD. Sixteen analytes correlated with cognitive decline and disease severity. In particular, MCI individuals showed the most significant associations, with a set of ten plasma proteins predicting progression to AD (sensitivity 85%, specificity 88%, and accuracy 87%). These biomarkers might be potentially useful to select patients for clinical trials and assess individuals with subjective memory complaints (Hye et al., 2014).
- A study using the iTRAQ-labelled proteomics technique reported a set of plasma analytes associated with early pathophysiology by examining their alterations at both asymptomatic and symptomatic stages of autosomal dominant AD. After comparing 81 proteins across asymptomatic and symptomatic mutation carriers, as well as related non-carriers, minor alterations were found at the asymptomatic stage versus the symptomatic stage, with plasma concentrations of seven and 16 proteins significantly changed in asymptomatic and symptomatic mutation carriers, respectively. The analytes were represented by complement components C3, C5, and C6, apolipoproteins A-I, A-IV, C-I, and M, histidine-rich glycoprotein,

Biomarkers for Alzheimer's disease

heparin co-factor II, and attractin, which play a role in inflammation, lipid metabolism, and vascular health. Further inspections are necessary to validate this molecular profile (Muenchhoff et al., 2016).

- A recent investigation inspected serum biomarkers in a Han Chinese population via an unbiased iTRAQ approach. After discovering 22 differentially expressed analytes, nine potential markers were further validated. In particular, for the first time, alterations in serum concentrations of zinc- α -2-glycoprotein, fibulin-1, platelet basic protein, thrombospondin-1, S100 calcium-binding protein A8, and S100 calcium-binding protein A9 were observed in AD patients, compared to healthy controls. Since the data emphasized the role of A β metabolism and blood coagulation in AD pathophysiology, proteins associated with these two processes might represent peripheral blood indicators for AD (Shen et al., 2017).

Since it is clear that blood proteins are subject to variations in AD individuals, a blood biomarker for AD diagnosis should be plausible, particularly since promising biomarkers for AD diagnosis—A β peptides and proteins linked to inflammatory mechanisms—are not brain-specific but are commonly detected in the periphery and may undergo alterations following the progression of AD (Lista et al., 2013a,b).

Presently, however, there are no proteins (either transcripts or metabolites) in blood that have been acceptably replicated as AD biomarkers. Moreover, based on the literature, it seems arguable that a single plasma/serum marker alone will not be sufficient for diagnostic purposes. Instead, developing a combination of biological markers—i.e. a set of proteins combined with other blood-based, or even non-blood-based, markers (as neuroimaging markers)—appears as the most reasonable diagnostic strategy. However, it is still uncertain whether a unique molecular profile for AD will be identified that will satisfy multiple purposes. Rather, it is expected that there will be different sets of biomarkers for: (1) supporting AD diagnosis; (2) predicting AD outcome or conversion from MCI; and (3) monitoring disease progression (Thambisetty and Lovestone, 2010). More technical questions, such as whether, for instance, it is better to use mass spectrometry, rather than antibody arrays or another methodological platform/approach, are relatively unimportant. What is really crucial is how to use the components of all these approaches in combination (Lovestone, 2014).

In conclusion, there is evidence suggesting that the scenarios for identifying and validating blood-derived markers for early diagnosis of AD and prognosis are encouraging (Henriksen et al., 2014). This is highlighted by the recent formation of the Blood-Based Biomarker Interest Group (BBBIG), a key international working group of leading AD scientists from academia and industry, aiming at establishing global standards and best practices for the appraisal of blood-based biomarkers. In addition, a Professional Interest Area focused on Blood-Based Biomarkers (BBB-PIA), as a part of the Alzheimer's Association's

Biomarkers for Alzheimer's disease

International Society to Advance Alzheimer's Research and Treatment (ISTAART), has been created to support the harmonization process of pre-analytical and analytical protocols and to emphasize the need for a biorepository of clinical reference samples, enabling not only assay harmonization, but also the assessment of clinical performance (Henriksen et al., 2014; Snyder et al., 2014). International collaborations between academia and industry are key to accelerate the development of blood-based biomarkers and to avoid the limitations/challenges of CSF and imaging. To this end, the Alzheimer's Association ISTAART and BBB-PIA will facilitate collaborative efforts to accelerate progress in the AD blood-based biomarkers field (Henriksen et al., 2014; Snyder et al., 2014).

Challenges in searching for blood protein biomarkers

Blood, on the one hand, represents an invaluable source of biomarkers but, on the other hand, is not without shortcomings, and the quest for blood-based protein biomarkers poses major challenges. One challenge is the high degree of peptide and protein diversity. In this regard, post-translational modifications, amino acid side chain modifications, and different cleavages of the polypeptide chains generate a number of different protein isoforms in the plasma/serum proteome (Anderson and Anderson, 2002). A second challenge is the high level of variation in the range of plasma/serum protein concentrations (encompassing 10^{11} – 10^{12} orders of magnitude, from mg/mL to pg/mL) (Anderson and Anderson, 2002). Thirdly, approximately ten of the high-abundance proteins (HAPs) represent roughly 90% of the total protein mass in human plasma/serum: albumin (which alone represents approximately 50% of all plasma/serum proteins), immunoglobulins, transferrin, fibrinogen, α -2 macroglobulin, α -1 antitrypsin, C3 complement factor, and haptoglobin (Lista et al., 2013a). Unfortunately, HAPs cannot be considered informative as disease biomarkers, so potential biomarkers have to be sought in the remaining 10% of proteins, which are a complex mixture of highly heterogeneous middle- and low-abundance proteins (LAPs). However, these potential biomarkers are 'masked' by the presence of HAPs and are sometimes referred to as the 'hidden proteome' (Boschetti et al., 2007) (Fig. 6.1). In general, disease biomarkers vary in concentrations from ng/mL to pg/mL (Burtis et al., 2001). As a result, separation or removal of HAPs is paramount to enable us to identify and quantify most protein species in a biological sample.

Biomarkers for Alzheimer's disease

Fig. 6.1

A significant portion of the total protein content in plasma and serum is comprised of just a few proteins. Given that the plasma/serum proteome should contain a rich, unexploited source of disease-specific diagnostic information, the analysis of such biological fluid is particularly important when considering clinical questions. Unfortunately, plasma and serum include a narrow population of different high-abundance proteins (HAP). The ten most abundant proteins represent approximately 90% of the total protein content in human plasma/serum; the 22 most abundant proteins are supposed to embrace about 99% of the total protein mass. As a result, the tens of thousands of other different proteins and peptides, that should encompass all possible biomarkers of diseases, result to be buried and hidden under such few predominant HAP. The 'hidden proteome' expression refers to the low- and very low-abundance proteins (LAP). They constitute less than 1% of the total protein content.

HAP, high-abundance proteins; LAP, low-abundance proteins; IgA Total, Immunoglobulin A Total; IgM Total, Immunoglobulin M Total; Apo A1, Apolipoprotein A1; Apo B, Apolipoprotein B.

Owing to the wide concentration range and the inherent complexity of proteins (compared with other biological molecules), current proteomic technologies are able to investigate only a fraction of all dynamic biomarker-relevant changes that occur under different pathophysiological conditions (Thambisetty and Lovestone, 2010). However, novel strategies have been introduced, such as the untargeted ModifiComb approach to the analysis of post-translational modifications (Savitski, Nielsen and Zubarev 2006) and the SpotLight approach to the analysis of the 'hidden proteome' in blood that includes a simple enrichment step for polyclonal immunoglobulin G (Lundstrom et al., 2017).

Biomarkers for Alzheimer's disease

Pre-analytical and analytical bias

There are many pre-analytical and analytical sources of bias for blood protein biomarkers that may affect their future clinical applicability, as well as current research use; they are summarized in Box 6.1. Pre-analytical variables may affect the quality of the samples under scrutiny and subsequent data quality and can be broadly distinguished into two categories: technical (originating from sample collection, processing, and storage) and biological (deriving from intrinsic features of the individuals from whom the sample is drawn, i.e. age, sex, ethnicity, and lifestyle) (Ferguson et al., 2007).

Box 6.1 Types of pre-analytical and analytical bias

Preanalytical bias, preceding the point of actual sample analysis, can be dichotomized into technical or biological.

Analytical bias arises from discrepancies concerning sample-processing procedures, i.e. how samples are investigated.

Pre-analytical bias

Technical variables

- Blood derivatives (plasma versus serum)
 - Plasma: incubation time preceding separation of plasma from blood cells
 - Serum: clotting procedures
 - Serum: clotting time prior to preparing serum
- Sample handling procedures
 - Plasma: nature of anticoagulant (heparin, EDTA, citrate)
 - Plasma: adequate filling of the tubes during collection
 - Plasma: platelet contamination and activation
 - Serum: peptides resulting from coagulation events
 - Serum: peptides resulting from enzymatic activities
 - Serum: release of peptides from the blood clot
- Sample collection mode
 - Preparation of blood collection site (avoiding haemolysis)
 - Site of venepuncture (median cubital vein)
 - Way of collecting samples
 - Position of the patient (standing, lying, sitting)
 - Tourniquet application and needle bore size

Biomarkers for Alzheimer's disease

- Venous occlusion time length
- Collection tubes
 - Spreading of substances released from collection tubes
 - Silicones
 - Polymeric surfactants (PVP, PEG)
 - Clot inhibitors or activators
 - Polymeric gels in serum separator tubes
 - Rubber stoppers and plastics covering tube walls
 - Adsorption of serum/plasma proteins to tube walls
 - Red-top tubes
 - Serum separator tubes
- Temperature
 - Temperature for collection and transport practices within and between facilities
 - Short-term storage temperature (hours/days)
 - Long-term storage temperature (months)
 - Number of freeze-thaw cycles
- Protease inhibitor addition
 - AEBSF

Biological variables

- Immutable factors
 - Age, gender, and ethnicity
 - Genetic polymorphisms
- Potentially modifiable factors
 - Lifestyle factors
 - Diet
 - Obesity
 - Alcohol consumption
 - Smoking
 - Physical activity

Biomarkers for Alzheimer's disease

Analytical bias

- Sample-processing procedures
 - Liquid-handling methods (manual or robotic)
 - Buffer composition and sample dilution
 - Depletion of HAPs
 - Centrifugal ultrafiltration
 - Solid-phase extraction
 - Organic solvent extraction
 - Enrichment of LAPs
- Peptide ligand libraries
 - Plasma/serum desalting
 - Fractionation
 - Electrophoresis
 - Liquid chromatography
- Experimental protocols
 - Sample pH
 - Dilution factors
 - Chemistry of arrays
 - Amount of sample loaded onto the array/plate
 - Position of the sample on the array/plate
 - Sample binding/washing/drying methods
 - Type of matrix used
 - Instrument settings
 - Mass spectra acquisition settings
 - Energy and number of laser shots
 - Environmental factors (temperature, humidity)

AEBSF, 4-(2-aminoethyl)-benzenesulfonyl fluoride; EDTA, ethylenediaminetetraacetic acid; HAP, high-abundance protein; LAP, low-abundance protein; PEG, polyethylene glycol; PVP, polyvinylpyrrolidone.

Biomarkers for Alzheimer's disease

Discrepancies in procedures used for sample processing are the main source of analytical bias. These factors can exert major effects not only on the outcomes of a biomarker discovery study, but also on the subsequent validation phase. Proteomic studies are not conducted on whole blood, but on plasma and/or serum. Plasma is the liquid portion of blood that suspends cells such as red blood cells, leucocytes, and platelets, and it may be isolated from whole blood by centrifugation at low speeds in the presence of an anticoagulant (Issaq et al., 2007). Serum is plasma with clotting factors (e.g. fibrinogen) removed, and therefore can be isolated by allowing blood to clot (without any anticoagulant) before centrifugation. During the coagulation process for serum preparation, the concentrations of some proteins in the sample are altered and also protein fragments are released by platelets and other cells. The absence of most fibrinogen content makes serum protein concentrations lower than those in plasma. Other proteins may also be removed as a result of specific or non-specific interactions occurring inside the fibrin clot (Issaq et al., 2007).

The issue of proper selection of the optimal specimen (i.e. plasma versus serum) for proteomic studies has been thoroughly discussed (Hanash, 2012; Lista et al., 2013b). In any case, standardization is expected to be difficult, owing to the large number of variables in need of systematic study (Tuck et al., 2009). Ideally both sample types—plasma and serum—should be collected and analysed simultaneously.

Towards a blood-based model for patient screening and precision medicine therapeutics

The great majority of biomarkers currently in use to confirm the clinical diagnosis of AD are biochemical markers measured in the CSF and/or imaging biomarkers (e.g. obtained from PET imaging scans). Because such markers fail fully to capture the marked heterogeneity of AD pathophysiology, future efforts should be tailored at developing and validating a multi-tiered, multi-marker model. However, a major challenge will be the identification of an early inexpensive marker that may be used to screen for preclinical AD in a primary care setting. When available, such a marker would be invaluable to identify specific subgroups of high-risk individuals in need of more expensive (e.g. PET imaging) or invasive (e.g. CSF sampling) second-level diagnostic modalities. Accordingly, imaging/CSF screening is presently unfeasible in a general population setting, because of high costs of brain imaging and/or ethical limitations to lumbar puncture. Simple, non-invasive screening tools are therefore eagerly awaited (O'Bryant et al., 2016). Ideally, a screening test for AD in a real-world, primary care setting should be: (1) blood-based (i.e. simple, scalable, and not invasive); and (2) able to identify people who should not undergo second-level diagnostic assessment (because of the large number of disease-positive individuals). Current epidemiological data indicate that approximately 12% of people aged >65 years may have AD (Alzheimer's Association, 2016). If we estimate that approximately 20% are affected by any neurodegenerative disease in this age group, then

Biomarkers for Alzheimer's disease

approximately 80% are disease-negative. A cost-effective multi-tiered approach therefore should initially be able to exclude the highest possible number of disease-negative people. This would require a 90% negative predictive value, regardless of the positive predictive value (which is 20% or less for primary care tools) (O'Bryant et al., 2017). A primary care screening modality should be an imperative as soon as disease-modifying therapies become available, since effective screening will result in a markedly increased number of high-risk individuals in the general population who will seek prevention or treatment of AD. In addition, the availability of disease-modifying drugs will undoubtedly require patients to test positive on blood screening tools for subsequent referral to second-level tests (e.g. PET imaging and/or CSF sampling) for confirmation.

The economic implications of primary care screening merit comment. On the basis of a \$100 fee for a single AD blood test, the total cost for screening only 20 million people would be as high as \$2 billion. Using a 20% expected prevalence, and under the assumption of 80% sensitivity and 75% specificity, the resulting positive predictive and negative predictive values would be 48% and 93%, respectively. In a scenario in which 20 million people are screened, the results would be as follows: (1) 14,900,000 people would be excluded from second-level tests (of whom 500,000 would be false-negative); and (2) 5,100,000 individuals would be judged as in need of CSF sampling and/or PET imaging. With the cost for a single PET scan being \$5,000, the resulting financial burden for second-level PET imaging would total \$25 billion. However, the availability of a blood screening test in primary care would avoid PET imaging in nearly 15 million individuals, resulting in annual savings as high as \$73 billion. Such figures would be even higher when we consider that the total number of people aged ≥ 65 years worldwide was >600 million in 2016. These calculations simulate the major impact that blood-based screening of AD and the availability of disease-modifying therapies might have in the next few decades.

Another major implication of AD blood-based biomarkers concerns the implementation of the precision medicine paradigm for the treatment and prevention of neurodegenerative diseases (Hampel et al., 2016, 2017, 2018a,b). Specifically, such markers may be helpful in identifying specific subgroups showing different dysfunctions in key biological systems. Previous studies have shown the clinical utility of neuroproteomics in the discovery of new neurodegenerative disease biomarkers (Henchcliffe et al., 2011; Ho et al., 2011) in an unbiased fashion (i.e. not informed by current pathophysiological models). For instance, neuroproteomics highlighted the potentially prominent role played by neuroinflammation in the pathophysiology of AD and other neurodegenerative disorders (Durrenberger et al., 2015; Heneka 2014), leading to the hypothesis that neuroinflammatory mechanisms are paramount in AD pathogenesis, at least in a subset of patients. In this specific subgroup, the pathogenetic role of A β peptides, tau protein, and α -synuclein may be less prominent

Biomarkers for Alzheimer's disease

than originally expected. We may therefore delineate a scenario in which blood-based biomarkers are a prerequisite to CSF analysis and/or PET imaging; further profiling may be subsequently utilized to implement multi-model interventions targeted at specific patient subgroups (Fig. 6.2) within the precision medicine framework (Baldacci et al., 2018).

Fig. 6.2

Schematic depiction of multi-level biomarker-driven diagnostic and therapeutic model. First, a blood screen aids in determining which patients undergo PET or CSF confirmatory diagnostic procedures. If positive, refer; if negative, evaluate again in the future as needed. Second level is at the CSF and PET confirmatory diagnostics for specific pathophysiological markers (not disease presence, but pathology presence). The third level adds blood-based biomarker profiles of specific biological systems known to be altered in neurodegenerative disease that may be present in addition to the pathophysiological markers identified by PET and/or CSF. The second and third levels guide specific multi-modal interventions. As an example, a patient could be positive on blood screen and then undergo both CSF evaluation for amyloid, tau, and α -synuclein. The patient, then, also undergoes blood-biomarker profiling for inflammatory, neurotrophic, metabolic, and oxidative dysfunction. A positive finding for amyloid only would move the patient to amyloid-only therapy. A positive finding for amyloid, α -synuclein, and inflammation would move the patient to multi-modal therapy targeting amyloid, α -synuclein, and inflammation.

CSF, cerebrospinal fluid; PET, positron emission tomography.

Conclusion

The last two decades have been characterized by substantial advances in the field of blood-based biomarker investigation in AD and other neurodegenerative diseases. Human blood (plasma/serum) is the primary source of the proteome, and advanced technologies detecting even minor protein changes are key strategies to identify blood protein biomarkers. Compared with CSF markers, a validated blood-based AD biomarker has the potential to be fast, non-invasive, and cost-effective for early detection and diagnosis purposes. Moreover, since venepuncture is a routine and safe procedure (in contrast to lumbar puncture), the investigation of blood biomarkers is fully established in the clinical environment (O'Bryant et al., 2017).

The development of biomarkers mirroring all molecular pathophysiological mechanisms in the brain of patients with AD and other neurodegenerative disorders at distinct time points in disease evolution is expected to constitute the basis for personalized, tailored (i.e. adapted to the individual), biomarker-driven targeted treatments, in accordance with the evolving precision medicine paradigm (Hampel et al., 2016, 2017, 2018a). For this reason, in order to advance the development of the precision medicine paradigm in AD, the international Alzheimer Precision Medicine Initiative (APMI) and its cohort programme (APMI-CP)—available at <https://www.apmiscienc.com/>—have been launched recently by our consortium (Hampel et al., 2019). As a result, over the next few decades, a paradigm shift can be expected in which multimodal biomarker profiling, rather than clinical phenotypes, will guide therapeutic interventions. For instance, a patient showing prominent neuroinflammatory features might be treated with a special focus on brain inflammation, whereas evidence of early tauopathy will lead to tau-directed interventions. At that point, the clinical phenotype will be irrelevant and the treatment will be solidly rooted in the underlying pathophysiological underpinnings. An analogy can be found in cancer research and clinical care where classification paradigms for malignancies are expected to witness a transition from a 'tissue of origin' to an 'underlying molecular alteration(s)' model, resulting in what are hoped to be dramatically improved therapeutic outcomes (Baldacci et al., 2018).

Moreover, implementing a screening-diagnostic workflow starting with a blood-based test in primary care has the potential to increase access to second-level diagnostic tests (for instance, amyloid PET imaging) and provide a clear path for regulatory approval. Despite continuous research, several candidate blood-based biomarkers show restrictions that might preclude their application. For this reason, it is essential to establish close collaborations between academia, industry partners, and regulatory bodies to speed up the full development and validation of a blood-based biomarker assay for clinical use.

Clinical biomarkers in the diagnosis of dementia

Chapter: Clinical biomarkers in the diagnosis of dementia

Author(s): Robert Barber

DOI: 10.1093/med/9780198807292.003.0007

Introduction

This chapter focuses on the current clinical application of biomarkers in the diagnosis of dementia subtypes. Discussion of more advanced or research-orientated biomarkers is limited, and further references to these can be found in chapters covering neuroimaging (Chapter 12) and blood-based biomarkers (Chapter 6), as well as chapters on dementia subtypes (e.g. Chapters 30–34).

Over the past 25 or so years, the use of biomarkers to help detect and categorize brain diseases has firmly transitioned from the ‘bench to the bedside’, mirroring their more established and developed role in mainstream medical practice.

Biomarkers now feature in the diagnostic criteria for the common types of neurodegenerative dementia, vascular dementia (VaD), and prion diseases, augmenting diagnostic confidence and accuracy. Integrating

Clinical biomarkers in the diagnosis of dementia

this evolving 'toolkit' into everyday clinical practice is becoming ever more important.

As with any investigation, the clinician needs to evaluate how the evidence for and against the utility of a biomarker can be best applied to individual patients, ensuring their use and interpretation are timely and appropriately tailored. The preferences and expectations of patients should be explored, alongside information relating to the benefits, limitations, and risks of each test. Contextual factors that could influence the choice and interpretation of biomarkers will also need consideration, such as age, medical comorbidities, stage of disease, and the differential diagnosis under enquiry, and factors relating to the test itself such as the cost, availability, and acceptability.

This chapter focuses on the application of biomarkers to diagnostic practice in the assessment of patients with suspected dementia—the judgment to use biomarkers in this context centring on their perceived 'added value' in clarifying the diagnosis under question. This added value relates to the ability of biomarkers to both 'rule out' pathologies that may be responsible for cognitive impairment, including the so-called treatable or reversible causes, as well as profile the biological signatures of dementia subtypes to positively 'rule in' their diagnosis. The clinician will need to evaluate the relevance of information provided by biomarkers, and depending on the issue at hand, the absence of a pathologic finding can be as edifying as the presence of an abnormality. A final diagnosis of the dementia subtype will ultimately rely on the synthesis of information from the full clinical assessment, informed by the outcome of any investigations.

Sharing the results of a biomarker test often plays an important confirmatory role in the disclosure of diagnosis. Optimizing diagnostic accuracy offers patients the best information to adjust to their condition and plan ahead. It also reinforces a collaborative approach, reassuring patients that their concerns have been fully appraised.

Role of biomarkers

Broadly, biomarkers are biological characteristics that can be objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention (Biomarkers Definitions Working Group, 2001).

In the context of the clinical diagnosis of dementia subtypes, the core biomarker toolkit currently consists of imaging techniques and the analysis of CSF, as summarized in Box 7.1 and Table 7.1. Together they provide 'windows' into the structure, function, and pathology of the brain. Consensus guidelines and diagnostic criteria increasingly reference these tests. Indeed, as new technologies emerge and evidence of their utility grows, there has been a shift in the credence given to biomarkers in

Clinical biomarkers in the diagnosis of dementia

diagnostic criteria, from being a supportive feature to the status of an indicative or core feature.

Box 7.1 Clinical biomarkers used in dementia diagnosis

Main clinical biomarkers

- Neuroimaging:
 - CT
 - MRI: T1- and T2-weighted and FLAIR; plus other sequences, depending on diagnostic question
 - SPECT perfusion HMPAO
 - SPECT dopamine DaTscans
 - FDG-PET glucose metabolism
 - PET amyloid
 - CSF
- AD profile: CSF A β_{42} /phosphorylated tau/total tau
- Rapidly progressive dementia—prion diseases and infective and inflammatory forms of encephalitis

A β_{42} , β -amyloid peptide; CSF, cerebrospinal fluid; CT, computed tomography; DaTscan, dopamine transporter scan; FDG, fluorodeoxyglucose; FLAIR, fluid-attenuated inversion recovery; HMPAO, hexamethylpropyleneamineoxime; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

Clinical biomarkers in the diagnosis of dementia

Table 7.1 Summary of biomarker findings in the main types of dementia.

Diagnosis	Structural imaging	Functional imaging	CSF	Suggested sequence of tests ¹
AD	<i>Reduced</i> volume of medial temporal lobe structures	<i>Reduced</i> activity bilaterally in temporo-parietal cortex and posterior cingulate-precuneus on SPECT-HMPAO and FDG-PET <i>Increased</i> amyloid retention on PET (though application still not established in routine practice)	<i>Reduced</i> A β ₄₂ <i>Increased</i> phosphorylated tau (p-tau) <i>Increased</i> total tau <i>Reduced</i> ratio (A β ₄₂ /A β ₄₀)	Start with structural imaging—CT or MRI ² —especially looking for MTA If diagnosis remains unclear, consider FDG-PET (or SPECT-HMPAO if unavailable; FDG-PET is more accurate, however) SPECT perfusion (HMPAO) or FDG-PET can help differentiate between AD, VaD, and FTD If diagnosis remains unclear, consider LP to measure AD CSF biomarkers—or alternatively PET if available If all tests negative, then unlikely to be AD
DLB	Supportive biomarkers ³ Relative absence of MTA	<i>Reduced</i> uptake in putamen and caudate on DaTscan	–	Consider both structural imaging and DATscans from outset

Clinical biomarkers in the diagnosis of dementia

		<i>Reduced</i> uptake on 123-iodine-MIBG myocardial scintigraphy <i>Supportive biomarkers</i>³ Generalized low uptake on SPECT/PET perfusion/metabolism scan, reduced occipital activity, and relative preservation of posterior or mid-cingulate metabolism on FDG-PET (the cingulate island sign)		CT or MRI² looking for relative preservation of MTA DATscans offer high specificity and relatively good sensitivity—particularly helpful in patients with possible DLB If negative and clinical picture consistent, then diagnosis would be in keeping with possible DLB and consider repeating scan in future If diagnosis remains unclear and DLB still possible, consider MIBG SPECT, if available
VaD ⁴	<i>Presence</i> of cortical infarcts or strategic infarcts affect thalamus <i>Increased</i> deep white matter disease—shown as hypoattenuation on CT or hyperintense on T2-weighted and FLAIR MRI Greater relevance if extensive (>25% area) and confluent	Pattern of change on SPECT-HMPAO and FDG-PET is likely to vary, depending on distribution and extent of vascular disease	–	Start with structural imaging—CT or MRI² Overall—MRI is more sensitive than CT in detecting vascular changes The main causes of vascular cognitive impairment are large vessel strokes, small vessel disease, and microhaemorrhages—different MRI sequences

Clinical biomarkers in the diagnosis of dementia

				can help detect these changes T2-weighted images show infarcts; FLAIR shows white matter changes and lacunar infarcts T2* gradient echo (or susceptibility weighted imaging) can identify microhaemorrhages or microbleeds, suggestive of cerebral amyloid angiopathy or small vessel disease Additional functional imaging can be selected, depending on differential diagnosis under review 123-iodine-MIBG myocardial scintigraphy may offer greater discrimination than DaTscan in context of vascular-PD versus DLB, given it is not affected by brain vascular changes in the striatum which can mimic the pattern of nigral loss seen as a consequence of Lewy body disease

Clinical biomarkers in the diagnosis of dementia

FTD	<i>Reduced</i> volume of frontal/ anterior temporal lobes Changes can vary, depending on subtype: • Behavioural variant of FTD: varying degrees of atrophy occurring along the frontal-temporal lobe axis, occasionally including the parietal lobes • Progressive non-fluent aphasia: usually symmetrical, left-sided perisylvian atrophy (inferior frontal and antero-superior temporal regions) • Semantic dementia: usually asymmetrical (especially anterior left temporal pole) and significant ('knife edge' appearance of gyri) Atrophy may become more bilateral as the illness progresses, but usually	<i>Reduced</i> activity of frontal/ anterior temporal lobes	–	Start with structural imaging—CT or MRI², looking for frontotemporal pattern of atrophy If diagnosis remains unclear, there is good evidence to support use of SPECT-HMPAO or preferably FDG-PET perfusion, looking for reduced activity in anterior regions of the brain

Clinical biomarkers in the diagnosis of dementia

	atrophy still left > right hemisphere			

Note: The presence of these biomarker changes (in italics) provides additional evidence in support of the diagnosis. Conversely, the absence of these changes makes the respective diagnosis much less likely, especially if this is observed across all biomarkers.

¹ This is a suggested sequence, but there are many clinical factors that could vary this approach and should be taken into account.

² Choice of CT or MRI influenced by considerations such as nature of differential diagnosis, availability, tolerability, and contraindications.

³ Supportive biomarkers: these are biomarkers consistent with DLB that help in the diagnostic evaluation, but without a clear diagnostic specificity.

⁴ VaD is not a single disorder and results from a diverse range of vascular pathologies (Wardlaw et al., 2013).

A β ₄₂, β -amyloid peptide; AD, Alzheimer's disease; CSF, cerebrospinal fluid; CT, computed tomography; DaTscan, dopamine transporter scan; DLB, dementia with Lewy bodies; FDG, fluorodeoxyglucose; FLAIR, fluid-attenuated inversion recovery; FTD, frontotemporal dementia; HMPAO, hexamethylpropyleneamineoxime; LP, lumbar puncture; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; MTA, medial temporal atrophy; PD, Parkinson's disease; PET, positron emission tomography; SPECT, single-photon emission computed tomography; VaD, vascular dementia.

Clinical biomarkers in the diagnosis of dementia

In the future, the clinical use of biomarkers is likely to extend beyond facilitating diagnostic accuracy. This may include advancing pre-symptomatic detection and screening, predicting the risk of ‘converting’ from MCI to clinical dementia, profiling the often heterogeneous pathologies in individuals experiencing cognitive decline, tailoring therapies that target these changes, and then evaluating the impact of these therapies. Indeed, should new disease-modifying therapies emerge, it is highly likely this will accelerate the clinical need to provide biomarker testing prior to treatment, and healthcare systems would need to adjust to meet this new demand (Ritchie et al., 2017).

From a research perspective, biomarkers are already providing important insights into the pathogenesis, neurobiology, pre-symptomatic and longitudinal progression of dementia subtypes, and their symptoms. They are also integral to scientific and regulatory requirements of drug development and the execution of clinical trials. These roles include refining inclusion criteria, enriching the biological homogeneity of participants in clinical trials, assisting stratification, helping to reduce the number of patients required to power a study, monitoring drug pharmacokinetics including dose optimization, serving as surrogate outcome measures to validate drug responsiveness, and monitoring patient safety and adverse events.

The emergence of biomarkers has already contributed to a paradigm shift in how the diseases that underpin dementia, such as Alzheimer’s disease (AD), are understood (Albert et al., 2011; Dubois et al., 2010). A definitive understanding of the pathogenesis of such diseases remains to be determined, but we know pathogenic changes start in advance of clinical symptoms. Biomarkers can profile and track these changes, providing insights into both the pre-symptomatic and symptomatic phases of illness. This longitudinal approach broadens the perspective to view dementia as a disease with a distinct pre-dementia stage, including pre-symptomatic, then prodromal, phases. This creates opportunities to detect and hopefully prevent and/or modify the underlying diseases as early as possible.

Biomarkers are also axiomatic to a move towards a biological definition of conditions like AD (Jack et al., 2018), and combining biomarkers and genetics could lead to new approaches to defining and classifying dementia subtypes.

Need for biomarkers in diagnostic practice

Dementia is a major cause of significant morbidity and premature death, and is associated with substantial personal, family, and societal consequences. Providing a timely, accurate diagnosis is seen as a key step in helping to explain what has occurred and what is likely to follow. It will inform approaches to post-diagnostic support and help optimize pharmacological management, both in selecting the most appropriate treatment and in avoiding medications that could cause adverse effects. It

Clinical biomarkers in the diagnosis of dementia

can also facilitate access to clinical trials and other types of research. From a public health perspective, accurately detecting the prevalence and type of dementia helps to plan services and identify areas of unmet need.

Broadly, concerns about diagnostic practice have centred on both the underdiagnosis and misdiagnosis of dementia. Biomarkers can increase the proportion of patients who are correctly diagnosed.

Their value is reinforced by evidence showing the clinical diagnosis of the main subtypes of dementia can lack accuracy, when compared to autopsy-confirmed pathology. Nelson et al. (2011) found up to 30% of individuals presenting with the typical clinical phenotype of AD, as diagnosed by experts using established clinical criteria, did not have autopsy features of AD. Beach et al. (2012) also compared the accuracy of clinical diagnosis of AD with post-mortem findings and found similar concerns regarding the tendency to underdiagnose and misdiagnose a significant proportion of patients, with a sensitivity for AD of 71–87% and a specificity of 44–71%, respectively.

The sensitivity of the clinical criteria for frontotemporal dementia (FTD) can be as low as 36%, but this can be significantly improved by using neuroimaging (Mendez et al., 2007). Concerns also exist about the diagnostic accuracy of the clinical criteria for VaD (Roman et al., 1993), and the diagnostic accuracy of dementia with Lewy bodies (DLB) has been enhanced by the use of biomarkers (McKeith et al., 2017).

Individuals presenting with young-onset dementia, extensive psychiatric comorbidities, and rapid and atypical forms of dementia will also pose complex diagnostic issues where biomarkers can help clarify the underlying diagnosis.

Biomarkers in dementia represent a step towards a more accurate clinical appraisal of patients and are now incorporated in a number of major diagnostic frameworks and guidelines (such as Hort et al., 2010; McKhann et al., 2011; O'Brien et al., 2017; National Institute for Health and Care Excellence, 2018). Ultimately, they are the only way to look inside our bodies to see what may be truly happening.

Current clinical biomarkers

As noted earlier, this chapter focuses on neuroimaging and CSF biomarkers in clinical practice.

There are additional biomarkers that are relevant to certain specific diagnoses. Chapter 6, for example, provides an in-depth review of the emerging role of plasma-based biomarkers.

There are recognized genetic abnormalities associated with dementia that are usually inherited but can occasionally occur spontaneously. Examples include cerebral autosomal dominant arteriopathy with subcortical

Clinical biomarkers in the diagnosis of dementia

infarcts and leukoencephalopathy (CADASIL) (*NOTCH3*), Huntington's disease (*HTT* gene CAG trinucleotide repeat), and genetic forms of FTD (primarily *MAPT*, *GRN*, *C9orf72* expansion) and AD (APP, PS1, PS2).

Polysomnography, via sleep clinics, can be used to confirm the presence of rapid eye movement (REM) sleep behaviour disorder with atonia, which is indicative of DLB (McKeith et al., 2017). It can also help assess other sleep disorders that are associated with cognitive dysfunction such as sleep apnoea.

There is also growing evidence that myocardial scintigraphy also has utility in the diagnosis of DLB. This is another form of single-photon emission computed tomography (SPECT) that uses a tracer called metaiodobenzylguanidine (MIBG) that measures cardiac sympathetic innervation, with reduced MIBG binding being associated with DLB (McKeith et al., 2017).

Neurophysiological biomarkers include electroencephalography (EEG). This can provide supplementary evidence in the assessment of prion diseases such as Creutzfeldt-Jakob disease (CJD). Patients with CJD can have a characteristic repetitive pattern of bilateral periodic epileptiform discharge, though CSF and imaging biomarkers are more accurate. There may also be future roles for quantitative EEG and transcranial magnetic stimulation in the clinical differentiation of dementia, but currently these techniques are largely restricted to research (e.g. Cromarty et al., 2016). There is also emerging research interest in exploring the clinical utility of skin and nerve biopsies, olfactory and retinal characteristics, and abnormalities in gait patterns (see, for example, Donadio et al., 2017; Koychev et al., 2019).

Neuroimaging

Broadly, neuroimaging divides into 'structural' and 'functional' modalities. Together they provide complementary information; choosing which modalities to employ will depend on what question needs answering. Effective dialogue between the clinician and the radiologist will ensure the optimal imaging protocol is used for the differential diagnosis under question.

Structural imaging, comprising CT and MRI, captures information about the morphological appearance of the brain. Functional imaging yields information about the brain's biological activity through various 'lenses' that can sample different physiological characteristics.

All major guidelines recommend patients with suspected dementia should undergo structural imaging at least once in the course of their illness. Additional functional imaging is usually considered when the diagnosis remains in doubt and further clarification is indicated. The interpretation of functional scans should be informed by structural imaging.

Clinical biomarkers in the diagnosis of dementia

Occasionally, if the baseline neuroimaging is unremarkable (or there is an equivocal focal findings of uncertain significance), it may be relevant to repeat the investigation (usually after at least 6–12 months), depending on clinical developments.

Structural imaging in clinical practice

CT and MRI offer different advantages and disadvantages. As a general rule, CT is adequate for 'ruling out' most intracerebral lesions such as tumours, metastases, strokes, subdural haematomas, and hydrocephalus. It is also good for detecting acute intracerebral haemorrhage, bone abnormalities, calcification, and lesions with little or no water content (e.g. meningioma). Clinically, CT has tended to be used more widely than MRI, most likely reflecting its greater availability, speed, ease of use, and lower cost.

CT has a more limited role than MRI for 'ruling in' degenerative disorders, such as AD, though the development of multi-slice CT has made three-dimensional (3D) reconstruction possible, with images no longer limited to the axial plane. Most of the evidence for the utility of structural imaging in dementia subtypes is primarily from MRI studies.

Overall MRI is safer than CT, as it does not use ionizing radiation. However, scans take longer and can be less well tolerated and there are a number of important contraindications such as pacemakers and ferromagnetic objects in the eyes.

A major strength of MRI is its versatility to visualize changes in both grey and white matter, with greater resolution and clarity than CT—head-to-head, MRI will usually provide greater information to both simultaneously help 'rule in' and 'rule out' disorders. MRI is the structural imaging of choice for atypical or rapid dementias.

MRI images are 3D data sets derived from the behaviour and density of protons in water molecules when exposed to the electromagnetic environment of the scanner. An analogy has been made of how MRI creates images from the behaviour of protons with how the structure of a city can be visualized at night by mapping the pattern of streetlights. The inherent versatility of MRI lies in the variety of sequences that can be used to generate and detect different patterns of proton-related activity, which, in turn, can convey different types of information. A difference in water content of <1% is enough to distinguish between normal and abnormal tissue.

Routinely, the main MRI sequences are T1-weighted, T2-weighted imaging and fluid-attenuated inversion recovery (FLAIR). T1-weighted MRI provides excellent morphological details to study the extent and topography of atrophy. T2-weighted and FLAIR are helpful in identifying vascular disease, and the absence of hyperintensities on these scans is a strong indicator that the person's symptoms are unlikely to be due to vascular disease. These sequences also help in detecting hippocampal

Clinical biomarkers in the diagnosis of dementia

sclerosis and inflammatory, infective, demyelinating, metabolic, toxic, or infective changes. Other sequences exist and can be more relevant, depending on the differential diagnosis under assessment. For example, diffusion-weighted imaging is useful when there is rapid cognitive decline suggestive of a prion disease.

Table 7.2 summarizes the main MRI changes in less common forms of dementia.

Table 7.2 Structural neuroimaging in other diseases associated with cognitive impairment	
Disorder	Abnormalities
Variant Creutzfeldt-Jakob disease (vCJD)	Symmetrical hyperintensity on MRI in the pulvinar (posterior) nuclei of the thalamus, relative to the anterior thalamus (pulvinar sign). Hyperintensity of the dorsomedial thalamic nuclei, caudate head, and periaqueductal grey matter may also occur
Sporadic CJD (sCJD)	High signal changes in the putamen, caudate, and/or thalamus and cortical gyri (cortical ribboning) on MRI. Diffusion-weighted imaging has a high sensitivity and specificity for sCJD (especially in detecting cortical changes compared with other MRI sequences). These changes, when coupled with the absence of gadolinium enhancement and sparing of the white matter, points strongly to a diagnosis of sCJD
Progressive supranuclear palsy (PSP)	Brainstem atrophy and non-specific mild atrophy
Corticobasal degeneration	May have bilateral (symmetrical) frontal lobe atrophy—possibly extending posteriorly
Multisystem atrophy (MSA)	Olivopontocerebellar or basal ganglia atrophy, depending on variant
Normal pressure hydrocephalus (NPH)	Marked ventricular enlargement disproportionate to atrophy, with rounding of anterior horns of lateral ventricles

Clinical biomarkers in the diagnosis of dementia

Huntington's chorea (HC)	Bilateral caudate atrophy—may also have reduced volume of other basal ganglia structures and frontal lobes
CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy)	Evidence of subcortical infarcts and confluent hyperintensities on MRI, potentially extending into the temporal poles (which may be non-enhancing)
Infections/inflammation	May appear as multifocal/confluent areas of hyperintensities on MRI

Adapted with permission from Barber, R., and O'Brien, J.T. Structural brain imaging. In: Ames, D., et al. (Eds). *Dementia*, 5th. CRC Press: Oxford, UK. Copyright © 2017, Informa UK Limited, published by Taylor & Francis.

The interpretation of scans should be approached in a systematic way. Harper and colleagues (2014) recommended the following order:

- Check for any 'surgical pathologies' (such as tumours, haematomas, and arteriovenous malformations).
- Assess any signal changes (based on the premise that the appearance within a single tissue type should be relatively uniform and the presence of hyper- or hypointensity within the tissue can often reflect pathology).
- Assess any atrophy, noting its pattern and extent, including areas that appear persevered. This involves checking for general and lobar patterns of cortical atrophy, noting any asymmetry and anterior-posterior gradient, as well as any evidence of basal ganglia, brainstem, or cerebellum atrophy.

Functional imaging in clinical practice

Functional imaging provides estimates of the brain's biological activity. Clinically, this is in the form of regional cerebral blood flow via SPECT perfusion, glucose metabolism via ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET), dopamine neurotransmission via dopamine transporter scans (DaTscans), and estimates of amyloid burden via amyloid PET (though, to date, in most countries, this form of imaging has not established a clear foothold in clinical practice).

Clinical biomarkers in the diagnosis of dementia

Single-photon emission computer tomography perfusion

SPECT is widely used in medicine. Images are derived by gamma cameras capturing the activity of gamma-emitting radiopharmaceuticals that have been designed to target different diseases. In the context of brain disease, two tracers have been developed—one for studying dopamine transporter function, as discussed below, and the other being ^{99m}Tc -hexamethylpropyleneamine oxime (^{99m}Tc -HMPAO).

After HMPAO is injected, it passes through the blood-brain barrier and is taken up by neurons. Image acquisition should be within 4 hours. As blood flow is closely coupled with neuronal metabolism, the images provide an assessment of the regional cerebral blood flow. The images are converted into colour maps, allowing regional patterns of blood flow/activity to be compared. The grey matter is the most metabolically active area, so it has the highest signal.

Clinical interpretation of SPECT-HMPAO scans is based on whether activity is increased or, more commonly in the context of dementia, decreased. Importantly, the pattern of loss and perseveration should be assessed and the scans should be interpreted alongside a structural scan.

Increased signal can be associated with epileptogenic foci and can be used to guide surgical treatments of refractory epilepsy.

Dementia subtypes have differing patterns of loss. Typically, AD is associated with bilateral medial temporal hypoperfusion, often in conjunction with parietal lobe hypoperfusion. Behavioural variant FTD shows a distinct anterior-to-posterior gradient (Rascovsky et al., 2011), with the frontal lobe and anterior temporal lobe showing the greatest reduction in perfusion/activity, with relative sparing of posterior areas. In DLB, there can be hypoperfusion (and hypometabolism on FDG-PET) of the occipital and posterior parietal lobes. In VaD, changes are more varied and often patchy, reflecting the varied distribution of cerebrovascular disease.

Overall, a systematic review of SPECT-HMPAO studies indicated the technique offers the best differentiation between AD and FTD—the pooled sensitivity and specificity in distinguishing AD from FTD was close to 80%, whereas the results for distinguishing AD from VaD and AD from DLB varied between 70% and 75% (Yeo et al, 2013).

FDG-PET

FDG-PET uses technology that has been widely applied in oncology for many years. Radiolabelled FDG is used to track glucose metabolism. It has a short half-life of <2 hours, and its use is limited to specialist centres as a cyclotron is required for its manufacture.

SPECT-HMPAO and FDG-PET produce similar images in terms of the topography of changes, but FDG-PET offers greater spatial resolution.

Clinical biomarkers in the diagnosis of dementia

Head-to-head, it performs better than SPECT in the differential diagnosis of AD, reaching 90% specificity and 85% sensitivity for AD versus normal controls, compared to 70% for both indices in SPECT. However, if the clinical question relates to the differentiation of DLB and AD, then DaTscans would be the first-choice functional imaging modality.

FDG-PETs are also more sensitive at detecting changes than SPECT, and changes can be observed preclinically—one of the potential advantages of functional scans based on glucose metabolism and amyloid homeostasis is that changes can be detected before the anatomical changes of atrophy are evident on structural images.

Dopamine transporter scans (DaTscans)

DaTscans are licensed for the differential diagnosis of DLB and AD. The scans are based on measuring the activity of dopamine transporter molecules in presynaptic neurons using ^{123}I -ioflupane injection (^{123}I -FP-CIT). A reduction in signal represents dysfunction or loss of nerve terminals. DaTscans have a sensitivity of 80% and a specificity of 90% to distinguish DLB from AD. They are also abnormal in other neurodegenerative conditions—idiopathic PD, CBD, PSP, and MSA. DLB should therefore not be diagnosed solely on the basis of this or other biomarkers (McKeith et al., 2017).

A normal scan shows activity in both the putamen and the caudate nuclei, producing a comma- or crescent-shaped image. This pattern is preserved in drug-induced parkinsonism and AD. In DLB, graded abnormalities are seen. Characteristically, this starts with bilateral loss of signal in the putamen, with preservation of activity in the caudate nuclei; the tail of the ‘comma’ is lost, leaving the image of a ‘full stop’. If severe, then it can be difficult to see activity in the caudate as well or to distinguish the striatum from background activity, with an overall loss of the signal-to-noise ratio.

DaTscans have been shown to improve diagnostic confidence in patients who are likely to have DLB but who present with less clear-cut symptoms. Walker et al. (2015) showed using DaTscans considerably improved the clinician’s diagnostic confidence, particularly when the scan was abnormal. The added value of imaging was evident in patients presenting with only one core feature or only suggestive features of DLB and in individuals without signs of parkinsonism.

Positron emission tomography amyloid imaging

Amyloid PET scans have been licensed to assist in the diagnosis of AD since 2013. Its adoption into clinical practice, as noted earlier, has remained limited, constrained, in part, by funding and availability, but also by the uncertainty regarding its optimal application despite a number of consensus statements advising on this issue (Johnson et al., 2013; Royal College of Radiologists et al., 2016).

Clinical biomarkers in the diagnosis of dementia

Three fluorinated tracers have been commercially developed—florbetapir and florbetaben provide grey-scale images, and flutemetamol uses colour images. They all correlate with brain amyloid deposition, particularly with neuritic plaques, but also bind to amyloid in blood vessels. The pattern of amyloid deposition on PET does not seem to follow Braak staging of AD through the cortex.

The diagnostic indication for amyloid PET scans in clinical practice centres on improving the accuracy of diagnosing AD. Their recommended role is to provide supplementary biomarker information if AD remains a possible, yet uncertain, diagnosis after a full and comprehensive specialist clinical evaluation, including conventional imaging work-up (i.e. MRI or CT) and where there is an expectation, the results will influence management (Johnson et al., 2013; Simonsen et al., 2017).

As amyloid positivity is more common with age (e.g. present in 40% of those aged over 80 years) (Ossenkoppele et al., 2015), the test will be more robust in younger individuals. Amyloid PET imaging does not distinguish between AD and DLB (Donaghy et al., 2015), limiting its value in this diagnostic differential.

Measuring amyloid is also a key biomarker when selecting participants for amyloid-based therapy studies, and its presence can predict a higher risk of converting from MCI to AD over time (Herukka et al., 2017).

To date, the utility of amyloid PET imaging in clinical practice has been uncertain. However, emerging evidence indicates it can positively influence clinical decision-making, diagnostic confidence, and patient management (e.g. Boccardi et al., 2016; Rabinovici et al., 2019). Though head-to-head comparisons of PET and CSF biomarkers (see below) are limited and discordances can occur, they appear to offer similar diagnostic performance and correlate well with each other and post-mortem findings (Blennow and Zetterberg, 2018). However, it is important to understand they provide different types information about what is happening within the CNS (Jack et al., 2018). CSF measurements are based on the dynamic balance between the production and clearance of proteins, as reflected in their CSF concentration. Molecular imaging represents the protein load or damage that has accumulated within the brain over time and, unlike the CSF, provides topographical information. As such, low CSF β -amyloid can be considered a pathologic state that is associated with amyloid plaque formation but does not measure amyloid plaque load per se like PET imaging (Jack et al., 2018).

Cerebrospinal fluid

The CSF directly interacts with the extracellular space in the brain and this proximity offers insights into brain physiology (Molinuevo et al., 2018). The CSF protects the CNS via a number of mechanisms, including regulation of intracranial pressure, providing nutrients, and supporting metabolic homeostasis. CSF volume is about 150 mL in adults and it is

Clinical biomarkers in the diagnosis of dementia

renewed 3–5 times daily. Its main molecular constituents (80–85%) are derived from blood, with the remainder coming from the CNS (Tumani et al., 2017).

The CSF can be acquired via a lumbar puncture (LP). It is a relatively invasive, yet normally safe, procedure, but contraindications include raised intracranial pressure, with a risk of cerebral herniation, as well as thrombocytopenia or other bleeding diathesis, including ongoing anticoagulant therapy. Potential side effects include back pain and headaches, and a very small number of individuals will require a ‘blood patch’ (where a small amount of the patient’s blood is injected into the epidural space near the LP site to form a clot to prevent further loss of CSF) if the headache is severe or hospitalization, depending on the risks. Adverse events can be reduced by using atraumatic (pencil-point) LP needles (Nath et al., 2018) and generally are less prevalent with increasing age (Engelborghs et al., 2017). Standard CSF analysis comprises total protein, albumin, glucose, lactate, cell count, and depending on the differential diagnosis, bacterial, fungal, and mycobacterial stains, with culture, cytological staining, and immunoglobulin G (IgG) index and oligoclonal bands.

LP should be considered if the CNS changes could be caused by infection, inflammation, or autoimmune, demyelinating, or certain neoplastic disorders.

CSF analysis has an important role in rapidly progressive dementia. This includes prion diseases such as CJD. CSF real-time quaking-induced conversion (CSF RT-QuIC) is a highly sensitive (82–97%) and specific (99–100%) test for CJD (Lattanzio et al., 2017). Elevated protein 14-3-3, S100 β , and total-tau also occurs, but with lower diagnostic accuracy, though the profile varies by the molecular subtype of CJD.

LP is also indicated for the investigation of AD. CSF changes that are characteristic of an AD profile are reduced concentrations of β -amyloid peptide ($A\beta_{42}$) and increased concentrations of tau phosphorylated at threonine 181 (p-tau) and total tau (t-tau). These changes have high diagnostic accuracy for AD, with sensitivity and specificity reaching 85–90% (Olsson et al., 2016). This AD profile is thought to relate to the core pathology of AD. It is hypothesized that the reduction in amyloid CSF is due to its sequestration within brain tissue in plaques, supported by the correlation between low $A\beta_{42}$ CSF and positive amyloid PET scans showing increased amyloid levels. Tau protein is located in the microtubules in neuronal axons. In AD, tau becomes hyperphosphorylated (p-tau) and this disrupts the normal integrity of microtubules, impairing axoplasmic flow and ultimately leading to loss of neurons and connectivity. p-tau is relatively specific to AD and a key component of tangles. t-tau, in contrast, is seen as a ‘state marker’, reflecting the intensity of neurodegeneration or the severity of neuronal damage, and

Clinical biomarkers in the diagnosis of dementia

elevated levels are seen in other conditions such as prion diseases (Blennow and Zetterberg, 2018).

Other CSF biomarkers in AD also show good discrimination, including the ratio of $A\beta_{42}/A\beta_{40}$ and neurogranin.

There is emerging evidence that CSF biomarkers may be helpful in distinguishing AD from variants of FTD, but not DLB (Paterson et al., 2018).

Procedural, laboratory, and analytical factors can affect the result and efforts to standardize these elements to improve utility. Guidance on optimal practice for CSF collection (e.g. using polypropylene vessels) and processing has been recommended—fasting is not required, but consistency when samples are acquired is important (e.g. samples should be collected between 8 a.m. and 12 noon to avoid potential diurnal variation in CSF biomarkers) (Ahmed et al., 2014).

Integrated biomarker frameworks for diagnosis of AD

Jack et al. (2018) have also proposed a framework for integrating the different biomarkers in the diagnosis of AD. This is based on the pathologic process to which they potentially link, which is summarized as 'AT(N)':

A: abnormalities in amyloid detected by CSF $A\beta_{42}$ (or ratio $A\beta_{42}/A\beta_{40}$) and amyloid PET

T: abnormalities in tau detected by CSF phosphorylated tau and tau PET (currently only used as a research tool)

(N): neurodegeneration or neuronal injury detected by anatomic MRI, FDG PET, and CSF total tau ('N' is bracketed as the changes are not specific to AD and do not map directly to the neuropathologic findings used to diagnosis AD).

According to this framework, if abnormalities in all three AT(N) domains are detected in a patient with clinical dementia, the probability this is caused by AD is increased. Conversely, if all AT(N) domains are clearly within normal limits, then AD is unlikely.

The evolution of the various biomarkers in AD has been subjected to detailed modelling. Changes begin at least 10 years before symptoms and appear to emerge sequentially in the following order: CSF $A\beta_{42}$, amyloid PET, CSF tau, FDG-PET, and structural MRI, followed by clinical symptoms (Jack et al., 2013) (Fig. 7.1).

Clinical biomarkers in the diagnosis of dementia

Fig. 7.1

Aβ amyloid is identified by CSF Aβ₄₂ (dotted line) or PET amyloid imaging (dark grey). Elevated CSF tau (dashed line). Neurodegeneration is measured by FDG PET and structural MRI respectively which are drawn concordantly (light grey). By definition, all curves converge at the top right-hand corner of the plot, the point of maximum abnormality. The horizontal axis of disease progression is expressed as time. Cognitive response is illustrated as a zone (grey-filled area) with low- and high-risk borders. The vertical black line denotes a given time (T). Fig. 7.1B illustrates operational use of this model. Projection of the intersection of time T with the biomarker curves to the left vertical axis (horizontal dashed arrows) gives values of each biomarker at time T, with the lead biomarker (CSF Aβ₄₂) being most abnormal at any given time in the progression of the disease. Intersection of time T with the cognitive impairment zone gives cognitive impairment at that fixed point in time. Subjects who are at high risk of cognitive impairment due to AD pathophysiology are shown with a cognitive response curve that is shifted to the left. In contrast, the cognitive response curve is shifted to the right in subjects with a protective genetic profile, high cognitive reserve and the absence of comorbid brain pathologies—illustrating that two subjects with the same biomarker profile (at time T) can have different cognitive outcomes (denoted by circles at the intersection of time T and low vs. high risk cognitive profiles).

Interpreting biomarkers

An ideal biomarker is reproducible, stable over time, and widely available and reflects directly the relevant disease process (Biomarkers Definitions Working Group, 2001). Each biomarker will, in some aspect, fall short of this ideal.

It is generally accepted that a test that performs above 80% cut-offs for sensitivity and specificity can offer clinical utility. Low levels of sensitivity can lead to too many false-negative diagnoses, delaying access to treatment, and conversely suboptimal specificity could lead to

Clinical biomarkers in the diagnosis of dementia

overdiagnosis, running the risk of inappropriate treatment and unnecessary anxiety.

It is important to emphasize that depending on the clinical question under investigation, the added value of a biomarker can lie in its negative predictive value, i.e. finding those who truly do not have the disease, as much as in its ability to show typical patterns of change.

When interpreting a biomarker such as neuroimaging, there will be a need to evaluate the overall pattern of the result, weighing up any 'abnormal' and 'normal' elements, and to do this in the context of the overall assessment.

A number of factors impact on the utility and interpretation of biomarkers. These can be grouped by the limitations of what biomarkers per se can reveal and the limitations of the validation studies used to evaluate their utility.

Limits on what biomarkers can reveal

Biomarkers may not offer a direct measure of the underlying disease process

This is relevant to a number of common biomarker changes, as described in the following examples.

Atrophy on imaging

Atrophy on structural imaging represents the visual end point of significant neuronal loss over time and therefore is seen as a proxy for neurodegeneration. It does not directly reveal the cause of this change, though the extent, pattern, and evolution of atrophy can be indicative of a particular disease. For example, hippocampal atrophy (often captured by the composite visual rating of medial temporal lobe atrophy) occurs early and progressively in AD. It is a characteristic feature of this disease, denoting the presence of neuronal damage and correlates with neuronal loss and Braak neurofibrillary tangle staging. It has a sensitivity and specificity of around 80% for distinguishing AD from normal controls, and relative preservation of medial temporal lobe structures is the most robust structural imaging findings distinguishing DLB from AD (McKeith et al., 2017).

However, it is only a proxy for this disease and it would be incorrect to infer it directly diagnoses AD. It may be absent in atypical presentations of AD (especially in young onset) and is not specific to AD. Lesser degrees of atrophy can be observed in other diseases such as VaD and FTD, depending on subtype, DLB, CBD, PSP, and Huntington's disease. A proportion of cognitively unimpaired individuals will have hippocampal atrophy, especially with advancing age, though it is usually mild. Ultimately, structural imaging can provide secondary, but not primary, evidence of diseases like AD (de Leon et al., 2007).

Clinical biomarkers in the diagnosis of dementia

White matter and vascular scan changes

VaD results from a diverse range of vascular pathologies, including large vessel to small vessel disease and micro-haemorrhages (Wardlaw et al., 2013). New imaging techniques have improved the ability to detect the spectrum of vascular changes, but their relevance will need interpreting.

Imaging can confirm the presence of vascular disease in the form of infarcts, but their clinical relevance in causing dementia still requires interpretation—strokes can occur without causing cognitive impairment and at least 20% of lacunar infarcts are clinically ‘silent’. Diagnostic criteria for VaD require a temporal relationship between when the stroke occurred and when the onset of cognitive symptoms emerged (Roman et al., 1993). This link, however, is less clear-cut in vascular cognitive impairment secondary to small vessel disease that often evolves more gradually than stroke-related dementia.

Further, the location, size, and number of strokes are likely to be relevant when inferring their impact on the cognitive and non-cognitive symptoms of dementia. Attributing cognitive impairment to vascular disease is more robust if these changes are located in cortical areas intimately associated with cognition. It is also likely ‘non-vascular’ factors are also relevant. The most consistent predictors of cognitive impairment after stroke are global atrophy and medial temporal lobe atrophy (Casolla et al., 2018). Pre-existing AD pathology may interact to increase the risk of post-stroke dementia and can potentially ‘amplify’ the impact of an infarct (Snowdon et al., 1997). Periventricular white matter changes (e.g. seen as areas of hypoattenuation around the ventricles on CT) can be due to small vessel disease, but these changes are not a direct measure of the integrity of the circulation. This change also becomes very common with advancing age, so drawing inferences about its relationship to clinical symptoms can be challenging. In addition, while white matter lesions may have an ischaemic basis in older adults, these may also be driven by Wallerian degeneration, e.g. as a result of an underlying AD process (McAleese et al., 2017).

By convention, greater clinical relevance is ascribed to white matter changes when they are more extensive (affecting >25% of white matter), confluent, and located in deep white matter—so-called ‘WMH of presumed vascular origin’ by Wardlaw et al. (2013).

Molecular biomarkers

As discussed, DaTscans measure the integrity of dopamine neurotransmission in the nigrostriatal pathways using a radiopharmaceutical that binds to the presynaptic DAT transmembrane protein. Clinico-pathological studies indicate DaTscans have a sensitivity for DLB of around 80%, inferring 20% of patients who have the pathological hallmarks of this condition at death would be inaccurately classified in life as not having this disease (if the test was used as the sole

Clinical biomarkers in the diagnosis of dementia

determinate of the diagnosis). DLB is thought to result from abnormalities in the protein synuclein, which, in turn, causes dopaminergic cell loss and the changes in dopamine neurotransmission seen in the striatum. DaTscans therefore provide an indirect measure of this pathology. Potential explanations for false-negative scans include minimal synucleinopathy affecting this area of the brain with limited nigral neuronal loss or a balanced loss of dopamine across the whole striatum (McKeith et al., 2017).

The characteristic CSF and PET changes in amyloid and tau associated with AD do not confirm the presence of AD per se. It is more accurate to think in terms of probabilities and to consider whether the biomarker findings, in the context of the overall clinical picture, make AD more or less likely. Amyloid changes can also occur in other diseases and amyloid positivity is more common with advancing age (Ossenkoppele et al., 2015).

Clinical diagnostic categories are unlikely to be pathologically pure

Approaches to the classification of dementia are on the basis of clinical features, pathological motifs, and genetics. As argued by O'Brien and Herholz (2015), we should expect this classification to change, in line with new advances in knowledge and technologies, while accepting the concordance between these elements is likely to be incomplete in the interim.

One example of this is advancing age where individuals are likely to experience a range of brain changes. Individuals with dementia are also unlikely to have 'pure' pathologies. This can make the interpretation of biomarkers more complex (as a measure of single disease). Individuals affected by AD will have amyloid and tau changes, but a proportion will also have evidence of microvascular changes, activated microglia, and other protein abnormalities such as α -synuclein and TDP-43. This overlap in pathologies with age and between different dementias means there are additional explanations for biomarker changes. This pathological heterogeneity also means it may be hard to diagnose an individual patient by measuring only a single biomarker, as often multiple pathologies are the norm.

Limitations of biomarker studies

Subjects and diagnostic groups

The reliability and validity of biomarkers are often examined using highly selected subjects in research studies, which are less typical or representative of the patients seen in clinical practice.

It is also important to evaluate which diagnostic groups have been compared in validation studies. For example, a test validated on the comparison between subjects with AD and cognitively normal individuals

Clinical biomarkers in the diagnosis of dementia

does not directly provide information about its performance to distinguish individuals with AD from a different type of dementia. This is relevant as diagnostic difficulties in clinical practice often arise in the context of differentiating dementia subtypes, rather than distinguishing dementia from normality.

Diagnostic confirmation

The utility of biomarkers is often examined by comparing their correlation with clinical phenotypes and/or other biomarkers. Their confirmatory relationship with the autopsy neuropathological 'gold standard' diagnosis is, for a series of practical reasons, often challenging to achieve. In the absence of direct clinico-pathological correlations, there will be a degree of uncertainty regarding inferences drawn from biomarker tests applied during life. An added complexity to determining the utility of a biomarker is the latency between the time when it is collected (often in early-stage illness), compared with autopsy findings (often based on end-stage illness).

Standardization of measurements and thresholds used to define abnormality

If biomarkers are to successfully transition from 'bench to bedside', the tests need to be readily and reliably available, as well as cost-effective. Overcoming these issues has been challenging. For example, up until recently, there was a lack of harmonization and standardization in how CSF biomarkers should be collected and analysed. However, it is now possible to reliably measure key CSF biomarkers using fully automated assays (Blennow and Zetterberg, 2018). Variability has also existed in how neuroimaging biomarkers are acquired and measured (Frisoni et al., 2013). The move towards using standardized visual rating of scans, such as atrophy and white matter changes on structural imaging (Harper et al., 2015, 2016; Wahlund et al., 2017) and quantification of FP-CIT striatal uptake on DaTscans, can improve their utility in everyday clinical practice, though the lack of quantification of visual scales can place a ceiling on their full potential.

Using cut-offs for biomarkers offers practical appeal in clinical practice, as they have for many other tests such as defining thresholds for diabetes or hypertension. However, there are good reasons to be cautious about an over-reliance on such binary cut-offs. There is a tendency to think of biomarkers denoting individuals into positive versus negative disease status, but invariably biomarkers are continuous measures and ambiguous or indeterminate results will be obtained (McKhann et al., 2011). As outlined earlier, factors such as age and stage of disease progression imply a dimensional, rather than a dichotomized, approach and is more in accordance with the probabilistic inferences we can draw from biomarkers.

Clinical biomarkers in the diagnosis of dementia

This dimensional approach also accords with clinical practice. The interpretation of biomarker results that are clearly above or below established cut-offs is usually straightforward, especially when multiple biomarkers show a consistent picture. However, biomarker results are sometimes intermediate or inconclusive. Depending on the clinical context, it can be appropriate to keep an open mind about the significance or otherwise of this result in case it was on the cusp of a cut-off value and becomes abnormal with time.

Gaps in evidence

It should be noted there are gaps in our knowledge relating to a number of key issues. There has been relatively few studies directly comparing biomarkers, validating how they are optimally used together, or assessing their impact on outcomes such as overall patient well-being and quality of life (Frisoni et al., 2017).

Final comments

Biomarkers can optimize diagnostic practice, helping to ensure patients and their families receive the best possible advice and treatment.

Structural neuroimaging should be considered in the investigation of all patients with suspected dementia and, where possible, performed at least once during their illness. Functional imaging and, more recently, CSF biomarkers in the context of AD provide complementary information that can enhance diagnostic accuracy.

Each biomarker has strengths and limitations and they should not be interpreted in isolation or divorced from the clinical presentation—the overarching clinical evaluation of each patient will inform which biomarker/s to select and there will always be a need to interpret the relevance of the information provided by biomarkers in this context.

The evidence to support the optimal use of biomarkers in clinical practice is still actively evolving and it is very likely that new biomarkers, whether used individually or in combinations, will emerge to offer more comprehensive, detailed, and personalized insights into brain disease.

Molecular genetics and biology of dementia

Chapter: Molecular genetics and biology of dementia

Author(s): Abdul Hye and Latha Velayudhan

DOI: 10.1093/med/9780198807292.003.0008

Introduction

Worldwide the prevalence for dementia is increasing and the incidence doubles about every 5 years. It is estimated that 35.6 million people were living with dementia worldwide in 2010, with numbers expected to almost double every 20 years to 65.7 million in 2030 and 115.4 million in 2050 (Prince et al., 2013). It is known that dementia is caused by an interplay between genes and lifestyle and environmental factors (van der Flier and Scheltens, 2005). Recent advances in genetic and molecular biology in dementia have provided valuable insights into the pathogenesis of underlying dementia for not only in those with clear genetic aetiology, but also in those with no familial basis. This brings hope for future treatment strategies and therapeutic targets. In this chapter, we focus on the four most common types of dementia: Alzheimer's disease (AD), vascular dementia (VaD), frontotemporal lobar degeneration (FTLD), and Lewy body dementia (LBD).

Alzheimer's disease

AD is the most common form of dementia characterized by rapidly progressive cognitive dysfunction and behavioural impairment, affecting nearly 46 million people around the world. Pathologically, AD is characterized by severe atrophy and neuronal loss, extracellular neuritic plaques composed mainly of aggregated amyloid- β (A β), and intracellular neurofibrillary tangles (NFTs) consisting of hyper-phosphorylated tau protein.

Molecular biology

Amyloid and APP

The major component in plaques is A β , a 38- to 43-amino acid peptide, derived by the cleavage of the amyloid precursor protein (APP) (O'Brien and Wong, 2011). Cleavage of APP primarily occurs by α -secretase, followed by γ -secretase, to produce non-amyloidogenic products. This cleavage releases a large soluble ectodomain of APP (sAPP α) and a carboxyl terminal fragment (α CTF) (Zhang et al., 2011). The γ -secretase cleavage of α CTF produces APP intracellular cytoplasmic domain (AICD) and soluble peptide P3 (Chow et al., 2010), but a percentage of APP is cleaved by β -secretase (BACE1), rather than α -secretase, to produce sAPP β and β CTF. A subsequent cleavage by γ -secretase produces an A β and AICD fragment which are transported, via exocytosis, to the extracellular space (Masters and Beyreuther, 2006; Zhang et al., 2011). The main forms of A β produced by the amyloidogenic pathway are A β 1-40 and A β 1-42, with the latter being the more neurotoxic, which tend to aggregate into oligomers, protofibrils, and fibrils (Walsh and Selkoe, 2007). Ensuing A β plaque formation leads to localized microglial activation, cytokine release, astrogliosis, and a multi-protein inflammatory response (Eikelenboom et al., 1994; McGeer and McGeer, 1995). (See Fig. 8.1 for a summary of amyloid processing.)

Molecular genetics and biology of dementia

Fig. 8.1

APP processing: The APP is cleaved sequentially by enzymes termed secretases. BACE1 is an aspartyl-protease that sets the pace of A β generation. BACE1 cleaves APP in its luminal domain, generating a secreted ectodomain. The resulting 10kDa C-terminal fragments retained in the membrane, are subsequently clipped by γ -secretase, which acts at the transmembrane domain of APP to release A β . The α -secretase cleaves APP in the middle of the A β region, generating the α fragment, as well as a short C-terminal stub that is also cleaved by γ -secretase. Cleavage of α -secretase cuts APP within the A β region. Importantly, α -cleavage directly competes with β -cleavage for their common substrate APP. Subsequent cleavage of this fragment by a γ -secretase protease activity generates a secreted peptide of ~3kDa peptide (termed p3).

The 'amyloid cascade hypothesis', supported by genetics (discussed further in molecular genetics), has been the predominant model to explain AD pathogenesis. This theory suggests that APP mis-metabolism increases production, then deposition, of toxic A β and acts as a pathological trigger that leads to NFT formation, neuronal injury, and cell death (Hardy, 1992). This has been further supported by substantial genetic, biochemical, and pathological evidence (Barage and Sonawane, 2015). However, current evidence proposes that the failure or imbalance of A β clearance, rather than excess formation, is the main contributor to toxic deposition (Mawuenyega et al., 2010; Sperling et al., 2011), thus implicating mechanisms involved in the degradation of toxic A β , i.e. neprilysin, insulin-degrading enzyme (IDE), intracellular lysosomal degradation, and microglia activation, as of central importance in the development of A β pathology (Agostinho et al., 2010; Murphy and LeVine, 2010).

Tau and neurofibrillary tangles

Another hallmark in AD are NFTs, which are composed of the hyperphosphorylated microtubule-associated protein tau. A lot of neurons in the typically affected AD brain regions (entorhinal cortex, hippocampus, parahippocampal gyrus, amygdala, frontal, temporal, parietal, and occipital association cortices, and certain subcortical nuclei projecting to these regions) contain large, non-membrane bound bundles of abnormal fibres that occupy much of the perinuclear cytoplasm (Selkoe, 2001). Neurodegeneration, synaptic loss, and cognitive

Molecular genetics and biology of dementia

symptoms observed in AD patients are more associated with the density and distribution of NFT pathology than A β deposition (Dickson et al., 1995), although NFTs are not exclusive to AD but can occur in other neurodegenerative disorders such as Down's syndrome and frontotemporal lobe dementia.

In the adult human brain, six tau isoforms exist which are coded by a single gene located on chromosome 17 (Buée et al., 2000). By alternative mRNA splicing of exons 2, 3, and 10, six different isoforms are produced in the brain with apparent molecular weights of between 50–70 kDa (Fig. 8.2). The isoforms differ by the presence or absence of one or two short inserts in the N-terminal half (0N, 1N, and 2N, respectively) and have either three or four microtubule-binding motifs in the C-terminal half (3R- and 4R-tau) (Gong et al., 2005). In the fetal brain, only the shortest tau isoform (3R-tau) is found, whereas all isoforms are present in the adult brain. However, fetal tau is more extensively phosphorylated than adult tau (Lee et al., 2001). Prominent features of the primary structure of tau are the three or four imperfectly repeated stretches of 31 and 32 residues in the C-terminal half, which make up the core of the microtubule-interacting unit (Lee et al., 1989).

Fig. 8.2
Tau isoforms.

Hyperphosphorylated tau also forms insoluble aggregates, paired helical filaments (PHF), the primary component of NFTs found in AD and other tauopathies (Iqbal et al., 2008). Tau isolated from AD brains has a 4-fold increase in levels of phosphorylation (Kopke et al., 1993) and all tau isoforms are found to be aggregated in PHFs (Grundke-Iqbal et al., 1986). The current consensus is that A β precedes and induces a cascade that results in NFT and other pathologies (Mudher and Lovestone, 2002). Furthermore, genetic studies suggest that increased A β production demonstrates the enhanced development of tau pathology (Blurton-Jones and Laferla, 2006).

Even though the relationships between A β plaques and tau pathology remain unclear, they both finally converge to cause widespread and progressive cell death and neuronal loss. Post-mortem analysis indicates

the medial temporal lobe (MTL), including the hippocampus, parahippocampus, and entorhinal cortex, to be the first affected by AD pathology (Braak et al., 2006). As disease progresses, substantial neuronal loss in the cerebral cortex, specifically the lateral temporal and medial parietal lobes, is observed, followed by atrophy of the lateral parietal and frontal lobes (Nestor et al., 2004). During the course of the condition, an AD sufferer will have extensive atrophy of the temporal, parietal, and frontal cortices, with relative preservation of the primary occipital and primary sensorimotor cortex (Braak et al., 1993, 2011). The extent of clinic symptoms due to AD is more strongly correlated with the anatomical extent and number of NFTs in the cortex (Ingelsson et al., 2004). This observation has led to the 'tau propagation' hypothesis where tau may systemically develop and progress independently throughout the brain (Frost et al., 2009). Recent animal models strongly point towards NFT propagation from the MTL to the cortex being driven by A β (Lewis and Dickson, 2016; Pooler et al., 2015) (see Fig. 8.2).

Inflammation

Ageing is the strongest risk factor for developing AD, putatively in part as result of chronic inflammation during ageing, known as 'inflamm-ageing' (Cevenini et al., 2013), believed to be caused by both clinical and subclinical infections, as well as exposure to non-infective antigens over the course of a person's lifetime (De Martinis et al., 2005).

Neuroinflammation associated with AD is often viewed as a secondary response to A β deposition and neuronal cell death. However, there is the possibility that later neuroinflammatory response can be as pathologically relevant as an inducer. Neuroinflammation in AD is often viewed as a double-edged sword where activated microglia and reactive astrocytes, the immune cells of the brain, have both beneficial effects by degrading A β (Koistinaho et al., 2004) and adverse effects by producing cytotoxic substances that contribute to disease progression (Akiyama et al., 2000). A degree of activation is required for microglial phagocytosis of A β (Richard et al., 2008), but overstimulation ultimately may lead to neuronal cell death.

Overproduction of inflammatory molecules can affect various aspects of disease progression. Firstly, senile plaques contain many other constituents besides A β , e.g. acute phase proteins and complement factors (Akiyama et al., 2000). These A β -associated proteins have been shown to affect transport, fibrillogenesis, and deposition of A β (Eikelenboom et al., 2011; Veerhuis et al., 2005) and thereby disturb the balance between A β deposition and removal. Secondly, the cytokine interleukin-1 (IL-1) has been reported to affect A β production and deposition *in vitro*, by promoting synthesis and processing of APP (Shafteel et al., 2008).

Thus, it is becoming more evident that neuroinflammation has a substantial role in the pathogenesis of AD. It is likely that in order to

intervene in disease progression, appropriate action has to be taken against inflammation.

Synaptic dysfunction and neuronal loss

The consequence of amyloid and tau pathology is the significant loss of neurons; this loss is more pronounced in AD than normal ageing (Masliah et al., 1993). Synaptic dysfunction—ranging from altered synaptic dynamics and plasticity processes to full-blown synapse loss—is the earliest pathological feature of AD (Sheng et al., 2012). It likely begins years before functional deficits become apparent during the incipient preclinical phase of AD and is widely believed to be mediated by the accumulation of toxic A β species (Benilova et al., 2012). Since the first report of a significant correlation between synaptic loss and dementia severity (Davies et al., 1987), the effect of neurodegenerative diseases on synaptic proteins has been a subject of wide research. In AD, synapse dysfunction has been reported to occur very early in affected regions, such as the frontal or temporal cortex, and correlates more closely with cognitive decline than A β plaques or NFTs (DeKosky and Scheff, 1990; Scheff and Price, 2006; Terry et al., 1991). Levels of numerous synaptic proteins, a useful measure of synaptic integrity, are reduced in both human AD cases (Honer et al. 2003) and virtually all transgenic AD mouse models (Crews et al., 2010). However, the degree to which synaptic proteins change in AD is synapse type- and brain region-specific; distinct neurotransmitter systems also appear to be differentially affected by AD progression (Gsell et al., 2004). In this regard, cholinergic transmission seems to be affected very early, while GABAergic signalling appears to be relatively preserved, even in late AD (Davies et al., 1998). Investigating the synaptic targets affected by AD pathology, as well as the mechanisms by which this synaptotoxicity is mediated, would be highly informative and may provide novel therapeutic targets.

This is further corroborated with recent imaging biomarker studies in living patients. Even though it is very difficult to quantify the density and synaptic functioning directly in humans, FDG-PET (Herholz, 2012; Mosconi et al., 2006), functional MRI (fMRI) (Brickman et al., 2003), and EEG (De Waal et al., 2012) provide useful biomarkers for synaptic dysfunction and network connectivity in AD progression (de Wilde et al., 2011). These imaging biomarkers have, in fact, been important in helping to differentiate between disease stages and are predictive for risk of progression from normal cognitive function to MCI and AD (Sperling et al., 2013).

Molecular genetics

More recently, the advent of genome-wide genotyping has led to more genetic variants being identified as associated with AD. These genes draw attention to possible alternative pathogenesis pathways underlying AD such as lipid metabolism, the immune system, and so on. Additionally, next-generation sequencing (NGS) has continued to broaden the potential

Molecular genetics and biology of dementia

applications of searching for genetic contributors to AD. These NGS approaches have been applied to identify rare variants in patients with AD such as variants in triggering receptor expressed on myeloid cells 2 (TREM2), phospholipase D member 3 (PLD3), unc-5 homolog C (UNC5C), a kinase anchor protein 9 (AKAP9), and TM2 domain containing 3 (TM2D3).

AD can be divided into early-onset AD (EOAD) (<65 years) and late-onset AD (LOAD) (≥ 65 years), depending on its age of onset. Both EOAD and LOAD have a strong genetic component. Although the majority of people with AD do not present with autosomal inheritance, a few families present autosomal dominant transmission, particularly in EOAD. Meanwhile, even in LOAD, the non-Mendelian heritability is up to 80% (Gatz et al., 2006). Firstly, we will discuss the linkage studies that led to the discovery of mutations in *APP*, *PSEN1*, *PSEN2*, *a disintegrin and metalloprotease 10* (*ADAM10*), and *APOE*. Then we will summarize and evaluate the information obtained from GWAS of AD. Finally, we will outline the efforts to identify less frequent and rare variants by using NGS.

EOAD comprises the minority of all AD cases (5–10%), with an onset normally between 30 and 65 years of age. In most cases, EOAD follows a classic Mendelian inheritance pattern, usually autosomal dominant, though it can present without any family history ('sporadic' EOAD). Even though autosomal dominant AD is very rare (<1% age-specific prevalence), these discoveries of causative mutations have provided the foundation for unravelling the pathogenesis of AD and are now at the centre of current diagnosis and drug development research. Highly penetrant mutations in three genes are considered the main risk factors for EOAD: *APP* (Citron et al., 1992; Murrell et al., 1991), *PSEN1* (Tanzi et al., 1991), and *PSEN2* (Sherrington et al., 1996). These mutations have been shown to alter A β production to increase the A β 1-42 to A β 1-40 ratio, leading to dementia. *PSEN1* mutations are the most common and most severe cause of autosomal dominant AD, with full penetrance and age of onset occurring as early as 25 years of age 47. To date, almost over 200 mutations have been discovered in the three genes; for further details, readers are referred to the mutation database at <http://www.alzgene.org/> (Ferencz and Gerritsen, 2015).

LOAD is considered to be a multifactorial disease; however, there is a considerable genetic involvement. Early genetic studies in LOAD concentrated on genes involved in A β production. This led to the discovery of the best-known risk gene for LOAD, the *APOE* gene located on chromosome 19 (Pericak-Vance et al., 1991). Apolipoprotein E (ApoE) protein is the major cholesterol carrier in the brain and has key roles in neuronal growth, tissue injury repair, and immune regulation. ApoE binds to numerous cell surface receptors which are implicated in lipid delivery and transport, as well as mitochondrial function and glucose metabolism. The *APOE* gene has three allelic variations ($\epsilon 2$, $\epsilon 3$, and $\epsilon 4$) encoding different protein isoforms that differ in two sites of the amino acid sequence (Corder et al., 1993). The most common variant is APOE $\epsilon 3$

(77%), while $\epsilon 2$ (8%) and $\epsilon 4$ (15%) alleles are less common (Bagyinszky et al., 2014). On the other hand, the frequency of $\epsilon 4$ carriers in the AD population is much larger at approximately 60% (Van Cauwenberghe et al., 2016) and this equates to an approximately 4-fold greater risk for LOAD than the $\epsilon 3$ allele (Genin et al., 2011). Naturally, ApoE binds to A β peptides and effects the clearance of soluble A β and its aggregates (Bu, 2009; Castellano et al., 2011), but the APOE $\epsilon 4$ variant is less efficient in the clearance of A β (Bell et al., 2012). In addition, transgenic mouse models that express APOE $\epsilon 4$ show an inhibition of cyclophilin A signalling at the pericytes of brain blood vessels and this results in degeneration of these vessels, leakage of the blood-brain barrier (BBB) and neurodegeneration independent of A β (Bell et al., 2012). The $\epsilon 4$ allele is found to increase the risk for AD but is also implicated in the reduction in age of onset (Corder et al., 1993; Sando et al., 2008) and increases the rate of cognitive decline (Riley et al., 2000; Wilson et al., 2002). In addition, the APOE $\epsilon 4$ allele has also been found to have a stronger association with risk in women than in men (Altmann et al., 2014; Genin et al., 2011). The risk effect in heterozygous $\epsilon 4$ carriers is estimated at 3-fold, whereas a 15-fold risk is reported in homozygous $\epsilon 4$ carriers (Bu, 2009; Corder et al., 1993; Saunders and Roses, 1993). In contrast, the APOE $\epsilon 2$ allele is considered to be protective and to delay disease onset (Farrer et al., 1997; Mahley et al., 1996), although in certain populations APOE $\epsilon 2$ has been shown not to have protective effects in relation to AD (Kim et al., 1999). More recently, substantial evidence has supported a protective mechanism whereby the APOE $\epsilon 2$ allele reduces the accumulation of A β pathology in the ageing brain (Grothe et al., 2017).

Nonetheless, the presence of the APOE $\epsilon 4$ allele alone is not sufficient for the development of AD pathology (Farrer et al., 1997). In close proximity to the *APOE* gene, two possible candidates have been suggested as increased risk of AD: *TOMM40* (encoding translocase of outer mitochondrial membrane 40 homolog) (Takei et al., 2009) and *EXOC3L2* (exocyst complex component 3-like-2) (Seshadri et al., 2010). Various other candidates have been identified but have very modest association with AD. These include *ACE* (angiotensin-converting enzyme) (Kehoe et al., 1999), *ADAM10* (Kim et al., 2009), *CHRNA2* (cholinergic receptor, nicotinic, beta2) (Cook et al., 2004), *DAPK1* (death-associated protein kinase 1) (Li et al., 2006), *IL-8* (interleukin-8) (Li et al., 2009), *MTHFR* (methylenetetrahydrofolate reductase) (Chapman et al., 1998), and *SORL1* (sortilin-related receptor) (Rogaeva et al., 2007). These targets suggest that other biological mechanisms may be involved in AD pathogenesis (Ferencz et al., 2012).

More recently, efforts have been made by GWAS to identify a number of novel loci for LOAD, including polymorphisms in *SORL1*, *BIN1*, *CR1*, *CLU*, and *PICALM* (Harold et al., 2009; Hollingworth et al., 2011; Jones et al., 2010; Lambert et al., 2009; Naj et al., 2011; Seshadri et al., 2010). These discoveries have highlighted pathways related to cholesterol and lipid metabolism, energy metabolism, immune system, inflammatory

responses, endosomal vesicle cycling, and risk genes connected with A β and tau pathology. Large meta-analyses continue to be published and identify new susceptibility genes, adding further weight to implicated pathways in AD (Escott-Price et al., 2014). In a continued effort, more GWAS studies have revealed several additional susceptibility loci located in gene-dense regions: MS4A6A locus, HLA-DRB5 locus, ZCWPW1 locus, SLC24A4/RIN3 locus, NME8 locus, and CELF1 locus (Van Cauwenberghe et al., 2016); however, it is not clearly determined which genes in these regions are responsible for the association. Interestingly, a recent GWAS has identified novel genetic loci associated with hippocampal volume (Hibar et al., 2017) and novel AD loci encoding in proximity to the gene that encoded for tau (*MAPT*) (Jun et al., 2016). While none of these identified risk loci achieve the magnitude of APOE ϵ 4, they do provide vital information on the pathological pathways implicated in the disease process.

NGS studies and GWAS on very large cohorts have also revealed rare variants associated with AD. Multiple rare missense variants in TREM2 (1–2% frequency) have been reported to increase the risk for LOAD (Abduljaleel et al., 2014; Guerreiro et al., 2013b; Jonsson et al., 2013) and FTD (Guerreiro and Hardy, 2013). Individuals homozygous for TREM2 variants develop Nasu-Hakola disease characterized by early-onset cognitive problems with bone fractures and cysts. The most common disease-associated variant in TREM2 (R47H) is found within European populations and is reported to have an effect size comparable to APOE ϵ 4. TREM2 is a highly expressed receptor in microglia where it is thought to have an important role in phagocytosis (including A β) and inflammatory pathways (Guerreiro et al., 2013a; Takahashi et al., 2005).

Vascular dementia

VaD is the second most common dementia after AD, accounting for about 20% of all dementia worldwide (Gorelick et al., 2011). However, its genetic component remains poorly understood, especially when compared to other causes of dementia such as AD and FTD (Ikram et al., 2017). VaD may result from brain damage caused by numerous strokes or minor blood clots that block branches of blood vessels in the brain (Gorelick et al., 2011). Three broad subclassifications of VaD have been defined, based on underlying neuropathology: multi-infarct dementia, strategic infarct dementia, and subcortical vascular encephalopathy (Gorelick et al., 2016). A single study in 24 twins which attempted to determine the heritability of VaD was unable to identify a significant genetic component (Bergem et al., 1997). While this could suggest that the environment plays a larger role, a careful interpretation is warranted, given the limited sample size and the heterogeneity in VaD definitions (Ikram et al., 2017).

In recent years, cerebral amyloid angiopathy (CAA) has also been identified as an important risk factor for vascular cognitive impairment and dementia (Greenberg et al., 2004). CAA, a common small vessel disease (SVD), is caused by excessive A β deposition in the vasculature of

Molecular genetics and biology of dementia

the brain, especially in the walls of the leptomeningeal and cortical vessels (Esiri and Wilcock, 1986; Ghiso and Frangione, 2001). Besides haemorrhagic brain injury, CAA is associated with widespread ischaemic tissue injury, including white matter hyperintensities (WMHs) and microinfarcts (Reijmer et al., 2016). CAA frequently occurs as a comorbidity in AD but is also diagnosed in patients without other neurological diseases (Esiri and Wilcock, 1986; Ghiso and Frangione, 2001). In the general population, sporadic CAA occurs in elderly people (and is highly prevalent in AD brains), but rare hereditary forms are severe and have an early onset (van Opstal et al., 2017).

Single-gene disorders

A well-known monogenic disorder is cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), which is the most frequent heritable cause of VaD and results from mutations in the *NOTCH3* gene, mainly involving the cysteine residue, on chromosome 19q12 that cluster in exons 3 and 4 (Chabriat et al., 2009).

In hereditary cerebral haemorrhage with amyloidosis of Dutch type (HCHWA-D), an autosomal dominant form of CAA, a Glu693Gln point mutation in the *APP* gene leads to accumulation of A β in vessel walls (Maat-Schieman et al., 2005; Maat-Schieman et al., 1994). Mutation carriers develop symptoms early in life, usually between 50 and 60 years. Several variants of familial conditions related to stroke and/or dementia have been identified such as hereditary cerebral haemorrhage with amyloidosis of Icelandic type (HCHWA-I) from mutation in the *CST3* gene (Revesz et al., 2009). Inherited amyloidosis of the transthyretin (*TTR*) gene is a late-onset autosomal dominant condition characterized by deposition of TTR in the extracellular space of several organs, due to mutations in the *TTR* gene located on chromosome 18 (Vidal et al., 1996). Familial amyloidosis of Finnish type (FAF), or gelsolin-related amyloidosis occurring worldwide, is a rare autosomal dominant condition caused by G654A or G654T point mutations of the *gelsolin* gene. Chromosome 13-related CAAs include familial British dementia (FBD) (Vidal et al., 1999) and familial Danish dementia (FDD) (Vidal et al., 2000), which are novel forms of cerebral amyloidosis with extensive CAA (Frangione et al., 2001) due to mutations in the *ITM2B* (integral membrane protein 2B) gene. FBD is the current term for a rare autosomal dominant condition occurring in three British pedigrees, originally described as familial presenile dementia with spastic paralysis (Worster-Drought et al., 1933). Another monogenic form, first described in 1989, is Fabry disease (FD), an X-linked lysosomal disease due to a mutation in the *GLA* gene (Xq22), resulting in absent or reduced α -galactosidase activity that leads to accumulation of glycosphingolipid (globotriaosilceramide) in different organs (Ikram et al., 2017; Pastores and Lien, 2002).

Molecular genetics and biology of dementia

Other more rarely described single-gene disease entities are the COL4A1-A2 gene-related arteriopathy, which is a possible cause of small vessel arteriopathy and intracranial haemorrhages (Lanfranconi and Markus, 2010), and retinal vasculopathy with cerebral leukodystrophy, which now subsumes three previously considered separate entities (cerebroretinal vasculopathy, hereditary endotheliopathy, retinopathy, nephropathy, and stroke, and hereditary vascular retinopathy), and the disease is due to the *TREX1* gene and is associated both with SVD neuroimaging features and, in some cases, pseudotumoural lesions surrounded by vasogenic oedema (DiFrancesco et al., 2015; Richards et al., 2007). Finally, the cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), is a single-gene disorder directly affecting cerebral small blood vessels, caused by mutations in the *HTRA1* gene encoding HtrA serine peptidase/protease 1 (HTRA1), which has been described in Asians and recently in some European cases (Bianchi et al., 2014; Fukutake, 2011; Nozaki et al., 2015). Clinically, the disease is characterized by recurrent lacunar strokes associated with rapidly progressive cognitive impairment, seizures, and psychiatric disturbances (Bianchi et al., 2014; Fukutake, 2011; Nozaki et al., 2015). Although single-gene disorders are believed to account for a small proportion of cases, their prevalence is probably underestimated, and systematic studies on well-defined phenotypes and larger series are needed to help further understanding of the pathogenesis of VaD (Tan and Markus, 2015).

Candidate gene studies

Several candidate genes have been identified for sporadic VaD and most of the genes play a role in lipid metabolism [matrix metalloproteinase 1 (MMP1); matrix metalloproteinase 3 (MMP3); matrix metalloproteinase 9 (MMP9); methylenetetrahydrofolate reductase (MTHFR); paraoxonase 1 (PON1); paraoxonase 2 (PON2); very low-density lipoprotein receptor (VLDLR); sterol regulatory element binding transcription factor 2 (SREBF2), ACE I; angiotensinogen (AGT)], and inflammation [insulin-like growth factor 1 receptor (IGF1R); interleukin-1 alpha (IL-1 α); interleukin-1 beta (IL-1 β); IL6; tumour necrosis factor (TNF); transforming growth factor beta 1 (TGF β 1)] (Lee and Kim, 2013). However, most of these genetic findings have not been replicated and/or show only weak associations ($0.01 < p < 0.05$) (Ferencz and Gerritsen, 2015).

GWAS

Two GWAS have been reported to identify genetic risk factors for VaD. A retrospective study in Koreans (84 VaD patients, 200 controls) did not detect any genetic association (Kim et al., 2013), and a prospective study in the Netherlands (67 patients, 5700 controls) identified an association with the variant rs12007229 near the androgen receptor gene on the X chromosome, which was replicated in a German population (221 cases,

213 controls) (Schrijvers et al., 2012). However, large-scale hypothesis-free studies are needed for gene discovery in VaD (Ikram et al., 2017).

Dementia with Lewy bodies

Dementia with Lewy bodies (DLB) becomes more common with increasing age and accounts for about 5% of all dementia cases in older populations (Hogan et al., 2016). The clinical and neuropathological features of DLB overlap with those of Parkinson's disease (PD) and AD (Walker et al., 2015). Due to these overlapping features, DLB is often considered as part of a spectrum, with DLB placed between PD and AD (Meeus et al., 2012).

Biology

Pathology in DLB is characterized by Lewy bodies and Lewy neurites in the brainstem, limbic system, and cortical areas (Fujishiro et al., 2008; McKeith et al., 2004). The main pathological change is the production and accumulation of abnormal α -synuclein in Lewy bodies and neurites, which is phosphorylated, nitrated, and truncated, has abnormal solubility, prompts the production of oligomeric species, aggregates into fibrils, and is ubiquitinated (Hashimoto et al., 2004; Mukaetova-Ladinska and McKeith, 2006; Spillantini et al., 1998; Tofaris and Spillantini, 2007). DLB is classified among α -synucleinopathies for these reasons with Lewy bodies or LBDs, together with PD (Goedert et al., 2001). Although genetic mutations and multiplications of the gene have been found in familial cases, the mechanism by which this protein aggregates in sporadic cases of PD, DLB, and MSA is not fully understood (Tofaris and Spillantini, 2007).

DLB has other pathologic changes such as neuron loss, microvacuolation, and AD pathology distinguished by A β deposition in the form of diffuse and senile plaques, as well as early changes of NFT pathology (Garcia-Esparcia et al., 2017). Whether the amount of α -synuclein pathology (i.e. Lewy bodies and neurites) in the cerebral cortex is predictive of dementia in LBDs is a matter of controversy (Jellinger and Attems, 2008; Parkkinen et al., 2005, 2008). Cholinergic and dopaminergic denervation of the neocortex probably accounts, at least in part, for cognitive deficits in LBDs (Garcia-Esparcia et al., 2017). Synapses are primarily damaged in the neocortex in DLB (Hashimoto and Masliah, 2003; Kramer and Schulz-Schaeffer, 2007; Mukaetova-Ladinska and McKeith, 2006; Overk and Masliah, 2014; Schulz-Schaeffer, 2010). Additional molecular alterations in the pathogenesis of DLB include impaired autophagy, the ubiquitin-proteasome system of protein (Miki et al., 2016), as well as altered responses to protein misfolding (Baek et al., 2016).

Genetics

Candidate gene studies

The first genetic studies involving DLB patients which mainly focused on families with multiple affected members with variable phenotypes, ranging from DLB to PD and AD, identified two disease-associated loci 2q35-q36 and 2p13 (Bogaerts et al., 2007; Gasser et al., 1998) and twelve disease-associated rare variants in six genes (*SNCA*, *LRRK2*, *PSEN1*, *PSEN2*, *APP*, *SNCB*) (Vergouw et al., 2017). Rare disease-associated variants have also been identified by candidate gene studies in series of unrelated DLB patients such as glucocerebrosidase (GBA) (Nalls et al., 2013; Vergouw et al., 2017).

Association studies

Exome sequencing in 111 pathologically confirmed DLB patients found that approximately 25% of cases carried a pathogenic mutation or risk variant in *APP*, *GBA*, or *PSEN1*, and the APOE ϵ 4 risk allele was significantly overrepresented in DLB patients (Geiger et al., 2016). Studies with candidate genes have shown a strong association between DLB and the APOE ϵ 4 allele (Tsuang et al., 2013; Vergouw et al., 2017). Microtubule-associated protein tau (MAPT) H1G haplotype has also been associated with an increased risk for DLB. However, the exact functional variant at the MAPT locus is still unknown, and additional studies are warranted (Labbe et al., 2016).

A GWAS has been recently reported for DLB (Guerreiro et al., 2018). In this two-stage GWAS, which included samples from 1743 patients with DLB (1324 with pathological diagnosis) and 4454 controls (1216 patients with DLB versus 3791 controls in the discovery stage; 527 versus 663 in the replication stage) from 22 centres of ten countries confirmed previously reported associations: APOE, SNCA, GBA, and a novel candidate locus CNTN1. Additionally, the authors estimated the heritable component of DLB to be about 36% (Guerreiro et al., 2018).

Other relatively new and unbiased genetic approaches, such as whole exome and genome sequencing studies, have not yet been reported (Vergouw et al., 2017).

Frontotemporal dementia

The term frontotemporal lobar degeneration (FTLD) describes a pathology of the frontal and temporal lobes, commonly associated with cerebral deposition of misfolded proteins (Lashley et al., 2015). A variable percentage of people with FTD, between 20% and 40%, present a positive family history of neurodegeneration, and approximately one-third of familial cases show an autosomal dominant pattern of inheritance of the phenotype (Rainero et al., 2017; Rohrer et al., 2009). Behaviour variant FTD (bvFTD) shows the highest percentage of positive family history at around 30–50% of patients, whereas in patients with semantic or progressive non-fluent aphasia, the frequency is much lower (Rainero et al., 2017). However, only 10–30% of pedigrees show a clear autosomal

Molecular genetics and biology of dementia

dominant inheritance pattern of the phenotype (Le Ber, 2013). A recent study suggested that, even in patients with late onset, FTD is a genetic-based disease with different inheritance modalities (Borroni et al., 2014b).

Biology

The neuropathology associated with FTD is highly heterogeneous. From this perspective, the FTD spectrum can be split into two major categories: FTD-tau, where pathological inclusions contain fibrillar hyperphosphorylated tau; and FTD-transactive response DNA-binding protein (TDP), characterized by neuronal and glial inclusions immunoreactive for TDP-43 (Rainero et al., 2017). In addition, there is a small group of tau-negative and TDP-negative cases that are immunoreactive to components of the ubiquitin-proteasome system (FTD-UPS) or the fused in sarcoma protein (FTD-FUS) (Josephs et al., 2011). In some cases, however, molecular classification is still uncertain (Rainero et al., 2017).

Molecular genetics

The *MAPT* gene, linked to chromosome 17, was the first mutated gene associated with FTD, and it was discovered among families who presented with FTD and parkinsonism (Hutton et al., 1998; Spillantini et al., 1998). *MAPT* mutations cause 10–20% of familial FTD and 0–3% of sporadic FTD (Benussi et al., 2015). Specifically, this gene is located on chromosome 17q21, and it consists of a non-coding exon followed by 14 coding exons (Andreadis et al., 1992). Alternate splicing of exon 10 decides the number of amino acid repetitions (3R or 4R), while alternative splicing of exons 2 and 3 establishes the number of 29 amino acid N-terminal insertions (0N, 1N, 2N), which mediate tau interactions with the plasma membrane (Brandt et al., 1995; D'Souza and Schellenberg, 2000). At present, 72 different *MAPT* gene mutations and polymorphisms have been reported, including 44 that are clearly pathogenic (<http://www.molgen.ua.ac.be>), accounting for 5–20% of familial FTD cases (Rainero et al., 2017). Depending on the type of *MAPT* gene mutation, the neuropathological phenotype varies in morphological characteristics, severity, and distribution. Mutations in exons 1 and 10 (as well as in the intron following exon 10) are associated with neuronal and glial tau deposition, while mutations in exons 9, 11, 12, and 13 lead to deposits of tau filaments, mainly in neurons (Hutton et al., 1998). Mutations in exons 12 and 13 lead to the formation of NFTs with paired helical and straight filaments (indistinguishable from those seen in AD) (Ghetti et al., 2015). Although the clinical phenotype is highly variable, earlier age of onset, parkinsonism, and oculomotor deficits should lead the clinician to suspect *MAPT* mutation in the patient; however, the lack of a clear correlation between *MAPT* gene mutations and clinical features indicates that additional genetic and/or environmental factors can produce significant phenotypic variations (Rainero et al., 2017).

Non-MAPT FTD

The progranulin (*GRN*) gene, a protein-coding gene with 13 exons located on chromosome 17p21, was found to be responsible for another 5–20% of familial FTD cases and 1–5% of sporadic ones (Baker et al., 2006; Cruts et al., 2006). *GRN* encodes progranulin, a ubiquitously expressed growth factor precursor, which, together with its products, is implicated in a wide range of biological processes such as inflammation and wound repair, as well as in pathological conditions, including tumourigenesis (Ahmed et al., 2007; He and Bateman, 2003). Progranulin is predominantly expressed at the level of activated microglial cells and this finding seems to point to its regulatory role in the inflammatory response in the brain (Rademakers et al., 2008; Philips et al., 2010). Homozygous carriers of the T-allele of rs5848 have a 3-fold increased risk of developing FTD-TDP, compared with homozygous C-allele carriers (Rademakers et al., 2008). Worldwide, 149 different *GRN* gene mutations have been described (<http://www.molgen.ua.ac.be>). Of these, 67 are clearly pathogenic (Rainero et al., 2017). Recent studies have shown in FTD patients carrying the *GRN* gene mutation that the ubiquitinated neuronal inclusions contain, as a major component, TDP-43 (Rainero et al., 2017). A loss of function of progranulin leads to defective ubiquitination, resulting in accumulation of TDP-43. Mutation penetrance is very high, with 90% of carriers manifesting symptoms by the age of 75, and the associated phenotypes are remarkably variable, both between families with different *GRN* mutations and among members of a single family (Rainero et al., 2017).

Hexanucleotide expansion repeats in the open reading frame of chromosome 9 (C9orf72)

A strong association between FTD and ALS has been known for many years. A locus for frontotemporal dementia-amyotrophic lateral sclerosis (FTD-ALS) was found on chromosome 9q21 in 2006, and in 2011, a repeat intronic expansion (GGGGCC) was identified in the *C9orf72* gene (Benussi et al., 2015; DeJesus-Hernandez et al., 2011; Renton et al., 2011). In healthy individuals, there are 2–24 non-coding hexanucleotide GGGGCC repeats, and expansion to hundreds to thousands of repeats occurs in some FTD and ALS (Benussi et al., 2015; Seelaar et al., 2011). Haploinsufficiency through the loss of gene expansion, gain of function with secondary RNA toxicity, or both, are the proposed pathogenic mechanisms (Benussi et al., 2015). The neuropathology associated with the *C9orf72* mutation is a combination of FTLD-TDP and ALS (Hsiung et al., 2012). Clinically, the predominant phenotype in these patients is bvFTD associated with ALS, although the presentation may vary widely, even within the same family (bvFTD or ALS or a combination of both diseases) (Murray et al., 2011; Van Langenhove et al., 2013).

Other rare FTD Mendelian genes associated with FTD

Mutations in the TAR DNA-binding protein 43 encoding gene (*TARDBP*) have been linked to both ALS and FTD-TDP, suggesting that TDP-43 dysfunction is mechanistic in causing disease; however, while 5% of familial ALS patients have a *TARDBP* mutation, these are rarely found in FTD or in FTD associated with motor neuron disease (FTD-MND) (Sreedharan et al., 2008; Tripathi et al., 2014). TDP-43 is an RNA-binding protein that forms heterogeneous nuclear ribonucleoprotein (hnRNP) complexes encoded by *TARDBP* on chromosome 1. The current list of *TARDBP* gene mutations includes over 40 different missenses, most of them residing in the C-terminal glycine-rich domain, encoded by exon 6 and involved in protein-protein interactions (Rainero et al., 2017). Although, in the literature, *TARDBP* mutations have been appreciated as a cause of ALS phenotypes more than pure FTD ones, they can give rise to the full FTD-ALS continuum, even to early-onset pure FTD, with no evidence of ALS, even in advanced FTD disease stages (Rainero et al., 2017).

The 'fused in sarcoma' (*FUS*) gene is located on chromosome 16q11.22 and is also a member of the hnRNP family (Sieben et al., 2012). Mutations in *FUS* are seen in ALS (50 mutations reported to date) (Sieben et al., 2012). Only four mutations have been described in FTD-MND patients, with an additional two cases with pure FTD with no overlap with MND (Benussi et al., 2015; Umeda et al., 2013).

The valosin-containing protein (VCP) is involved in protein degradation, membrane fusion, transcriptional activation, and apoptosis (Seelaar et al., 2011). In 2004, mutations in VCP were described in patients with inclusion body myopathy, Paget's disease of bone (PDB), and FTD. This was named FTDP43 inclusion body myopathy (Benussi et al., 2015). Mean age of onset ranged from 40 to 60 years (Seelaar et al., 2011). Musculoskeletal symptoms mimicking scapulohumeral dystrophy or limb girdle dystrophy were observed in 80% of patients, features of PDB in 45%, and FTD in 38% (Seelaar et al., 2011). FTD usually develop later on in the disease, classically as a behavioural variant, and early language involvement is rare. There are 19 known pathogenic mutations, with a frequency of 1.6%, and family history is positive in 80% (Benussi et al., 2015).

Pathological mutations of the chromatin-modifying 2B (*CHMP2B*) gene, located on chromosome 3p11.2, was first described in 2005 in a Danish family with autosomal dominant FTD, with a mean age at onset of 55 (range 46–65) years, and was called FTD-3 (Irwin et al., 2015). The most common presentation is the behavioural variant of FTD. Clinical features include a frontal lobe syndrome, cognitive impairment with parkinsonism, dystonia, and pyramidal signs, followed later by myoclonus (Seelaar et al., 2011; Sieben et al., 2012).

Molecular genetics and biology of dementia

Spinocerebellar ataxia type 17 (SCA-17) or Huntington's disease-like-4 is a rare autosomal dominant disorder caused by the expansion of the CAG/CAA repeat (coding glutamine) in the TATA box-binding protein (*TBP*) gene (Bruni et al., 2004; Lasek et al., 2006). Ataxia is common, followed by dementia (Bruni et al., 2004; Koutsis et al., 2014). The presence of neuropsychiatric symptoms, including frontal dysfunction (personality change, emotional lability, apathy, irritability, disinhibited behaviours) at the outset of the disease may mimic FTD (Bruni et al., 2004; O'Keeffe et al., 2007). Onset is variable and ranges from 3 to 75 years. Affected patients have >47 repeats and develop neurologic or psychiatric symptoms (Bruni et al., 2004; Koutsis et al., 2014; O'Keeffe et al., 2007). Reduced penetrance is reported at 44–46 repeats. Other symptoms include parkinsonism, chorea (Huntington's disease-like), dystonia, and pyramidal signs (Bruni et al., 2004; Koutsis et al., 2014; Stevanin and Brice, 2008).

Mutations in the sequestosome 1 (*SQSTM1*) gene were initially identified as a cause of PDB, a common disorder of bone metabolism characterized by increased tissue turnover. However, mutations in *SQSTM1* have been found in both sporadic and familial ALS patients (Fecto et al., 2011) and also in FTLN patients (Rubino et al., 2012). *SQSTM1* is an 11-exon gene located on 5q35 and it encodes p62, a 440-amino acid adapter protein containing several proteins. However, at present, no clear genotype-phenotype correlations have been demonstrated (Rainero et al., 2017).

Homozygous deletions of exon 5 of the gene encoding optineurin (*OPTN*) have been described in Japanese siblings affected by ALS (Maruyama et al., 2010). The heterozygous triggering receptor expressed on myeloid cells 2 gene (*TREM2*) is a 5-exon encoding gene on 6p21.1, and *TREM2* mutations modulate the risk of FTD, in addition to increasing susceptibility to AD (Borroni et al., 2014a). A study identified different homozygous mutations in *TREM2* in three Turkish probands among 44 identified with FTD spectrum-like disease (Guerreiro et al., 2013a). Fourteen different mutations have been identified since in *TREM2* and an increased frequency of rare heterozygous *TREM2* variations were also detected in AD patients (Jonsson et al., 2013). Two new genes have been reported to be mutated in patients with FTD: *CHCHD10* (coiled-coil helix-coiled-coil-helix domain containing 10), which is located on chromosome 22 and encodes a mitochondrial protein that is enriched at cristae junctions in the intermembrane space; and *TBK1* (TANK1-binding kinase 1), which is located on chromosome 12 and encodes a serine/threonine kinase that plays an essential role in regulating inflammatory responses to foreign agents (Freischmidt et al., 2015; Zhang et al., 2015).

GWAS

In the first GWAS on FTD patients, a group of 515 individuals affected by FTLN with autopsy-proven TDP-43 inclusion pathology (FTN-TDP) were compared with 2509 healthy controls and an association with three single-nucleotide polymorphisms (SNPs) mapping to a single linkage

disequilibrium block on 7p21 was shown (Van Deerlin et al., 2010). Later, a two-stage GWAS was performed in a large cohort of 3526 FTD patients, in comparison with 9402 healthy controls, and a significant association at 6p21.3, HLA locus, together with a potential novel locus at 11q14, encompassing RAB38/CTSC (the transcripts of which are related to the lysosomal pathway), were found for bvFTD (Ferrari et al., 2014), suggesting that immune system processes, and possibly lysosomal and autophagy pathways, are potentially involved (Ferrari et al., 2014). A novel genetic insight into FTD and its clinical subtypes using a joint-SNP gene-based approach in 3348 clinically identified FTD cases and 9390 controls identified an association of the *TOMM40* and *APOE* genes with bvFTD, and the *ARHGAP35* and *SERPINA1* genes with progressive non-fluent aphasia (Mishra et al., 2017). The APOE-locus association with bvFTD indicates its potential risk-increasing role across different neurodegenerative diseases, whereas the novel genetic associations of *ARHGAP35* and *SERPINA1* with progressive non-fluent aphasia point towards a potential role of the stress signalling pathway in its pathophysiology (Mishra et al., 2017).

Conclusion

Molecular genetics of neurodegenerative disorders has come a long way, with the advent of large-scale GWAS and the most recent NGS. This has given us some great insight into the possible underlying mechanisms involved in these diseases. Interestingly, there is a common theme among the neurodegenerative diseases, and these genetic studies have outlined several pathways such as immune response, lipid metabolism, protein folding, and protein transport. This has led to several innovative approaches to targeting novel drug therapies, and many others will be discovered. Finally, most dementias are multifactorial and are not caused by genetic factors only. Therefore, more research is needed, particularly investigations of epistasis and gene-by-environment interaction.

Psychiatric assessment of older people

Chapter: Psychiatric assessment of older people

Author(s): Jonathan Huntley, Alan Thomas, and Rob Stewart

DOI: 10.1093/med/9780198807292.003.0009

Aims of the psychiatric assessment

The psychiatric assessment of the older person aims to provide an understanding of the symptoms the person is experiencing, so that diagnoses can be made and appropriate management plans formed. It is also a crucial opportunity to engage the person and commence a therapeutic relationship. A thorough assessment of all the potential needs of an individual is likely to take more than one assessment. The initial assessment should aim to gain an overall understanding and prioritize which areas should be the focus of any immediate management plans and any other areas that may need further subsequent assessment. In many ways, the structure of an initial psychiatric assessment is the same as in younger people, consisting of a thorough history taking, a detailed mental state examination, and a physical examination. However, both the balance of areas examined and the specific questions used should be adapted for older adults.

Psychiatric assessment of older people

Context of assessment

The immediate context of the assessment is the starting point and provides important information. Clinicians need to be flexible, to ensure the initial assessment is conducted in the most appropriate context, whether in the patient's home, an outpatient clinic, or residential care or on an inpatient ward. There are significant benefits to initially assessing patients at home, for both the patient and the clinician. Assessing someone at home allows them to be at their best in their environment, giving a more realistic assessment of mood, cognition, and general behaviour, and allows a more thorough assessment of their context, including family dynamics and their home environment, than would be possible in the clinic. Observing the general level of cleanliness, evidence of trip hazards such as loose carpets or objects on the floor, and, after permission, a quick inspection of the fridge and kitchen can provide important information into environmental risks and the level of function (Ng and Atkins, 2012). Note should be made of the level of clutter or hoarding, trip hazards, and fire safety, including the presence of smoke alarms. There may also be written care plans available from carers or district nurses and it is useful to ask the patient to show the clinician their medication, both to confirm doses and to look for evidence of compliance. These benefits of home assessments are complemented by evidence suggesting that patients (Jones, 1987) and general practitioners (Hardy-Thompson et al., 1992) prefer home assessments to outpatient appointments. In addition, home visits are more flexible than, and as time-efficient as, outpatient clinic assessments (Benbow, 1990) and are associated with less non-attendance (Anderson and Aquilina, 2002) and more effective follow-up.

There is clearly a wide range of other contexts in which older people are assessed, including inpatient units, acute hospital settings, police stations, general practice surgeries, care homes, and day services. A significant number of referrals to old age psychiatric services come from wards in general hospitals, and assessment of patients by old age liaison services requires further specialist skills and approach, which will be discussed in Chapter 24. Another common setting for conducting an assessment is in a care home. In this context, it is important to gather initial information from social services, records of previous medical assessments that may have been made prior to moving into the care home, and any available care records from care staff. This will help to ascertain the reason the patient is living in a care home and enable the focus of the assessment to be on current issues. If the assessment takes place in the outpatient setting, simple factors such as whether the individual was able to arrive on time, if they drove or came on public transport, and who is with them can provide useful information about function.

Along with the geographical location of the assessment, the time frame is also important. Is the assessment urgent or routine? How has the person accessed the service? Who referred them and why? This information

Psychiatric assessment of older people

should be available from the referral documents prior to meeting the person and provides important context before a face-to-face meeting. In addition, there are several patient factors that need to be considered in advance, if possible. Is a translator required, or are there any cultural sensitivities around the timing or location of the assessment that should be considered? Are there any potential risks to the clinician in conducting the assessment, particularly with home visits? Is there any information from the referrer about important sensory or communication difficulties that may require additional resources (e.g. use of Braille or picture boards)? If the referral has been made by primary health services or social services, it is important to access as much information as possible about the person in advance of the assessment.

The psychiatric assessment

At the start of the assessment, it is important to clearly introduce yourself, explaining who you are and why you are there. It is not uncommon for individuals to not be aware that they have been referred, as this may have been precipitated by concerned relatives. Tact and sensitivity are needed to explain the concerns others may have about the patient and also to explain the reason for, and the purpose of, the assessment. If a person refuses to be assessed, then it may be necessary to consider the potential urgency and risk and whether an assessment will need to be arranged subsequently under the Mental Health Act. In these circumstances, clear communication with the referrer and other relevant agencies, such as social services, is vital.

A collateral history from a relative or friend is almost always useful and should form part of the assessment, particularly in people with cognitive impairment. It is therefore important to ask permission to speak to a relative or friend, although this should be done sensitively. It is usually better to speak separately to a relative or friend to gain collateral history, and then to speak individually to the patient. However, often the patient will request to have a friend or a relative present throughout the assessment, and this can also provide a useful insight into their communication, awareness of potential behaviour or symptoms, and relationship dynamics. During the general introduction, it is also clearly important to clarify whether the patient has any visual or hearing aids they require and is comfortable and able to engage in an assessment as best they can. Table 9.1 summarizes the general approach set out in this chapter.

Table 9.1 General approach to history and examination.

History	Mental state examination
History of presenting complaint	Appearance and behaviour

Psychiatric assessment of older people

Past psychiatric history	Speech
Past medical history	Mood
Medication and allergies	Thought
Drug and alcohol history	Perception
Family history	Cognition
Personal history	Capacity
Premorbid personality	Risk
Social history	
Forensic history	Physical examination

History

As with all psychiatric assessments, the history is the main focus. For individuals referred to a service, the presenting complaint may be stated by the referrer. However, it is useful to ascertain why the individual thinks they are being assessed and how aware they are of the assessment. In people with cognitive impairment, it is not uncommon for them to be unaware of any difficulties and therefore to deny any 'presenting complaints', and a simple opening question such as 'how can I help you' or 'what brings you to clinic' may be met with a denial of any difficulties and an expression of surprise or anger at the referral. A more open question such as 'is there anything that has been concerning you?' or 'do you have any concerns about your memory?' may be a useful starting point, or engagement in a neutral topic of conversation to begin with to build rapport.

History of presenting complaint

The major focus of an assessment is to identify what the main problems are, what has led up to the current presentation, and why the person is seeking help or been referred now. The duration, pattern of onset, and time frame of the presenting problems are important and may help differentiate acute versus chronic confusional states and identify any clear precipitating factors. Decisions as to which open and more closed questions to ask will be framed by the context and most obvious presenting symptoms. For example, a memory assessment will precipitate questions relating to duration, pattern of onset, and progression of memory difficulties. In contrast, a report of low mood will precipitate questions regarding the onset and duration of depressive symptoms,

Psychiatric assessment of older people

including sleep disturbance, fatigue, or loss of interest in living and previously enjoyed activities, which may be more prevalent in late life depression than in younger adults (Fiske et al., 2009). When assessing the duration of illness or evidence of change with time, it can be helpful to ask how they were at a point in the recent past, e.g. last Christmas, and how things have changed since then. If there is concern regarding cognitive impairment, it is also important to cover the range of non-cognitive symptoms that occur in dementia, including social interaction, mood, paranoia, hallucinations, agitation, sleep, and wandering. Questions should also be asked about difficulties with everyday function, recording specific examples and noting areas that may require further specialist assessment by occupational therapy or social services. A collateral history will be very useful here, as having the opinion of an informant regarding what the main issues are and how they have developed and presented may help to build a more complete picture of recent events and the main problems that may need addressing.

Past psychiatric and medical history

It is important to establish as clear a history as possible of previous or concurrent psychiatric and medical illnesses. Medical comorbidity is common in patients referred to old age psychiatric services (Loi and Chiu, 2011), and therefore, it is the norm, rather than the exception, to have multiple physical conditions that may impact on mental health, and vice versa. An account of whether the person has had any previous diagnoses of psychiatric illness, including how that was managed (e.g. inpatient versus outpatient, pharmacological versus psychological therapy), and the context is useful, given the relapsing-remitting nature of many psychiatric conditions. A history of the severity of any previous episodes of psychiatric illness is important, including history of self-harm or aggression, use of the Mental Health Act, and length of episodes. If possible, a history of which treatments have proved beneficial in the past or whether any medications have been unsuccessful or led to side effects is important. Establishing what factors have been helpful or unhelpful in managing previous episodes and how the person wants to receive support can aid recovery. As with all areas of the history, a collateral history from an informant or from the general practitioner (GP) is often necessary, as patients may forget or brush over previous illnesses. It is useful to confirm any medical conditions recorded on GP referral records, both to establish the past medical history and as a way of assessing whether the patient has impaired recall of major events or illnesses.

Physical health conditions can have an enormous impact on mental health and as full a history as possible of previous and current physical conditions is important. Specific attention should be paid to common 'vascular risk factors' that increase the risk of dementia such as diabetes, hypertension, hypercholesterolaemia, stroke, and myocardial infarction (Gorelick, 2004). A sense of the patient's understanding or anxiety relating to their physical health is also important, as this may help assess the precipitant for the current presentation. It is also helpful to try and

Psychiatric assessment of older people

establish who else is currently involved in the person's care, to enable clear communication between specialties and prevent unnecessary investigations or conflicting management strategies. Any recent hospital admissions and ongoing outpatient care should be noted, including any forthcoming procedures or investigations.

Medication

Polypharmacy is very common and many medications may have side effects that impact on mental health. For example, the impact of anticholinergic side effects of common medications on cognition may be missed or underestimated (Bishara et al., 2017). Any recent additions or changes to medication should be noted, particularly if the patient has recently had an admission to a general hospital.

Treatment adherence should also be assessed, and a benefit of home assessments is the ability to ask patients to show you their medication. This helps to assess both their awareness of what medication they are meant to be taking and why, and enables a more accurate record of what medication is actually taken. Tablet blister packs, dosette boxes, and dates can be checked to identify if there is any evidence of accidental or deliberate non-compliance. It also aids an assessment of the risk of accidental or deliberate overdose by demonstrating what medication is in the house and how it is accessed.

Any known drug side effects or allergies should be recorded, along with any other relevant observations or reports such as difficulties with swallowing medication, opening blister packs, or administering insulin.

Drug and alcohol history

Alcohol use in older people is common (O'Connell et al., 2003) and abuse of other substances may also be an issue (Kuerbis et al., 2014). Previous and current alcohol and illicit drug use should therefore be assessed, as should potential dependence on analgesics (particularly opiates) or benzodiazepines. Alcohol intake should be assessed in terms of daily or weekly units and any evidence of hazardous drinking and impact on physical health and psychiatric symptoms.

Family history

A brief family history of psychiatric or medical illnesses is useful, although it may be difficult to corroborate this information. This allows assessment of illnesses that may have some increased risk in first-degree relatives, but also experience of illness in the family (e.g. experience of a parent or sibling with depression or dementia) that may impact on the person's awareness or concern about their own symptoms. It also allows an assessment of the family tree, including whether there are any living relatives. Asking about family history is also an opportunity to assess

Psychiatric assessment of older people

recall of autobiographical information as part of the assessment of cognitive function.

Personal history

A personal history sets the context of the individual and is important for understanding the patient as a person. It enables an insight into important events in their life that shaped them and may have continued impact or relevance. In many cases, particularly in individuals with cognitive impairment, it also enables a way of assessing autobiographical memory that may seem less confrontational than more formal cognitive assessment. It can also be a useful line of questioning to build rapport and demonstrate interest in the individual. For this reason, it may often be helpful to move to the personal history near the beginning of the interview, because patients may happily talk about their early life, as important dates or anecdotes from early life may be more easily remembered than more recent events.

Relevant areas include any significant difficulties around birth and early development, and a brief understanding of their childhood context can be helpful in identifying current relational dynamics.

An overview of schooling and academic ability, such as school-leaving age, examinations passed, and any higher education or vocational qualifications, can be helpful, particularly when assessing cognitive function and evidence of decline. However, often patients may have left school at age 14 or have limited education due to socio-economic or cultural reasons, so care should be taken not to infer the level of intelligence from education. A brief overview of their employment history is also useful, including reasons they stopped work, any concerns about current employment, and the range of employment, as these provide important insight into their life and the potential impact of any medical or psychiatric illness.

Family and personal relationships are also key in understanding a person's history and current circumstances, both in terms of support and areas of conflict or distress. Information about their relationship with parents and any siblings, including ongoing relationships, is useful. A history of relationships, including marriage and current partner, any children, and grandchildren and their level of contact and involvement, is important, as an assessment of the social network and level of support available from friends and family is a crucial part of both assessment and considering management options.

Premorbid personality

Establishing a sense of a patient's premorbid personality may help to provide evidence of recent change. It can be useful to establish if they are predisposed to anxiety, depression, grandiosity, or aggression and to identify personality changes that may accompany dementia, particularly

Psychiatric assessment of older people

FTD. Asking how a patient sees themselves now and asking an informant how they have changed can be helpful in this respect.

Social history

The social history provides an opportunity to gather information about a patient's current social setting, the level of support or care needs, and everyday function. Information on the type of accommodation (e.g. flat, house, bungalow) and whether it is privately owned or rented and what agencies (e.g. social services, housing association) are involved is useful. It is also important to ask about access—do they have stairs and, if so, are they able to manage them? Do they live in a block of flats, and is there a working lift? How often do they leave their accommodation? It is also helpful to ask about the setting—do they feel their neighbourhood is dangerous, safe, isolated, or noisy? The quality of relationship with neighbours can be key both for support and potentially in the development of symptoms (e.g. persecutory delusions or partition delusions in late-onset psychosis).

It is helpful to ask about the patient's current range of social activities and hobbies. What do they enjoy doing and who do they see on a regular basis? Are they a member of any clubs or societies? Asking if they are able to do activities they used to enjoy may give clues towards cognitive or functional change or depressive symptoms. Do they have any ongoing responsibilities or childcare, e.g. looking after grandchildren?

Any areas of function not already addressed in the history should be explored here. Is the patient able to manage ADLs such as washing, cooking, cleaning, using the telephone or Internet, and shopping? Do they have professional carers, and, if so, are these privately funded or coordinated by social services? What services do carers provide and how often? Do they feel this is enough, or too much? Do they continue to drive or are they able to use public transport? Have they had any incidents or near misses when driving or got disorientated and lost when out of the house? Asking an informant about driving safety can be important and it may be necessary to ask the patient to stop driving in order to allow further assessment to take place. Clinicians should be aware of Driver and Vehicle Licensing Agency (DVLA) guidelines on driving for patients, including the requirement for all people with a diagnosis of dementia to inform the DVLA and to adhere to these. Driving is discussed in more detail in Chapter 57.

Finances should also be enquired about. How do they manage their finances, pay bills, or access any pensions or benefits? Is there a lasting power of attorney in place? Do they have any concerns about finances? The possible risk of financial exploitation and abuse of older people needs to be considered and safeguarding concerns raised with social services if this is suspected (Crosby et al., 2008). Although this may not be a discussion for an initial assessment, it may also be important to establish

Psychiatric assessment of older people

if the patient has any wishes for future care, and this may lead to important discussions around advance care planning.

Forensic history

It is important to ask whether the patient has a forensic history, both as part of the autobiographical history and to inform risk assessment.

Collateral history

Finally, and as indicated several times already, a collateral history from an informant who knows the patient well is often critical in gaining a full understanding of the presenting complaint and individual. This may be from a caregiver, friend, or family member. It is important to establish how well the informant knows the person and how frequently they have contact, as this may impact on how reliable any observations of change in behaviour are. For example, observations from a family member who lives with the person will differ from a friend who only has intermittent telephone contact. Asking an informant for their account and opinion of what the main issues are can be helpful both to provide information and to establish the priorities for management. With the permission of the patient, it may be helpful to have a conversation with an informant away from the patient, as a carer or family member may be reluctant to speak openly about their concerns in front of the patient. Although it is not generally appropriate to carry out a formal assessment of this, care may be needed to pick up any evidence that the informant may themselves have cognitive impairment or a mental disorder influencing the accuracy of the information provided, as well as wider considerations of reliability such as ulterior motives or safeguarding issues. Multiple informants may be required where these complications are suspected.

Mental state examination

Appearance and behaviour

As in all areas of psychiatry, the appearance and behaviour of the individual can provide an enormous amount of diagnostic information. Personal appearance may give information about whether they are able to maintain personal and dental hygiene, shaving, and cleanliness. Are they dressed appropriately for the setting and temperature? Does it seem like their clothes fit and are washed, or are they put on incorrectly or stained? If they live alone, are they able to maintain their own washing and dressing? A benefit of conducting home visits is the ability to assess the home environment. Is the home clean and tidy or disorganized, dirty, and demonstrating potential evidence of neglect, environmental dangers, hoarding, or squalor that may require urgent intervention? Poor self-care may be present in a range of conditions, including dementia, depression, and psychotic illnesses (Pavlou and Lachs, 2008).

Psychiatric assessment of older people

Alongside observation of the physical appearance, how is the patient's demeanor and eye contact? Are they calm and cooperative with the assessment, or hostile and aggressive? Are they agitated or anxious, picking at their hands or clothing? Do they seem distracted and have difficulty attending to you or the conversation, which may indicate delirium, depression, or psychosis? Do they show the characteristic minute-by-minute fluctuation often seen in delirium? Are they able to answer questions and engage, or are they constantly looking to a family member or friend for support and reassurance, which may suggest cognitive impairment, anxiety, or depression? In older people, psychomotor changes can be especially prominent in affective disorders, with agitation a common feature of depression (Fiske et al., 2009). Apathy is common in early dementia and may be mistaken for depression (Robert et al., 2009). However, a patient with apathy may be able to engage well when directly addressed and show a reactive mood.

The presence of relevant medical comorbidity may also be evident. For example, is there a tremor or evidence of hemiparesis? Is there significant deafness or visual impairment? Are they mobile or chair- or bed-bound? Observations of this kind will also obviously depend on the setting of the assessment, as seeing a person in an acute hospital setting may create a different set of expectations around their appearance and behaviour, compared to assessing someone in an outpatient clinic or in their own home.

Finally, what is their posture and body language towards you and others? Are you able to build a rapport with the person, or are they guarded, dismissive, hostile, or irritable? Are they inappropriately tactile or flirtatious in their manner? Do they turn away or refuse to look at you, or make threatening or aggressive gestures? It is important to maintain your safety and that of the individual, and therefore, note any aggressive postures and terminate the assessment if necessary.

Speech

The assessment of speech should note the rate, rhythm, and volume. If speech is abnormally rapid, can it be interrupted and, if so, for how long? Are there any spontaneous pauses or will it continue indefinitely? However, in older adults, it is more common to experience patients with impoverished or quiet speech and dysphasia, which may occur in dementia and neurological conditions. As depression is more common than mania in older adults, a reduced rate and poverty of speech is more often seen than loud or increased rate of speech. Finally hearing impairments are common in older people, and therefore, the quality of speech or apparent understanding may be due to deafness, rather than receptive dysphasia. The assessment of dysphasia is covered in detail in Chapter 11.

Psychiatric assessment of older people

Mood

The assessment of mood follows a similar approach to that in younger adults. However, some features of depression are more prominent in older than younger adults. In addition to asking about the subjective experience of low or elevated mood, subjective complaints of poor memory and concentration are also common among depressed older adults (Fiske et al., 2009). Depressive illness in older adults may also be accompanied by more prominent psychomotor retardation or anxiety than in younger adults. Therefore, a presentation of anxiety and agitation in an older adult warrants a careful assessment for depression. In depressed older people, thoughts of wanting their life to end may be present, but active suicidal ideation is rarer and any suicidal thoughts should be taken seriously and carefully assessed (see Risk assessment, p. 150).

Objective assessment of affect needs to consider medical comorbidity. Parkinson's disease may lead to reduced facial expression, which needs to be considered when assessing affect. Cerebrovascular disease may be associated with mood lability, which may present as apparently spontaneous, but typically short-lived, episodes of weeping without any substantial lowering of mood, particularly following stroke (Calvert et al., 1998). Elevation of mood tends to be less significant in mania in older adults than in younger people and may also be seen in FTD.

It is also the case that older adults may be more reluctant than younger adults to discuss their feelings and may minimize their symptoms. Therefore, close attention needs to be paid if a patient is apparently dismissive about their mood.

Thought

Form of thought, sometimes described under 'speech', rather than 'thought', in the mental state examination, may be difficult to assess in patients with dysphasia. The presence of organic brain disease or acute confusional states may also present with apparent thought disorder, and disentangling a 'pure' functional thought disorder from cognitive impairment can be challenging. Abnormalities in the form of thought (including thought withdrawal, broadcast, and insertion) can occur in schizophrenia, depression, and bipolar illness. However, formal thought disorder is less common, and possibly even absent, in late-onset schizophrenia (Howard et al., 2000). Incoherence of thought is common in dementia and more common in advanced disease, although it can also occur in the early stages. As with pressured speech, a few minutes' observation during an appropriate point in the conversation may help to delineate the severity of formal thought disorder according to the length of time a coherent theme (or response to a question) is maintained before moving off-topic. It may also be helpful in delineating persistent thought disorder accompanying psychotic states from the more fluctuating mental state characteristic of delirium.

Psychiatric assessment of older people

Delusional ideation in older adults may take different forms, depending on the underlying condition. Within AD, paranoid and persecutory delusions are common. These have been divided into delusions of theft, harm, morbid jealousy, and abandonment (Reeves et al., 2012).

Misidentification phenomena are also common in AD and include a range of beliefs such as 'phantom boarder' (the belief that someone else is living in their home), the belief that people seen on television are really present in the room, the 'mirror sign' (where patients fail to recognize themselves in the mirror, believing themselves to be a stranger), Capgras syndrome (the belief that a relative or carer has been replaced by an imposter), and belief that 'this house is not my house' (the inability to recognize one's home environment) (Reeves et al., 2012).

Within severe depressive illness, mood-congruent nihilistic delusions may be present. In late-onset schizophrenia, persecutory delusions and partition delusions are common (Howard et al., 2000), and while complex and sophisticated delusions are unusual in dementia, these remain typical of schizophrenia in either its early- or late-onset forms. As with other aspects of the mental state, delusional beliefs may be expressed in delirium but are characteristically fluctuating and inconsistent.

Perception

Perceptual abnormalities may be auditory, visual, olfactory, gustatory, or tactile. As well as occurring in psychoses, perceptual abnormalities may be described in patients with primary visual or auditory pathology or in delirium and forms of dementia, particularly LBD and PDD. Delirium is a common cause of perceptual abnormalities, particularly visual and tactile hallucinations, and should always be considered.

Auditory hallucinations may range from simple, unstructured sounds to voices heard in the second person or third person, as a running commentary, or as thought echo. Hallucinations of unstructured sounds may occur in acute organic states. However, more complex auditory hallucinations and specifically hearing voices are most characteristically experienced in schizophrenia or affective psychoses (Oyebode, 2015).

In comparison to auditory hallucinations, visual hallucinations more characteristically occur in organic states, rather than in functional psychosis (Waters et al., 2014). Visual perceptual abnormalities may range from illusions to fully formed hallucinations (Norton and Corbett, 2000). In some cases, it may be difficult to be sure whether the visual hallucination is truly occurring in the absence of a real stimulus or whether it is a misperception resulting from poor eyesight or some other defect in visual processing. Charles Bonnet syndrome presents with complex visual hallucinations, usually in association with visual system pathology, but without significant cognitive impairment, alteration in consciousness, or demonstrable psychopathology (Ffytche and Howard,

Psychiatric assessment of older people

1999). The characteristic visual hallucinations in LBD are often complex and of people or animals (McKeith et al., 1996).

Olfactory hallucinations may occur in epilepsy, particularly temporal lobe epilepsy, schizophrenia, and other organic states (Velakoulis, 2006). Late-onset schizophrenia may be more likely than early-onset schizophrenia to present with visual, tactile, and olfactory hallucinations and third-person, running commentary, and accusatory or abusive auditory hallucinations (Howard et al., 2000).

Cognition

A detailed description of cognitive assessment is provided in Chapter 10. Cognitive assessment is obviously crucial in the assessment of the older person. In some settings, it may be appropriate to formally assess the cognitive function of an individual early in the assessment, as an understanding and interpretation of other symptoms or reliability of the description of events may depend on establishing whether there is evidence of cognitive impairment. During an initial assessment, a broad assessment tool such as the MMSE (Folstein et al., 1977) or Montreal cognitive assessment (MoCA) (Nasreddine et al., 2005) may be sufficient to provide evidence of whether cognitive impairment is present. However, a more detailed cognitive assessment is often very useful and necessary to enable the diagnosis of subtypes of dementia and give a full understanding of preserved abilities and areas of specific difficulty. In situations when cognitive assessment is refused or is not feasible, some clues as to impairment may be gathered, as mentioned, from the history and other aspects of the examination (e.g. observing for fluctuating attention, characteristic of delirium), but a reliable informant account is likely to be invaluable.

Insight and capacity

The assessment of insight is important, as willingness to engage with services and treatment plans is strongly influenced by an individual's insight into their illness. The clinician should therefore aim to engage the individual and understand their opinions on whether they may have an illness and require treatment, rather than challenge them over their beliefs about their illness. People with dementia often lack insight into their cognitive difficulties, and therefore, a collateral history is paramount.

The assessment of capacity is also an essential skill for those working with older people and is discussed in more detail in Chapter 52 and Chapter 58. The Mental Capacity Act 2005 (Department of Health, 2005) clearly sets out the steps involved in the assessment of a person's capacity to make a particular decision at a specific time or in a specific situation. It is assumed that all older adults have capacity to make decisions, unless proved otherwise. The assessment of capacity firstly requires there to be an impairment of the mind or brain. Secondly, there

Psychiatric assessment of older people

needs to be an assessment as to whether any such impairment is sufficient to impair decision-making capacity. Standard questions set out in the Mental Capacity Act are whether the person can: (1) understand relevant information; (2) retain the information (long enough to make a judgment); (3) use or weigh the information; and (4) communicate the decision, ensuring attempts have been made to overcome any sensory or communication difficulties. While the assessment of capacity is a very important skill, as capacity is specific to a particular decision or function, it should only be formally assessed in response to a specific request or question.

Risk assessment

Risk assessment is an important part of the psychiatric assessment of older adults. This includes areas that are common to patients of all ages and more focused areas where individuals with cognitive decline may be vulnerable. Table 9.2 demonstrates possible areas of risk assessment.

Table 9.2 Areas for risk assessment.	
Deliberate self-harm	Risk of self-harm or suicide
Accidental self-harm	Accidental overdose or non-compliance, self-neglect, falls, fire, wandering
Harm to others	Emotional or physical harm, due to aggression, sexual disinhibition, unsafe driving, carer stress, risk to children
Harm from others	Emotional or physical harm, due to violence, elder abuse, financial exploitation
Social and environmental risk	Poor hygiene, cleanliness, hoarding, trip hazards, fire risk, social isolation, loneliness
Physical health risk	Frailty, deterioration in physical health, self-neglect

Deliberate self-harm is less common in older than younger adults, and acts are more likely to represent failed suicide attempts than acts of self-harm (Dennis and Owens, 2012). Older adults may express that they feel they have lived long enough and are ready to die, or wish they would die. However, the belief that life is not worth living should not be considered normative in later life (Van Orden et al., 2015). A detailed exploration of whether any planning or preparations for death have been made (e.g. writing a will, looking up methods of suicide online or in books, speaking

Psychiatric assessment of older people

to euthanasia clinics, stockpiling medication, writing suicide notes) should be made. Following a failed suicide attempt or an act of self-harm, establishing the intent at the time, the perceived lethality, and the timing (e.g. timed to prevent or allow discovery) may help to assess the risk of further attempts.

Accidental self-harm is significantly more common in older than younger people, particularly in those with cognitive impairment. This includes falls, and referral to a local falls clinic for further assessment may be indicated. Lack of compliance or inability to administer medication appropriately can lead to accidental harm, as could unintended self-neglect. Assessment of driving is important for older people, particularly those with a diagnosis of dementia. The DVLA requires that any diagnosis of dementia is reported and patients should be asked if there have been any recent incidents or near misses and ensure that they know of the need to inform the DVLA.

It is important to assess for harm to others. This may be due to physical or verbal aggression, and people with dementia may develop aggressive behaviour, which may precipitate the need for institutionalization (Gilley et al., 2004). Asking an informant whether there have been any incidents of physical aggression is important, as patients with dementia may not recall such incidents. However, they are a significant cause of carer stress and risk and are often challenging to manage.

The assessment of social and environmental risk factors may require a multidisciplinary approach, with occupational therapy or social services assessments providing professional assessment of the environment and any areas that could be addressed.

Physical examination

A brief physical examination is appropriate. If there is any evidence the patient is physically unwell or delirium is suspected, then examination of cardiovascular, respiratory, and gastrointestinal systems prior to referral to colleagues at the general hospital may be indicated. A brief neurological examination of tone, power, sensation, and gait may identify evidence of parkinsonism or stroke. Physical examination is covered in more detail in Chapter 11.

Further assessment

The aim of the initial psychiatric assessment is to formulate a differential diagnosis and prioritize areas that may require immediate action and those that require further assessment. Inpatient admission and assessment may be necessary if there are significant immediate risks or severe behavioural disturbance. If there are no urgent risks identified, further assessment may take place in the community. The use of crisis resolution and home treatment teams for older adults is becoming more widespread and this provides an option for intensive monitoring and assessment in the community; however, the effectiveness of these

Psychiatric assessment of older people

services remains unclear (Streater et al., 2017). It may be appropriate to request an assessment of ADLs or function in the home environment by an occupational therapist. This may help clarify the degree of functional impairment in an individual with early cognitive impairment or could provide an assessment of whether equipment or adaptations to the home could enable a person with dementia to maintain independence or reduce environmental risks.

Similarly, it is often appropriate to refer the patient and family to social services for a care needs assessment or carer assessment. This is important to identify the social care needs of the patient and to access any necessary support, including carers, meals on wheels, and access to day centres, and also to plan for a potential move into residential or nursing care. If there are any urgent concerns regarding safety, vulnerability, abuse, or exploitation, then urgent referral to social services for safeguarding assessment may be necessary.

The medical assessment will usually require further investigations to identify any underlying medical problems that may be causing or contributing to the presentation. As a minimum, blood tests to examine urea and electrolytes, full blood count, thyroid and liver function, and folate and vitamin B deficiencies are required. In many cases, particularly if any abnormalities are detected on neurological examination or if there is cognitive decline, neuroimaging [computed tomography (CT) or MRI] is often appropriate. In cases of borderline cognitive decline or where the differential diagnosis of dementia is unclear, a detailed neuropsychological assessment by a psychologist may be very helpful to identify the pattern and extent of impairment (Jacova et al., 2007).

Principles of management

Having completed an initial assessment, the management plan should develop according to the differential diagnosis and any identified areas of urgent need or those that require further assessment. There are a wide variety of management options open to the old age psychiatrist, based on the diagnosis, urgency, and wishes of the patient and family. The clinician may commence, titrate, and monitor pharmacological treatment or provide or refer for non-pharmacological treatments, including psychological therapy, both of which are discussed in detail in Chapter 13 and Chapters 16, 17, and 18. As in all areas of psychiatry, a holistic approach is paramount, with consideration of the social, functional, and physical needs of the patient as important as psychiatric or psychological management. Perhaps more than in all other groups, liaison with other health care professionals and other agencies, such as primary care, social services, family members, and voluntary agencies, forms a standard part of care. Throughout the assessment and management process, the psychiatrist has an essential leading role using his or her expertise to make key decisions, supervise other team members, and ensure the patient's care is optimally and ethically delivered.

Clinical cognitive assessment

Chapter: Clinical cognitive assessment

Author(s): Sean O'Dowd

DOI: 10.1093/med/9780198807292.003.0010

Introduction

A comprehensive assessment of cognition in the older patient demands a methodical approach, encompassing detailed history-taking from both the patient and an informant with interrogation of the various cognitive domains. In addition, given cognitive symptoms frequently do not occur in isolation, a complete assessment of cognition should also be accompanied by a careful neurological and psychiatric examination.

The forum in which the assessment takes place may influence the extent and focus of the examination; in this chapter, the setting is that of the outpatient 'memory clinic', although many services offer cognitive evaluation in the home setting which can provide context-specific information on functional performance. Assessments of older cognitively impaired patients on acute medical or surgical wards often pose greater logistical challenges, but a broadly similar approach should be feasible. It is crucial, however, to ensure that any such ward-based assessment is not

Clinical cognitive assessment

confounded by reduced alertness or attention (most typically a delirium, or other types of intercurrent toxic-metabolic encephalopathy). In this case, a reduced assessment is more appropriate, documenting orientation levels and the ability to follow sequential commands as a measure of attention and deferring a more detailed assessment until the patient's baseline is regained (see Chapter 37 for a more detailed exploration of delirium).

History-taking

As a rule, the history of the patient with cognitive symptoms should be taken both directly from the patient, as well as separately from an informant—usually a spouse or close family member. Most well-structured memory clinics request in advance that the patient attends with an informant, and are structured so that each can be interviewed separately and then together. Despite these arrangements, a proportion of patients arrive at such clinics unaccompanied. This can be instructive—attending alone is a powerful predictor of the absence of cognitive impairment and/or the presence of subjective memory complaints (Larner, 2014). However, as always, context is important and an elderly widowed patient attending alone cannot be viewed in the same light as a younger patient in full-time employment who attends without their partner. Hence, as noted earlier, domiciliary visits can be more revealing to clarify the domestic circumstances and provide practical insights into functional abilities.

The history elicited from the patient and informant should begin with broad, open questions, e.g. 'why are you here with us today?', 'are you concerned about your memory?', 'what trouble have you had recently with your memory?'. The questioning strategy should become more targeted, as the information provided begins to yield clues as to the salient cognitive domains affected. Many cognitive clinicians will commence the interview by asking autobiographical questions. These often put the patient at ease and provide some information as to the psychosocial context of the individual, as well as early information on the integrity of long-term memory. Educational and cultural exposure is a key factor in assessing performance on structured cognitive tests. Autobiographical deficits are relatively unusual as a presenting complaint in the memory clinic and most commonly point to one of three possible aetiologies: excessive alcohol use, long-standing poorly controlled temporal lobe seizures, or affective disorders (with or without a psychogenic component).

The patient who presents with established multi-domain global impairments will often pose a challenge in terms of accurate classification, but establishing the first cognitive domain affected from the informant usually has considerable value in distinguishing the diagnostic phenotype. Using broad categories, caregivers can usually quite readily identify which of memory, language, visual function, or behaviour disturbance was the first to become evident. Some features

Clinical cognitive assessment

which can be helpful in distinguishing the aetiology of cognitive disturbance are listed in Table 10.1.

Table 10.1 Discriminating features in common neurodegenerative diseases		
Disease	History	Clinical findings
Alzheimer's disease	Repetition of the same question with rapid forgetting of the answer Getting lost on familiar routes	Disproportionate deficits in categorical > letter fluency Amnesic deficits that do not improve with cueing
Frontotemporal dementia (FTD)		
Behavioural variant (bv)	Loss of empathy Eating changes Rigid behaviours and stereotypies Social inappropriateness Disinhibition Lack of insight	Poor rapport-forming with examiner Concrete abstraction Deficits on Frontal Assessment Battery
Semantic dementia	Difficulty with naming objects Inability to understand meaning of words	Fluent, but empty, speech Poor word recognition Surface dyslexia
Progressive non-fluent aphasia	Mispronunciation of words New or recrudescant stammer	Agrammatic, telegraphic speech Difficulty with repetition of multisyllabic words Orobuccal apraxia (e.g. cannot whistle or yawn to command)
Logopenic aphasia (often underlying AD pathology)	Slow speech and difficulty with naming objects	Prominent anomia and word-finding pauses Impaired sentence repetition

Clinical cognitive assessment

	Longer sentences are not understood	
Frontotemporal dementia with motor neuron disease (FTD-MND)	Rapid progression of a behavioural syndrome and/or language deficits, often with prominent delusions and/or hallucinations (transient)	Muscle atrophy Fasciculations (limb or tongue) Spastic or nasal speech Focal weakness
Progressive supranuclear palsy (PSP)	Falls (often retropulsion) Profound apathy and/or impulsivity Slowed movement and thinking	Frontalis overactivity Axial rigidity, retrocollis Slow vertical saccades or vertical gaze palsy Loss of postural reflexes
Dementia with Lewy bodies	Visual hallucinations Fluctuating cognitive ability Falls, tremor REM sleep behaviour disorder	Mild parkinsonism Disproportionate visuospatial dysfunction
Corticobasal syndrome	Difficulty using objects with one hand Limb having 'a mind of its own'	Limb apraxia Stimulus-sensitive myoclonus Parkinsonism May develop non-fluent language syndrome
Huntington's disease	Family history (autosomal dominant) of movement disorder or prior psychiatric diagnoses or suicidality	Generalized chorea
Vascular dementia	Vascular risk factors	Pyramidal signs

Clinical cognitive assessment

	May have stepwise decline, but frequently do not	
Creutzfeldt-Jakob disease (CJD)	Rapid cognitive decline Neuropsychiatric features Movement disorder	Ataxia, tremor, myoclonus
Normal pressure hydrocephalus	Gait deterioration Slow cognitive processing Urinary incontinence	Apractic magnetic gait Hyperreflexia

Memory

The patient with typical anterograde episodic amnesic impairment may struggle to illustrate their difficulties with examples, as opposed to the patient with subjective cognitive complaints who can provide detailed examples of what they perceive as memory failure. An attempt should be made to distinguish true medial temporal 'rapid forgetting' from working memory failures where attentional components are more at play. In the latter, patients will retrieve the missing information or item, or at least recognize it when re-presented, unlike the patient with amnesic mild cognitive impairment (MCI) who may not. In the truly amnesic patient, the accompanying informant will frequently volunteer examples of rapid forgetting and repetitive questioning, into which the patient may have limited insight. In day-to-day life, the informant may report that the patient who enjoys television viewing can no longer recall or 'follow' the plots of soap operas or movies, or that an erstwhile sports fan cannot remember the outcomes of important sporting encounters, minutes or hours after watching them.

It is important to gauge the extent of functional impact of the reported amnesic symptoms. This can be broached by asking if important appointments/engagements have been missed; if there has been repeated difficulty recalling PIN numbers for banking cards; and if there have been episodes with safety implications such as inadvertent repeat dosing, or omission of, medications or failure to turn off electrical appliances, etc. Difficulties in managing finances (less easy to identify in the era of direct debits) or keeping up-to-date with car taxing and insurance dates may be identified. Many patients with preserved insight in the early stages of an amnesic cognitive syndrome will begin to use memory aids such as lists or written or electronic reminders. Functional impairment can be more difficult to establish where the informant or other family members have always, or more latterly, assumed some of the responsibilities of the patient (e.g. the doting spouse or son/daughter who insists on laying out

Clinical cognitive assessment

clothing for the older patient, preparing their meals, and generally running the household) and/or where this is downplayed due to fear of a negative diagnosis.

Visual memory is important to explore also—topographical disorientation (TD), such as route-finding difficulties in familiar localities, is a sensitive marker for possible parieto-occipital degeneration and may be a harbinger of the posterior cortical atrophy (PCA) variant of Alzheimer's disease (AD) or dementia with Lewy bodies (DLB). The neuroanatomical basis of TD is complex but is largely felt to derive from a failure to access stored allocentric spatial memory, along with landmark agnosia.

Prosopagnosia—the inability to recognize familiar faces—is a rarer finding, implicating the ventral occipitotemporal 'what' visual pathways and should not be confused with the relatively innocuous phenomenon of being 'unable to put a name to a face'. Prosopagnosia can have quite dramatic manifestations with patients not recognizing close family members, or even their own reflection in the mirror, i.e. the so-called 'mirror' sign. This can, in turn, overlap with, or develop into, delusional misidentification.

Executive function

Executive function is an umbrella term that encompasses a set of higher-order processes (such as inhibitory control, working memory, and attentional flexibility) that govern goal-directed actions and adaptive responses to the environment. Dysfunction in this cognitive domain may be elicited by enquiring into the patient's ability to plan ahead, remain focused on a task to hand, and/or multi-task. Speed of cognitive processing is also of relevance. Informants will often report that the patient with executive dysfunction can successfully accomplish single tasks if uninterrupted by other demands on their attention but struggles if more than one stimulus is presented. Difficulties of this nature reflect impairments in dorsolateral prefrontal cortex function. In more advanced cases, patients with executive dysfunction lose cognitive flexibility and can become very rigid in their thinking, with a narrowing in their behavioural and motor repertoire. This can be distinguished from obsessive-compulsive disorder by the lack of insight held by the patient. Poor judgment, e.g. while driving, can be reported; alternatively, caregivers may report uncharacteristic vacillation/indecisiveness. Loss of inhibitory control (indicative of orbito-frontal dysfunction) can lead to marked behavioural change: poor table manners and other faux pas in social etiquette (e.g. skipping a queue), inappropriate jocularity or over-familiarity, or sexually inappropriate themes or behaviours. Loss of inhibitory control can also become evident in dietary behaviours—patients can develop an incorrigible 'sweet tooth' and have limited awareness of satiety, with hyperphagia and food cramming behaviours. An extreme manifestation is hyperorality, with oral exploration and sometimes consumption of inedible objects. With anterior cingulate dysfunction, empathy and interpersonal warmth may be lost, sometimes superseded by cold and callous behaviour. In other respects, the patient

Clinical cognitive assessment

may become apathetic and uninterested in themes previously of importance to them, e.g. the previously immaculately attired individual who loses all interest in grooming and personal hygiene. Apathy is also strongly associated with frontostriatal dysfunction. With frontal lobe lesions, impulsivity can also emerge—characterized by the patient ‘acting before thinking’; this is particularly striking in the motor impulsivity seen in progressive supranuclear palsy where the patient jumps to the standing position from his seat only to retropulse backwards again due to postural instability—the ‘rocket’ sign.

Language

Patients and families relatively rarely volunteer language as a difficulty, but on careful questioning and observation of the patient’s spontaneous speech, it can become apparent that what was perceived as a ‘memory’ problem is, in fact, a disorder of language. While formal, prescriptive examination of the various elements of speech has a useful diagnostic value, much can be gleaned in the office by simple interaction with the patient. The patient’s fluency and their ability to understand the content of speech and its prosody are instructive. Paraphasias (incorrect word substitutions) should also be noted—phonemic errors, such as ‘dork’ for ‘fork’, or semantic errors such as ‘brother’ for ‘husband’.

Slow, faltering, effortful speech with long word-finding pauses, producing a low output of words per minute—often with phonemic errors—is suggestive of a progressive non-fluent aphasia (PNFA). As this syndrome advances, grammar becomes parsimonious with omissions of conjunctions, prepositions, definite or indefinite articles, etc., although the intended meaning of speech is usually still conveyed. This is often referred to as ‘telegrammatic’ speech. For example, a patient who wishes to say ‘close the door as it is cold’ may only manage to utter ‘close-door-cold’. Patients can also have immense difficulty with repetition of multisyllabic constructs, e.g. ‘unintelligible’ or ‘caterpillar’. Many of these patients also have a demonstrable orobuccal apraxia, which is a deficit in use of the lips, tongue, and pharynx to perform skilled, learnt motor tasks such as mimicking how to blow out a candle or suck through a straw. Comprehension, for single words at least, is spared, although the patient may struggle with comprehending instructions with increasing syntactic complexity.

Another aphasia variant is the logopenic aphasia characteristic of AD. These patients demonstrate preserved grammatical structure and, as such, seem relatively fluent, but production rate is slow and speech is punctuated by long, dramatic pauses as they search for single words, often mid sentence. Compensatory strategies, such as circumlocution (attempts to describe the relevant word by other means, e.g. ‘the thing for digging’ for spade) or supraordinal substitution (e.g. ‘bird’ for ‘owl’), are often employed. While single-word repetition is relatively spared, repetition of sentences is impaired, in keeping with the theory that the

Clinical cognitive assessment

mechanism for the syndrome is one of a phonological short-term memory deficit (Gorno-Tempini et al., 2011).

Semantic failure is an even more striking form of language dysfunction. The patient's comprehension of the intrinsic meaning of a word is altered, which can rapidly become disabling. In tandem with this, confrontational naming is impaired. The patient will often fare no better when presented with non-verbal cues (e.g. visual, tactile), i.e. they present with semantic memory failure beyond language alone. This underscores a more universal decline in conceptual knowledge. For example, a patient may no longer recognize the purpose or function of a tool or implement, e.g. a corkscrew or nail clippers. Reading may be characterized by surface dyslexia, whereby native English speakers do not recognize irregularly pronounced words, particularly those of lower frequency usage, e.g. they may read 'sew' as 'su' or 'dough' as 'doog'; the error presumably arises as the patient has lost the semantic context of the word. Each of these aphasia syndromes is associated with abnormality in specific cortical areas: the left posterior frontal and insular regions in PNFA; left posterior perisylvian or parietal atrophy in logopenic aphasia; and the (left) anterior temporal lobe in semantic aphasia. See Table 10.2 for some useful clinical pointers in approaching the patient with aphasia.

Table 10.2 Tasks that may be used to assess speech and language functions in primary progressive aphasia.

Speech/ language function	Task	Behavioural measures	Variant in which impaired
Speech production			
Grammar	Picture description task; story retelling (e.g. picture aided); constrained syntax sentence production task	Grammatical structure; mean length of utterance; speech rate; accuracy of content; melody; prosody; specific error types in word selection; articulation	Non-fluent/agrammatic variant
Motor speech	Motor speech evaluation, including	Effort; hesitations; presence of	Non-fluent/agrammatic variant

Clinical cognitive assessment

	multiple repetitions of multisyllabic words; diadochokinesis of speech articulators; spontaneous speech	apraxia of speech or dysarthria; specific types of speech sound errors; factors that affect articulation (e.g. word length in syllables)	
Confrontation naming	Single-word retrieval in response to pictures, sounds, foods, and odours	Error rate; delay in naming; factors that affect naming accuracy (e.g. familiar versus unfamiliar items, nouns versus verbs, semantic category); error types (e.g. semantic errors, phonemic errors)	Severe deficit in semantic variant with semantic errors; moderate impairment in logopenic variant with phonemic errors
Repetition	Oral repetition of words, pseudowords, phrases, and sentences	Factors that affect repetition accuracy (e.g. predictability of the phrase, sentence length, grammatical complexity); error types	Logopenic variant with phonological errors
Sentence comprehension	Matching orally presented sentences to pictures; answering yes/	Factors that affect comprehension (e.g. grammatical	Non-fluent/agrammatic variant, effect of grammatical complexity;

Clinical cognitive assessment

	no questions; following directions	complexity; reversibility of the sentence, e.g. 'The boy was kicked by the girl' versus 'The ball was kicked by the girl')	logopenic variant, length, and frequency effect
Single-word comprehension	Word-picture matching; word-definition matching; synonym matching	Factors that affect comprehension (e.g. familiarity; frequency; grammatical word class)	Semantic variant
Object/people knowledge	Picture-picture matching; odd- one-out; semantic associations; gesture-object matching; sound-picture matching	Factors that affect object knowledge (e.g. familiarity, semantic category)	Semantic variant
Reading/ spelling	Lists including regular and irregular word lists, from various word classes, matched for other factors; pseudowords matched to words in length	Factors that affect reading/ spelling accuracy (e.g. regularity, frequency, word class); error types (e.g. regularization, phonologically plausible errors, articulatory distortions)	Semantic variant with 'regularization' errors; logopenic variant with phonological errors

Classification of primary progressive aphasia and its variants.

Visuoperceptual function

Visuospatial dysfunction may be quite subtle in its presentation. The archetypal higher-order visual syndrome in the memory clinic is Balint's syndrome, typically indicative of PCA. PCA is most often a manifestation of Alzheimer pathology, but DLB, corticobasal degeneration, and, more rarely, prion disease can underlie this presentation. Patients with PCA can present with myriad visual symptoms (Box 10.1) and frequently have spent a considerable period of time with ophthalmological assessments or even have a functional psychiatric diagnosis before the true diagnosis is determined. The full classical triad of optic ataxia, oculomotor apraxia, and simultanagnosia is rarely seen in practice, but these signs should be sought. Optic ataxia refers to an inability to accurately identify the spatial location of a visual cue in the peripheries, in spite of normal visual fields; it is ameliorated when an acoustic cue is added (e.g. the examiner holds a set of car keys within the patient's field of vision and asks them to point to them; they cannot perform this or do so with faltering, searching movements—localization of the target improves dramatically when the examiner jangles the keys). Oculomotor apraxia refers to an apparent inability to direct conjugate gaze to a target on command, in spite of the presence of a full range of extraocular movements, when completing a spontaneous visual search. Simultanagnosia is the phenomenon where a patient cannot appreciate a visual scene in its entirety, e.g. the 'Boston Cookie Theft' scene is described piecemeal, and not seen as a whole. Another test to elicit this is to place a number of items in the patient's field of view and ask them to describe what they see—the patient with simultanagnosia will describe one item only, yet can identify each of them when presented individually. Clinical clues to the presence of an emergent PCA syndrome include left/right disorientation and dyscalculia, which are also dominant parietal lobe functions which may accompany Balint's. The latter can be elicited by enquiring into how readily and accurately a patient can manage simple arithmetic such as small cash transactions, or if there is a history of difficulty with interpreting numbers such as display prices, pinpads, or mobile telephone keypads.

Box 10.1 Visual manifestations of posterior cortical atrophy

- Glare sensitivity
- Simultanagnosia
- Optic ataxia
- Optic apraxia
- Visual field deficits

Clinical cognitive assessment

- Complex visual hallucinations
- Impaired depth perception
- Impaired contrast sensitivity
- Alexia
- Visual crowding
- Prosopagnosia
- Palinopsia
- Achromatopsia
- Prolonged colour after images
- Visual disorientation
- Reverse-size phenomena
- Mirror sign
- Illusion of movement of static objects
- Akinetopsia
- 180° upside-down room tilt illusion

Less ‘canonical’ visuoperceptual symptoms can often manifest in DLB and AD. An enquiry into driving accuracy can frequently be instructive—a litany of clipped kerbs, near misses, or minor road traffic accidents can be disclosed, or sometimes, tellingly, a loss of parking accuracy. Some patients will acknowledge subjective concerns and will have spontaneously curtailed journey lengths and frequencies, but a caregiver estimation of safe performance is much more reliable and robust (Iverson et al., 2010). Dressing apraxia is another indicator of visuoperceptual dysfunction—the patient has been observed to place clothing on inside-out, or back-to-front.

Other cortical visual symptoms can include positive phenomena such as palinopsia (persistent perception of a visual image despite its physical removal from the visual field) and cerebral polyopia (single targets perceived as multiple). Visual hallucinations should be directly enquired about—complex, recurrent visual hallucinations are almost pathognomonic of DLB, in the absence of retinal disease. Sometimes caregivers will be astonished to hear the patient endorse the experience of visual hallucination, as they may not have volunteered it before. Frequently, the hallucinations of DLB are well formed of people and animals; the patient will often recognize the individuals. Insight is preserved and the experience—typically, but not universally—is not

Clinical cognitive assessment

distressing. A *forme fruste* of visual hallucination (which is usually spontaneous, in the absence of a visual stimulus) is pareidolia. These are visual misperceptions of a visual stimulus, such as attributing animate characteristics to an inanimate scene, e.g. perceiving a face in a carpet or wallpaper pattern. Even more subtle can be the 'sense of passage' experienced as a prelude to more frank hallucinatory experiences in DLB—the patient reports a sense of someone having 'passed by' an adjacent window or 'passed just over the shoulder' where no such stimulus existed. These experiences of a sense of passage or presence are sometimes referred to as 'extracampine' phenomena and may also feature in Parkinson's disease.

Auditory cognition

Less well explored as part of the cognitive assessment is the domain of auditory cognition, but it merits some attention. Many patients and their caregivers will attribute some, or all, of their cognitive difficulties to poor hearing. Hearing loss in itself is significant to identify as it has been shown to be independently associated with incident all-cause dementia (Lin et al., 2011) and older adults with hearing loss are at greater risk of dementia than those with normal hearing (Davies et al., 2017). The mechanisms by which hearing loss may contribute to cognitive decline remain to be elucidated. Assessing for a higher-order 'central' contribution to the perceived hearing difficulties can be difficult, but some clinical pointers may include difficulty with understanding speech versus other sounds, recognizing familiar voice or music, or difficulty locating sounds generated in the same room (Hardy et al., 2016).

Praxis

Apraxia refers to difficulty in execution of skilled, purposeful movements, in the absence of weakness or sensory or comprehension deficits. Apraxia has several potential neuroanatomical correlates, but the dominant inferior parietal and prefrontal regions are most commonly implicated. Patients and informants will often allude to their difficulties as 'disorientation' or 'lack of coordination'. On careful history-taking (and examination), however, it will become apparent that the symptoms described are, in fact, higher-order cortical problems. Useful questions to elicit apractic symptoms include enquiry as to loss of skills using tools and household equipment, e.g. microwaves, dishwashers, or remote control units for TVs. Such difficulties can, of course, overlap with executive dysfunction. In the last decade, a useful line of questioning relates to loss of skills required to use a mobile telephone or computer; informants will often report inaccurate text messages or, quite tellingly, that the patient has withdrawn entirely from the use of modern technological devices. In each case, it is important to ascertain, insofar as possible, any visual contribution to these difficulties, underscoring the need for a careful neurological examination. Patients with apraxia will often have insight into their difficulties, particularly where there is a focal apraxia of a limb such as that seen in the corticobasal syndrome—the

Clinical cognitive assessment

patient will frequently report 'it just doesn't do what I want' and are frustrated at their poor ability to execute or mime movements. An extension of this is the rare manifestation of lesions of the supplementary motor area and/or the corpus callosum in the form of alien limb phenomenon. The affected limb is apractic, with reflexive grasping, and can appear to levitate or move autonomously, most dramatically with intermanual conflict. In some cases, the patient can fail to recognize the limb or even deny ownership of it.

Time course of symptoms

Having clarified whether there are specific cognitive symptoms, it is important to establish the rate of symptom progression.

Neurodegenerative processes, such as AD, DLB, and frontotemporal dementia (FTD), generally progress insidiously over years, although more aggressive phenotypes are recognized (Gaig et al., 2011; Lee et al., 2017; Schmidt et al., 2011). Static symptoms are more indicative of a fixed structural deficit (e.g. after a stroke or an acquired brain injury) or can be a feature of the 'worried well'. Static behavioural symptoms over serial assessments, in the absence of functional impairment, in a patient suspected of FTD raises the possibility of the FTD phenocopy, an increasingly recognized entity typically seen in younger patients and often presenting with underlying comorbid psychiatric features, but lacking in any overt progressive neurodegenerative changes on serial imaging (Gossink et al., 2016).

A stepwise progression in symptoms is supportive of a vascular aetiology, or at least a contribution, to the presentation. Fluctuating symptoms raise a number of possibilities, and diurnal fluctuation should be specifically enquired after, as this is highly suggestive of DLB (McKeith, 2002). Where there are pointers in the history towards fluctuating cognition, this can be quite easily assessed by means of a simple four-point questionnaire (Ferman et al., 2004). Delirium is perhaps the most dramatic manifestation of fluctuating alertness and attention, and a prodromal history of apparently easily precipitated, frequent, or prolonged delirium should bring DLB to the fore of the clinician's mind (Jicha et al., 2010; Vardy et al., 2014). More prolonged periods of fluctuation, over weeks to months, raise the possibility of autoimmune or metabolic encephalopathies.

Other neurological symptoms

As cognitive dysfunction is frequently accompanied by other neurological symptoms, it is important to assess for these. In particular, motor symptoms are important to elucidate, as patients with extrapyramidal disorders and motor neuron disease (MND) can present with early prominent cognitive symptoms to the memory clinic. A large prospective study identified that almost 14% of patients with MND satisfied diagnostic criteria for FTD at diagnosis; a further 34% had deficits on cognitive testing, predominantly in frontal-executive function (Phukan et

Clinical cognitive assessment

al., 2012). It is not unusual for some of these patients, particularly those with salient language deficits, to be referred in the first instance to a memory clinic, before motor symptoms become overt. Up to 20% of patients with the atypical parkinsonian disorder progressive supranuclear palsy (PSP) present with a frontal lobe behavioural syndrome, before classical motor features are evident (Donker Kaat et al., 2007). While overt parkinsonism in DLB is easy to identify, in practice, it may be quite subtle, or indeed absent, in the early disease stage, and there is a poorly quantified proportion of patients who receive an autopsy diagnosis of DLB without ever having manifested clinically evident (or perhaps clinically recognized) extrapyramidal features (Savica et al., 2013). Patients should be asked about tremor, stiffness, slowing up in execution of movements, and balance and gait changes. Useful clinical questions include: enquiring about speed of dressing, slowness and discomfort on turning over in bed, size and legibility of handwriting, change in posture (caregivers will frequently endorse this—identifying a more anteroflexed posture and more rounded shoulders), and speed of walking. Useful, validated toolkits have been published which can aid the non-movement disorder expert in the assessment of patients with suspected DLB (<https://research.ncl.ac.uk/diamondlewy/assessmenttoolkits/>).

Unexpected and/or frequent falls should also raise the possibility of an extrapyramidal or other motor disorder in the mind of the cognitive specialist. Weakness, particularly focal and insidious weakness, may herald a pyramidal or an amyotrophic process such as MND. The patient should be asked about muscle cramps, frequently an early feature of denervation in MND, and about respiratory symptoms indicative of evolving respiratory muscle weakness such as dyspnoea on minimal exertion and orthopnoea (intolerance of lying flat). Similarly, early bulbar symptoms, such as altered speech intelligibility or dysphagia, imply a more diffuse process than cortical dementia alone and should prompt consideration of an associated amyotrophic or atypical parkinsonian process. Weight loss is associated with the advancing stages of all neurodegenerative diseases but is particularly striking in MND, in which it can be an early feature, presaging many of the classical motor features. The mechanisms for this are poorly understood; it may be due to an innate hypercatabolic state associated with the disease process (Korner et al., 2013) and is often in excess of the extent of any dysphagia which is present.

If motor deficits are described as occurring in an abrupt and/or a stepwise fashion, consideration needs to be given to a potential vascular contribution to cognitive symptoms. Cognitive symptoms emerging simultaneous with an acute-onset neurological deficit should prompt an exploration of the history to ascertain the extent, if known, of cerebrovascular disease and other vascular risk factors. The contribution of macrovascular and microvascular cerebral disease to cognitive impairment and to the clinical picture of AD has long been recognized

Clinical cognitive assessment

and a history of stroke, transient ischaemic attack, hypertension, dyslipidaemia, and/or diabetes should be checked for.

Hyposmia is a robust predictor of α -synucleinopathy (and hence DLB). This lack of perception of odour is qualitatively different from the preserved perception of, but poor ability to *discriminate*, odours seen in patients with early AD. Autonomic dysfunction, such as postural dizziness, marked urinary sphincteric dysfunction, constipation, or erectile failure in men, may also support an incipient DLB process. While a pattern of irritative lower urinary tract symptoms emerging in tandem with cognitive symptoms is a relatively common and non-specific picture (often reflecting the coincidental higher prevalence of both symptoms in older people), it should raise the possible differential diagnosis of normal pressure hydrocephalus in the clinician's mind, especially if there are associated gait difficulties and/or lower limb parkinsonism.

Sleep and cognition

It is crucial to assess sleep quality, both in the patient's estimation and that of the bed partner, if relevant. Poor-quality sleep is increasingly recognized as a harbinger of amnesic cognitive impairment and AD (Blackwell et al., 2014; Lim et al., 2013). Whether this is a prodromal marker of neurodegeneration, or a contributor to it, remains hotly debated. Hypersomnolence (excessive daytime somnolence) is a supportive feature in the DLB diagnostic criteria. This symptom merits further enquiry, as fragmentation of nocturnal sleep from obstructive sleep apnoea or periodic limb movements of sleep may be contributory and can be easily remediated. Parasomnias can be divided into rapid eye movement (REM) sleep behaviour disorder (RBD) and non-REM sleep parasomnias. The former can usually be identified quite readily from questioning of the bed partner who will describe dream enactment behaviour. The typical account is one of purposeful, often violent, movements which can result in injury to either the patient or the bed partner. Loud vocalization usually accompanies the motor phenomena. The patient can usually be roused easily and will classically describe dreams with violent or threatening themes. Notably, the aggressive nature of the dream enactment is often at odds with the patient's waking personality. RBD tends to manifest most reliably in the second half of the night, since the proportion of time spent in REM sleep accumulates overnight. The presence of RBD is highly predictive of incipient α -synucleinopathy—91% of patients with the syndrome develop a neurodegenerative disease over long-term follow-up, almost invariably with α -synuclein pathology (Iranzo et al., 2014).

Other psychiatric symptoms

An important component of the cognitive assessment is the elucidation of affective symptoms which may underlie some, or much, of the patient's reported difficulties. This can be done both in a qualitative fashion by direct enquiry into symptoms of anxiety and depression, and semi-

Clinical cognitive assessment

quantitatively by use of self-completed questionnaires such as, *inter alia*, the Hospital Anxiety and Depression Scale (Zigmond and Snaith, 1983), a simply administered and widely validated tool for the identification of affective symptoms. Abnormally high scores in either the depression or anxiety scales should alert the cognitive clinician to a possible contributory role for these symptoms in either the presentation of the patient or their subsequent cognitive test performance. Both anxiety and low mood affect attentional capacity and working memory; in this context, the concept of ‘depressive pseudodementia’ has long been recognized as a manifestation of mood disorders, dating back to descriptions of ‘melancholic dementia’ of the nineteenth century. However, one must be cautious about blithely attributing all cognitive symptoms purely to mood disturbance, particularly in the older patient cohort; learning and memory deficits in the presence of depression predict evolution into dementia over time in older cohorts (Heser et al., 2016). Furthermore, later-life depression is widely recognized as a harbinger of neurodegenerative disease; older patients demonstrating neuropsychiatric symptoms, such as apathy, depression, irritability, agitation, and night-time behavioural disturbance, have a higher risk of subsequent MCI (Geda et al., 2014), while anxiety, depression, and apathy are validated supportive clinical features in the diagnosis of DLB (McKeith et al., 2017). As such, follow-up of older patients who present with cognitive symptoms in the setting of a mood disorder is appropriate, with reassessment once affective symptoms have been effectively treated.

Psychotic symptoms accompanying cognitive impairment are important to identify as they may have diagnostic significance, as well as being a source of considerable morbidity in their own right. The well-formed, frank visual hallucinations associated with DLB have been discussed earlier; the patient typically has insight into the unreality of these visions, at least early in the disease trajectory. Hallucinations in other modalities can occur in DLB and sometimes are underestimated in the clinic—in particular, auditory and haptic (hallucinations of touch). Hallucinatory symptoms are not specific for DLB; they can accompany other neurodegenerative conditions but are less commonly seen in the earlier stages. Delusions and paranoid ideation are further neuropsychiatric symptoms encountered not infrequently in the memory clinic. Delusional phenomena can vary from mood-congruent nihilistic delusions in the depressed older patient to more discrete classical syndromes such as Capgras syndrome (where the patient believes a spouse or other loved one has been replaced by an imposter) and ‘phantom boarder’ syndrome (where the patient believes that someone else lives, uninvited, in their home). Reduplicative paramnesia is the term appended to a belief held that a location (most commonly, the home) has been duplicated and exists in two places at once. There continues to be a debate as to whether the latter syndromes constitute truly delusional experiences or are misidentification phenomena due to perceptual dysfunction. Othello syndrome refers to pathological jealousy experienced by the patient who believes their spouse is being unfaithful; there is some evidence (and

Clinical cognitive assessment

clinical experience would suggest) that the latter is much more commonly seen in DLB than AD or other dementias (Hashimoto et al., 2015).

Psychotic symptoms traditionally were considered rare in FTD; in recent decades, however, there has been recognition of a prevalence rate of approximately 10%, with a particular preponderance in patients carrying mutations in *C9ORF72* and *GRN* (Shinagawa et al., 2014).

Background medical history

As in any clinical assessment, it is important to take a detailed background medical, surgical, and medication history. Stroke, liver disease, malignancy, or chronic pain syndromes, among others, may be highly relevant. Polypharmacy is frequently encountered in the older patient cohort and numerous centrally acting medications (which may be prescribed for mood, pain, or sleep) can impact cognition. High-potency opioid transdermal patches can often be overlooked as relevant components of the medication history by patients and caregivers. Other contributors may be less obvious—it is important to be mindful of the potentially deleterious effects of drugs with anticholinergic effects or of the cumulative effects of some older anticonvulsants on cognition in patients with long-standing epilepsy.

Family history and genetics

Family history is of great relevance in the assessment of a young-onset dementia patient but may be perceived by some as of less importance in a patient presenting over the age of 65. However, this is not strictly true. A patient with one parent diagnosed with dementia under the age of 80 has double the chance of developing dementia themselves (Wolters et al., 2017). This is likely attributable to polygenetic and other factors, since familial autosomal dominant (Mendelian) AD is very rare in this age group, with a <1% chance of identifying a causative Mendelian gene, even with two affected first-degree relatives over the age of 65 (Loy et al., 2014). FTD, however, is a much more familial entity, and an assiduous family history should strive to elicit other potential presentations of FTD or its causative gene. There may be a family history of family members, for example, having been institutionalized for unclear reasons, suffering from apparent alcoholism, or receiving diagnoses of schizophrenia, MND (with and without dementia or behavioural disturbance), or dementia attributed to other causes such as AD or vascular dementia. Two genes associated with FTD can have highly variable age of onset and penetrance—*C9ORF72* and *GRN*—and thus may merit consideration if a multigenerational family history of dementia or other behavioural problems emerges.

Social history and driving

The social history is key to contextualizing the patient's symptoms; the nature of their home and family supports and the physical context of the domestic environment are important practical pieces of information. A

Clinical cognitive assessment

domiciliary visit can provide valuable insights into these aspects. Alcohol intake, smoking, and recreational drug use should not be overlooked in the memory clinic, particularly the former. Increasing evidence points to a role for alcohol in hastening cognitive decline (Bos et al., 2017). Diet may be relevant, as up to 11% of patients over 65 years have clinically relevant deficiencies in vitamin B12 levels (Lindenbaum et al., 1994), with its attendant negative effect on cognitive performance. Educational exposure and occupation are also key pieces of information, as they will colour the interpretation of subsequent formal cognitive testing. If not already established in the assessment of functional impact of symptoms, it is also crucial to enquire at this point as to whether the patient drives or not. This important piece of information may have significant medicolegal implications (see Chapter 57 for a detailed discussion of driving and dementia).

Cognitive examination: quantitative and qualitative assessments

A detailed patient and informant history will already have provided much qualitative information as to the cognitive syndrome at play. It is then important to examine the cognitive domains in an objective, standardized, and semi-quantitative manner. A multitude of bedside cognitive assessment tools exist; probably the most widely used in English-speaking countries are the Mini-Mental State Examination (MMSE) (Folstein et al., 1983), the Test Your Memory (TYM) (Brown et al., 2009), the Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005), and the Addenbrooke's Cognitive Examination (ACE) (Mioshi et al., 2006). The choice of assessment tool will depend on the circumstances; broadly speaking, the first three are effective screening tools but may not be adequately challenging, or sufficiently comprehensive, to detect subtle abnormalities. Certainly, the MMSE is a relatively blunt instrument, biased towards attention and mnemonic function, with little or no interrogation of frontal/executive function and limited language and visuospatial testing. It is prone to ceiling effects in early-stage cognitive syndromes and in those with significant educational exposure. The TYM incorporates more cognitive domains and is more robust than the MMSE in correlating with the outcomes of full detailed neuropsychological assessments (Koekkoek et al., 2013). A unique feature of the TYM is its ready self-administration and, as such, it is often effectively utilized in screening out subjective cognitive complaints in a time-pressured general neurology or psychiatry clinic, rather than as a semi-quantitative tool in a dedicated memory clinic. The MoCA is also more encompassing than the MMSE, but again it is better considered as an effective screening tool than providing a thorough, quantitative assessment. These tools are available in a multitude of languages, and normative data have been published.

The ACE (now in Version III) is perhaps the most detailed multi-domain bedside cognitive assessment tool used by cognitive clinicians. It is important to remember that bradyphrenia, perseveration, intrusions, apraxia, anxiety, or indifference cannot be conveyed on scoresheets but

Clinical cognitive assessment

are important to consider in the interpretation of any cognitive assessment, and the presence of these should be highlighted in a commentary on the test scoring. Similarly, motor and sensory impairments can influence performance and their presence should be noted. The ACE is scored out of 100, with subscores for attention, memory, fluency, language, and visuospatial function. Even within subscore, it is important that the clinician is aware of the 'flavour' of the deficits; for example, poorer performance in categorical (semantic) fluency than in letter fluency is indicative of an impaired search strategy, more in keeping with a medial temporal pathology, whereas impaired letter fluency implies executive dysfunction. An analysis of how patients reach their final score in memory is also important; for example, a significant improvement in the name-and-address recall item score with cueing is supportive of a dysexecutive retrieval problem than an encoding difficulty. One of the few weaknesses of the ACE is the absence of a test of visual memory; this can be performed by administration of the Rey-Osterreith complex figure or by using additional, bespoke, tools.

If time permits, deficits in any one or more domains should be explored further. For example, patients who appear to have prominent frontal dysexecutive features on the ACE should ideally also complete the Frontal Assessment Battery (Dubois et al., 2000), which incorporates tests of inhibitory control, set-shifting, and abstraction. The patient with frontal lobe dysfunction may not be able to conceptualize similarities between a table and a chair beyond their wooden nature or see beyond 'wheels' as a unifying theme linking a train and a bicycle. As the level of abstraction increases, they may flatly declare that there are no common themes, e.g. between a watch and a ruler. Similarly, patients can be asked to interpret common proverbs (e.g. 'too many cooks spoil the broth' or 'people in glasshouses shouldn't throw stones') for evidence of concrete thinking; however, this is probably only reliably interpretable in patients with a reasonable premorbid educational exposure and such tests can be very culturally specific. Another useful line of enquiry is the concept of cognitive estimates; for example, a patient is asked 'how many lions are in Dublin?'—the frontal patient may produce a bizarre or a highly inaccurate response. A simple test to unveil perseveration is the 'signe d'applause', wherein the clinician instructs the patient to copy precisely what he is about to do; the examiner claps three times. Patients with frontal dysfunction will clap several more times, often until they are instructed to stop.

Prominent amnesic dysfunction can be explored in more detail by asking the patient to relay recent current affairs or sporting news items of which they are aware. The amnesic patient will frequently engage in a certain amount of 'provoked confabulation' at this juncture. Retrograde memory will also be affected in neurodegenerative syndromes. Patients can be asked about landmark political, sporting, or natural or manmade disasters, e.g. general election or referendum results, the Olympic Games, World Cup competitions, extreme weather events, terrorist

Clinical cognitive assessment

attacks, etc. Typically one establishes a temporal gradient, with better preservation of more distant memories than more recent ones ('Ribot's law'). Sudden retrograde memory loss, the absence of a gradient, or an abrupt, precise cut-off point in time, with or without autobiographical memory loss, is often indicative of psychogenic or functional amnesia. One should also conduct tests of visual memory and recognition, e.g. the 'familiar' and 'unfamiliar' faces test of the Queen Square 'Green Book', with the former depicting well-known cultural figures and the latter a series of four previously unseen male faces, whom the patient is then asked to recognize from a panel of nine faces after a brief delay.

Language and visuospatial deficits elicited on the ACE can also be further explored with ancillary bedside tests. An assessment of reading, both comprehension of a written instruction (e.g. 'close your eyes') and verbal reading output (e.g. the passage from the Queen Square 'Green Book' or the Rainbow Passage), should be conducted where deficits in one or both of these domains are apparent.

The ACE does not incorporate definitive tests of praxis, but apractic attempts at cube and clock drawing can be observed. Formal tests for apraxia should be conducted as part of a complete neurological examination (see General neurological examination, column opposite), particularly if a prominent flavour of parietal deficit emerges from the history.

A cut-off score of 88 on the ACE is very sensitive for dementia, but at the cost of specificity; the converse is true for a cut-off of 82, increasing the chances of missing bona fide dementia cases. The Test Your Memory for Mild Cognitive Impairment (TYM-MCI) is a short, easily administered assessment tool, with visual and verbal recall aspects designed to optimize detection of amnesic MCI (aMCI)/AD. It is of particular utility for those patients with equivocal ACE scores (i.e. between 83 and 87) where there is suspicion of an evolving aMCI/AD process (Brown et al., 2017). Visual memory is affected early on in AD but is not routinely tested on many bedside cognitive assessment scales.

Neuropsychology and occupational therapy

Trainees and non-specialists often have the impression that access to specialist neuropsychology is necessary to run an effective memory clinic. While a huge asset to any memory service, many patients can be readily assessed and a diagnostic formulation established without referral to neuropsychology, access to which may be quite limited. Such patients encompass those with moderate deficits where the underlying process is clear, as well as those 'worried well' who have mild attentional symptoms without any evidence of any objective deficits. Similarly, patients with advanced dementia with global impairments will not benefit from detailed neuropsychometry. The discriminative value of neuropsychology lies in the assessment of those patients with early, mild symptoms and deficits and/or those whose results on cognitive assessment scales fall in the

Clinical cognitive assessment

equivocal range. Neuropsychological assessment is also useful at teasing out affective contributions to cognitive symptomatology. More rarely, it is useful in identifying psychogenic amnesia, or factitious cognitive disorders where themes such as effortful underperformance and approximate answering emerge.

The involvement of an occupational therapist (OT) is often also required for a robust and comprehensive cognitive assessment. In particular, the OT can perform practical and measurable assessments of functional capacity. This can be particularly useful in the domiciliary setting where the environmental and/or social contexts can be observed. Such assessments are especially valuable where there is a mismatch between patient and informant accounts of functional performance or where it is suspected that caregivers are compensating for a patient's deficits.

General neurological examination

As cognitive symptoms in neurodegenerative disease are reflective primarily of incipient or established focal atrophy, it stands to sense that other neurological signs may coexist with cognitive abnormalities. As such, a careful and detailed neurological examination is always warranted in the patient presenting with cognitive decline. Observation of the patient during the consultation, from the moment they are called from the waiting room, can yield much information long before one has recourse to the formalized neurological examination. The 'head turning sign', whereby the patient turns to the caregiver for assistance in providing the history, is a sensitive marker of cognitive impairment (Larner, 2012) and it may be more predictive of AD and aMCI than other syndromes (Fukui et al., 2011). Movement disorders—hypo- or hyperkinetic—will be readily apparent. Parkinsonism is the pre-eminent hypokinetic movement disorder and is defined by the presence of two or more of rigidity, bradykinesia, tremor, and postural instability; the latter three features can be identified by observation alone. Hyperkinetic movement disorders, such as chorea, are also easily discernible; it is worth noting that up to 11% of patients with Huntington's disease present after the age of 60 and that cognitive impairment, rather than the movement disorder, may be the greater source of disability in this group (Chaganti et al., 2017) prompting referral to a memory clinic before a movement specialist. Myoclonus (brief, simple, irregular muscle jerks) in the setting of cognitive decline suggests a broad differential; in the context of rapidly progressive dementia, it raises the spectre of prion disease (peak age of onset 65–74 years) (Puoti et al., 2012); more commonly, it is seen in AD and the atypical parkinsonian disorders, particularly DLB and corticobasal syndrome (Kiziltan et al., 2017).

The formal neurological examination should then be completed. Important cranial nerve abnormalities, not to miss, include visual field deficits, eye movement abnormalities, hypomimia, dysarthria, and/or other bulbar or pseudobulbar signs (e.g. a weak, fasciculating tongue or a spastic, atrophic tongue with strangled speech and a hyperactive gag

Clinical cognitive assessment

reflex). Listen carefully to the content of speech, but also to its volume (for hypophonia of parkinsonism) and intelligibility and for the phenomenon of tachyphaemia seen in extrapyramidal disorders (rapid, 'festinant', and often poorly decipherable speech). Frontalis overactivity is highly characteristic of PSP. A brisk jaw jerk is an upper motor neuron sign characteristic of, but not exclusive to, MND.

Muscles should be inspected for atrophy or fasciculations. Tone should be tested in the limbs, and rigidity or spasticity noted. Paratonia ('Gegenhalten') can be more difficult for the non-specialist to confidently distinguish but refers to a progressive increase in tone with manipulation of the limb by the examiner—this is frequently seen in dementia patients. Pyramidal weakness or other long tract signs, such as ankle clonus, hyper-reflexia, or extensor plantars, may be of relevance to the diagnostic formulation; such upper motor neuron signs are indicative of corticospinal tract dysfunction, pointing to vascular disease or possibly an anterior horn cell process such as MND. Patients should be assessed for bradykinesia (a decrement in amplitude with repetition of finger taps or other rapid alternating movements of the limbs). Appendicular and midline coordination should be tested by finger-nose, heel-shin, and heel-toe gait testing. Detailed sensory testing is probably unnecessary in many patients, but it is important to assess the general integrity of sensory function and to ensure there is an absence of sensory inattention in those with symptoms suggestive of apraxia, as unrecognized sensory deficits could lead to an inaccurate label of apraxia.

Frontal release signs, such as the grasp reflex, pout reflex, and palmomental reflex, are indicative of loss of frontal inhibition of primitive reflexes present from infancy. The grasp reflex is definitely present when the patient is clearly instructed by the examiner not to take the examiner's hand and/or to release it. The palmomental reflex may be less specific for neurodegenerative disease, with a prevalence of up to 25% in normal older adults (Jacobs and Gossman, 1980).

Dominant parietal function can be assessed by asking the patient to identify their right and left hands, as well as by tests of visual and sensory inattention. Cortical sensory signs, such as dysgrapaesthesia (inability to identify a simple digit traced on the palm), astereognosis (inability to identify an object placed in the palm without a visual cue), and poor spatial two-point sensory discrimination, are evident in many patients with parietal dysfunction. Tests for apraxia include requests to mimic hand/finger movements or to mimic gestures or activities such as washing teeth with an imaginary toothbrush, brushing one's hair, saluting a senior in the army, or demonstrating the gesture used for hitch-hiking.

Gait should be observed for stride length, base, foot clearance, arm swing, and turning performance. Parkinsonian gait and the 'magnetic' gait of normal pressure hydrocephalus and other movement disorders are thus identified. In contrast to when upright and weight-bearing, patients

with apraxia of gait can mimic bicycling movements when supine or trace a number on the floor with the feet while seated.

Physical assessment

Chapter: Physical assessment

Author(s): Rowan H Harwood and Rachel Cowan

DOI: 10.1093/med/9780198807292.003.0011

Philosophy and approach

Physical health problems in older people are manifold and various. They may be acute or long term; of different degrees of seriousness; with or without functional consequences; and may or not impact on others. They will be managed in different settings: at home, a primary care facility, a care home, as a hospital in-patient, out-patient, or in a day hospital, in an alternative community setting such as intermediate care, or at dentists', opticians', or audiologists' premises. The purposes and methods of assessment vary; there are common themes, but some are situation-specific.

Physical assessment

An older person with mental health (MH) problems requires physical assessment:

- To identify physical signs that support a psychiatric diagnosis, e.g. neurological features of dementia with Lewy bodies (DLB), vascular dementia, or Huntington's disease.
- The MH problem may be caused by a physical disorder, e.g. anxiety in thyrotoxicosis; adjustment disorder or depression in chronic pain, physical disability, or after a stroke; Korsakoff's psychosis.
- The MH condition may have physical consequences, e.g. weight loss, malnutrition, or inability to undertake activities of daily living (ADL).
- The MH condition may mimic a physical disorder, e.g. somatization, hypochondriasis.
- Physical and mental disorders may have shared features, e.g. fatigue, communication impairment, anorexia, constipation.
- Physical and mental conditions frequently co-exist, and their functional consequences add up or interact (Prince et al., 2007; Fox et al., 2014; Bunn et al., 2014).

Many aspects of both physiology and disease are alike, regardless of age. However, older people have some characteristic differences (Evans, 1990):

- Multiple pathologies are common, or almost universal (Barnett, 2012).
- Presentations of disease can be non-specific, atypical, or functional (e.g. falls, delirium, immobility, incontinence, 'not coping').
- Older people are more prone to complications, both of diseases and their treatments.
- The health of older people may deteriorate rapidly, reflecting frailty and loss of homeostatic reserve.
- Explicit rehabilitation is often required to restore function after illness or injury, and older people are vulnerable to deconditioning (loss of muscle mass, strength, and functional capacity) after a period of inactivity or bedrest.
- Their functional ability is more dependent on the physical and social environment.
- The end of life may be approaching.

Older people vary one from another in their health, abilities, behaviours, resources, and social arrangements more than younger people, so doctors must be flexible in their approach. Some older people are fit and active, and need the same approach to investigation and treatment as younger people. Others have a complex mixture of multiple acute and chronic medical, mental, and social disorders, and there may be multiple stakeholders as well as the patient (including relatives, carers, and

Physical assessment

services such as care homes). The social dimension is especially important, as older people are both dependent on, and vulnerable to loss of, human relationships and care arrangements. The geriatric medical approach to addressing these problems has developed into the framework of the Comprehensive Geriatric Assessment (CGA), which has five dimensions:

1. Medical (acute and chronic, including polypharmacy, adverse drug effects, and medicines management).
2. Functional (ADL, behaviour, safety).
3. MH (mental illness, cognitive disorders and psychological impact of disease).
4. Social (relationships, human support).
5. Environmental (accommodation, and adaptations to enable independence).

MH practitioners may recognize this as the biopsychosocial model. Assessment of these domains enables development of a multiprofessional management plan. The approach is demonstrated to maintain health and function, reducing mortality and the need for long-term institutional care (Stuck et al., 1993, Ellis et al., 2017). In the context of vulnerability, intercurrent illness, and progressive disease, the assessment and management plan are rarely static, but ever-changing—a continuous process, rather than a single event.

The ‘medical model’, based on diagnosis and specific curative medical treatment, is important, but in itself insufficient. Prevention, palliation, the giving of information, counselling or teaching, negotiation of goals, multi-disciplinary management, restoration of function, adapting the physical and social environment, and support for families and other carers are all equally important. The healthcare of older people draws on a variety of models or frameworks, depending on the problem and goals of treatment (Table 11.1).

Table 11.1 Models of healthcare for older people.

Model	Approach
Prevention	Anticipatory treatment to avoid ill health in high-risk groups
Medical	Diagnose, treat
Rehabilitation	Cycle of problem identification, analysis, multi-professional therapeutic intervention and reassessment, directed at maximizing physical and social functioning

Physical assessment

Palliative	Meticulous management of symptoms, open communication, attention to psychological, social and spiritual aspects, advance care planning
Person-centred care	Value and respect for personhood, individualized care, empathic understanding, communication and relationships to promote wellbeing and reduce distress
Recovery model	Emphasize hope, identify positive attributes and abilities, set achievable goals, take risks, accept failure
Social model	Environment and relationships adapted to individual's differing abilities

Frailty and crises

Frailty is defined as vulnerability to deterioration in the face of a stressor (Clegg et al., 2013). The stressor may be accident or injury, acute illness, iatrogenic (e.g. an operation or drug side-effect), psychological, social, or environmental (e.g. moving house, admission to hospital).

Recent research has attempted to define frailty among older people based on generic features. Many people with chronic ill health, including diabetes, chronic obstructive pulmonary disease, sensory impairment, severe mental illness, intellectual disabilities, or dementia are vulnerable, and they may or may not be frail in the sense applied to older people. Some diagnoses overlap or are closely related to frailty, for example, features of depression may be difficult to distinguish from frailty (Vaughan et al., 2015). Three models of frailty measurement have emerged:

1. The 'frailty phenotype': based on five risk factors for adverse events or death identified in an epidemiological study (unintentional weight loss, self-reported exhaustion, low energy expenditure, slow gait speed, and weak grip strength). Three or more being present defines frailty, one or two present defines 'pre-frailty' (Fried et al., 2001).
2. The 'cumulative deficits' model: uses a checklist of problems to derive a frailty index (FI, the proportion of problems present) (Mitnitski et al., 2001). The approach can be applied to any data set, giving comparable results; for example, the electronic frailty index (eFI) derived from routinely available UK general practice data

Physical assessment

(Clegg et al., 2016), or a simple practical operationalization, the Edmonton Frail Scale (Rolfson et al., 2006).

3. The Clinical Frailty Scale: a nine-point, ordinal, vignette-based scale based on medical problems and disability, which closely correlates to the cumulative deficits FI (Fig. 11.1) (Rockwood et al., 2005; Dalhousie University, 2018).

Fig. 11.1
The clinical frailty scale.

Reproduced with permission from Rockwood K, Song X, MacKnight C, Bergman H, Hogan DB, McDowell I, Mitnitski A. A global clinical measure of fitness and frailty in elderly people. *CMAJ*. 2005 Aug 30;173(5):489–95.

Frailty scores, such as the Edmonton Frail Scale or the Clinical Frailty Scale, have been applied to older surgical patients (to identify those requiring prospective CGA pre- and post-operatively), in emergency departments and 'acute frailty units' to identify patients requiring early multi-disciplinary assessment, and in general practice to identify people at high risk of hospital admission for pro-active case management or end-of-life care.

A crisis is a time of difficulty, risk, or danger, or a time when important decisions must be made. Crises characterize frail older people and result in disruption, distress, and risk of death, complication, or permanent functional loss. Crises may be due to acute physical illness or injury (especially resulting from falls); functional decline (dehydration, immobility, or incontinence); MH problems (delirium, psychosis, poor safety awareness), social or environmental disruption (e.g. death or illness of a spouse, absence of a family member or carer, holidays, hospital admission), or failure of care systems (e.g. home care being

Physical assessment

unavailable or a care home being understaffed). Much preventative, elective, and social care aims at avoiding crises.

Assessment of a crisis aims to describe and understand it ('history of presenting complaint'). It will often be unclear what the relative contribution of physical, mental, and social factors are at the point of crisis, in the context of multimorbidity, and non-specific presentation of disease. This often results in acute hospital admission, where the task is to identify or exclude physical illness, maintain or restore function, and make plans (including for non-hospital alternative care, or end-of-life care). MH crises in older people often present in this way, emphasizing the importance of well-integrated liaison MH services in acute hospitals (and, conversely, for MH teams to have confidence in recognizing and assessing physical health problems in both community and acute psychiatric settings).

Information gathering

Assessment of a complex older patient takes time. There is no avoiding this, although some tasks can be delegated or distributed among a multi-disciplinary team. An unwell older person may not have the stamina to continue a long history and examination session in one go. It may be necessary to do no more than is immediately necessary and come back later (a 'rolling' consultation). Knowledge of prior medical problems and experience can be invaluable.

The history is central to medical assessment. Assessment at the point of presentation or admission to acute services is unlikely to be comprehensive, and the nature of the problems may emerge or evolve over time. 'Information gathering' is a more prolonged process than 'history-taking' and may extend over several days or weeks. Further information is gained from:

- third-party, 'informant', or 'collateral' interview (including to establish a diagnosis, ascertain problems, and determine baseline function, e.g. in cognitive impairment or in severe mental illness, to assess falls or loss of consciousness, ascertain social and environmental resources, expectations, and care planning information);
- observation, for change or fluctuation (e.g. in delirium);
- assessment of wellbeing, behaviour, and function, which will likely involve families, nurses, and therapists. Multi-disciplinary working and communication is important.

Presenting symptoms

Physical symptoms may be 'typical', such as weight loss, pain, breathlessness, or disturbance of consciousness, or 'non-specific'. The classical non-specific presentations of disease in older people, or the so-

Physical assessment

called 'geriatric giants' (immobility, falls, confusion, incontinence, 'not coping') (Isaacs, 1992), are 'non-specific' because they can be caused by many different pathologies. Non-specificity can be overemphasized, however; most presenting symptoms in medicine are not specific to a single pathology. Breathlessness, for example, may be caused by cardiac, respiratory, metabolic, and psychogenic problems; or weight loss may be malignant, gastrointestinal, metabolic, or psychiatric.

The non-specificity of the presenting complaint should be explored by questioning about more 'typical' symptoms. Experienced doctors use 'inductive thinking' in making assessments of frail older people. The doctor 'tests' hypotheses about what the problem might be, using questioning, examination, or investigation. This requires knowledge of diagnostic possibilities, judged by the presenting complaint, symptoms, and prior history, or simply experience and suspicion. These hypotheses are tested by asking questions to try to rule things in or rule them out. The alternative is a 'checklist' approach to history-taking, seeking the presence or absence of multiple different symptoms, which is lengthy and inefficient. The repeated questioning involved may overwhelm someone with cognitive impairment or a mood disorder, or fatigue someone who is frail.

A key part of the history is to establish the time-course, which is often longer than is usual for most 'acute' medical problems, playing out over months or years. Change in ability is often as important as onset of a new problem, since chronic disease and disability are common. We may need to establish a 'baseline' ('do you usually have any problems with your health?'; 'what can you do when you are at your best?'). This can be conveniently specified in terms of level of function ('can you walk?'; 'do you get out of the house?'; 'who does the shopping?'; 'who pays the bills?'). Then establish if problems started suddenly, or if gradually, over how long, and if they had occurred before.

Problems with history-taking

History-taking can be difficult because of:

- Cognitive impairment
- Deafness
- Aphasia
- Language (older non-native English-speakers may never have learned English, or may have lost the ability with stroke or dementia)
- Anxiety, depression, or delusions
- Tiredness, lack of concentration, or loss of stamina.

For people living with dementia, forgetfulness is a problem, but other aspects are also important, such as problems with insight, abstract thinking, and the perception of changes over time. However, people living with dementia can often report accurately about symptoms that they are

Physical assessment

currently experiencing, although communication impairment may make this difficult. It is important to try to involve the person in describing what is wrong, even when you suspect that the information is unreliable. This is courteous, inclusive, and respects identity and 'personhood'—a 'patient-centred' approach. However, if the person cannot give a good account of their problems, do a mental state and physical examination, and seek your history elsewhere (from an informant, using the telephone if necessary). In the case of delirium, cognition and attention fluctuate, and history-taking may be easier if attempted again a few hours later.

Hearing problems, usually due to presbycusis or wax, are present in 60% at age 70–80, and 90% of those over 80. Take the opportunity to make a referral to audiology services for hearing assessment and management if indicated. Make sure hearing aids are in place, switched on, have working batteries (which last less than a week when in constant use) and are not blocked with wax. Find a quiet room to speak in or minimize background noise (turn off the radio or television). Talk a little louder and more slowly than usual, but do not shout. Let the person see your lips as you speak. Gesture can help. Writing questions down is very laborious.

Aphasia is a disorder of language, common after stroke and often in dementia (although less well-recognized in this condition). Receptive aphasia is inability to understand (spoken and usually written) language. Expressive aphasia is the inability to speak (or write). Both come in degrees of severity. Speak as if speaking to a competent but not fluent, non-first-language English-speaker. Keep it simple: avoid jargon or complicated words. Use short sentences. Avoid double negatives. Repeat if necessary, and use gesture, pictures, and writing. The patient or relatives may be able to help tell you what works best. A joint session with a speech therapist may also help.

Various people can help translate for non-English speakers. Relatives are often available, able, and willing. Many hospitals keep registers of staff who speak other languages, and who can help. A professional interpreter may be more difficult to arrange, but sometimes may be necessary, as they may be able to 'advocate' as well as 'translate'. A three-way telephone conference call with a translator can be arranged if the patient does not find the whole experience too bewildering.

The rest of the medical history

Past medical history obtained from the patient, general practitioner, or the medical records may be extensive. It is worth questioning labels. Who diagnosed dementia, ischaemic heart disease, epilepsy, or Parkinson's disease? What were the symptoms? Is the diagnosis still valid? Is the diagnosis still active? Diagnoses are not always accurate, but you need good reasons to contradict a specialist opinion.

Always quantify the impacts or effects of diagnoses. If there is arthritis, specify the joints affected. A stroke patient may have fully recovered,

Physical assessment

been rehabilitated to reasonable function without full recovery, or been left wholly dependent on others. The label alone is of little value. Heart failure, angina, claudication, respiratory disease, or arthritis can be quantified in terms of exercise tolerance or walking distance, including some formal scales e.g. the New York Heart Association heart failure classification (The Criteria Committee of the New York Heart Association, 1994), or Medical Research Council breathlessness scale (Fletcher et al., 1959).

‘General enquiry’ can be useful, but has to be brief, and may have a different slant than in younger people. Ask about dizziness, falls, constipation, bladder symptoms, eyesight, hearing, teeth, feet, appetite, and weight loss. It may be that you can be proactive in using the opportunity of an older person presenting to your services to address physical health problems that impact on their quality of life, but which otherwise may be neglected.

Drug history

Drug history and arrangements for medicines management are very important. Older people, on average, take more prescribed drugs than younger people and are more prone to adverse effects. About one in eight hospital admissions is caused or contributed to by a drug adverse effect (Duerden et al., 2013). Look out for and question the need for common culprits (Tables 11.2 and 11.3). Multimorbidity is an important driver behind polypharmacy, which may therefore be both appropriate and unavoidable. The ‘single-disease approach’—treating medical conditions in isolation—increases the risk of potentially inappropriate medication (Salisbury, 2012).

Table 11.2 Adverse effects of drugs, by drug type.

Drug	Common adverse effect
Antibiotics	Diarrhoea (including <i>Clostridium difficile</i>), rash, nausea, abnormal liver function
Anticholinergic drugs	Delirium, cognitive impairment, dry mouth, urinary retention, blurred vision, dyspepsia, constipation
Antidepressants	Falls, nausea, hyponatraemia, extrapyramidal (SSRI*), anticholinergic (tricyclics, paroxetine), drowsiness, mania

Physical assessment

Anti-epileptic drugs	Drowsiness, cognitive slowing or impairment, ataxia, paranoia, abnormal liver function, osteomalacia
Antiparkinsonian	Delirium, hypotension, dyskinesia, nausea
Antipsychotics	Drowsiness, extrapyramidal effects (including atypical antipsychotics), falls, impotence, anticholinergic effects
Benzodiazepines	Drowsiness, falls, cognitive slowing or impairment, withdrawal effects, paradoxical agitation
Cardiovascular (antihypertensives, anti-anginals, anti-arrhythmics)	Hypotension (especially postural), falls, heart failure, metabolic, delirium
Diuretics	Lower urinary tract symptoms, dehydration, hyponatraemia, hypokalaemia, hyperglycaemia, gout, hypotension
Laxatives	Diarrhoea, faecal urgency, faecal incontinence
Lithium	Polyuria, tremor
Non-steroidal anti-inflammatory drugs (NSAIDs)	Gastritis, peptic ulceration, renal failure, fluid retention
Opiates	Constipation, nausea, hallucinations, delirium, drowsiness, itch
Corticosteroids	Weight gain, thin skin, diabetes, osteoporosis, myopathy, psychosis (high dose)

*SSRI: selective serotonin re-uptake inhibitor

Table 11.3 Adverse effects of drugs, by adverse effect.

Physical assessment

Adverse effect	Possible culprit drug
Anorexia, nausea	Opiates, metformin, antibiotics, anticholinergics
Constipation	Opiates, anticholinergics, verapamil
Delirium	Anticholinergics (including tricyclic antidepressant, antiparkinsonian, surgical premedication, bladder instability drugs), opiates, drug withdrawal
Diarrhoea	Laxatives, antibiotics, metformin, proton pump inhibitors, NSAIDs*
Falls	Sedative and antidepressant drugs (TCA** and SSRI***), hypnotics, drugs causing hypotension
Hypotension	Diuretics, all cardiovascular drugs except digoxin, levodopa, antipsychotics
Oedema	Calcium channel blockers, beta blockers, fludrocortisone, NSAIDs*
Rash, pruritus, abnormal liver function	Any

*NSAIDs non-steroidal anti-inflammatory drugs;

**TCA tricyclic antidepressant;

***SSRI selective serotonin re-uptake inhibitor

People living with frailty or dementia are especially vulnerable to drug adverse effects; close attention to all aspects of clinical therapeutics is required. Ask about the indication, from the patient or carer, electronic care records (including the electronic Summary Care Record in the UK), or general practitioner (GP). For example, furosemide is often prescribed for ankle swelling. In the absence of overt signs of heart failure, no more than half of patients actually need it (ankle swelling may also be caused by dependency, immobility, hypoalbuminaemia, or venous/lymphatic obstruction).

Question whether drugs have been assessed for effectiveness—especially antidepressants, cholinesterase inhibitors, antipsychotics, and

Physical assessment

antiparkinsonian drugs. It is easy to commence a trial, and never follow it up, or fail to withdraw the drug if there has been no clear benefit. If there is good evidence of benefit, the drug should be continued. If not, consider or suggest a trial of stopping it. Dose minimization may be possible (e.g. can furosemide be reduced to 20mg/d in stable heart failure?).

'Tablet burden' is a real issue for an older person on 10 or more different drugs. Distinguish between preventative drugs (e.g. vascular: antithrombotics, cholesterol and blood pressure lowering; bone health: calcium and vitamin D, bisphosphonates), and those controlling active problems (e.g. anti-epileptic drugs, anti-arrhythmics, diabetic drugs, analgesics, anti-anginals, heart failure, and bronchodilators). If a preventative drug is causing problems, it should be stopped. The odds on a preventative drug doing good are usually too slim to justify side-effects ('numbers needed to treat' to prevent a single event are usually in the tens or hundreds). In very frail patients, or those at the end of life, drugs should be limited to those that are directly relieving symptoms or improving function.

Ask about medicines management and compliance. Patients may openly admit they do not take all of their tablets. Who supervises the taking of drugs, and whether compliance aids are used (e.g. a dosette box or blister pack)? Difficulties in swallowing medications may be easy to address with the help of a pharmacist, who can suggest alternative formulation or routes (liquids, transdermal preparations). Child-resistant containers are difficult to open and usually inappropriate.

Ask about allergies and previous adverse effects, specifying the exact reaction if possible. Calls to GPs and reviews of records may be needed to clarify. Many adverse effects get called 'allergies'—few actually are, but you will still need to know about them. If an expected drug is missing (e.g. a statin in vascular disease, ACE inhibitor in heart failure) efforts should be made to find out if there is a reason.

Social and functional history: activities of daily living (ADL)

These aspects cover two or three dimensions of CGA, but are interrelated and often collected together. They form the core of an occupational therapy assessment, but doctors should know about them, too. For many older people they are key to understanding problems and possible solutions.

A problem with function (a 'disability'), e.g. walking or safety awareness, may be the presenting problem. Function is the final common pathway for the effects of many different diseases, or combinations of diseases. Problems with walking may be due to pain, weakness, breathlessness, falling, vision, dementia, depression, or fear. In assessment, we may start with the disability and work 'backwards' to identify the signs and symptoms (impairments) that are associated with it, and from that, work out the underlying diagnoses. Function gives insight into cognition,

Physical assessment

confidence, physical ability, and available support networks. Deterioration in function can be an important indicator of a deterioration or relapse in MH. Usually it is problems with function that make independent living or discharge home from hospital difficult, and may necessitate professional domestic or personal care support, so assessing function is part of care and discharge planning. Documented function provides a baseline against which to assess subsequent changes in health. Quantifying function tells us about disease severity. Collateral history to corroborate the patient's account is often important.

The range of activities that might be considered is wide. As a minimum, ask about eating and drinking, mobility, continence, and behaviour. An otherwise fit older person might be asked about driving, shopping, cooking, and money management. Stair climbing, walking outdoors, walking indoors, dressing, getting to the toilet, wheelchair use, and bed to chair transfers can all be considered. If problems are identified, ask how they are overcome (who shops for food? how do you get to the toilet?). Falls are common—ask specifically—as is incontinence and other lower urinary tract symptoms (LUTS), e.g. urgency, pain, or dribbling. This may not be volunteered—develop a form of words that is not open to offence, but don't be embarrassed yourself ('Do you have problems with your bladder? Do you always get to the toilet on time?'). There are many ADL scales that can standardize and quantify assessment, including the Barthel Index, Bristol ADL scale, Disability Assessment in Dementia, and Amsterdam ADL scale.

'How do you occupy your time?' can be a revealing question, and give clues about abilities, social networks, priorities, and resources. Successfully completing the *Times* crossword is a good index of cognitive competence. Many people do little more than watch television: ask what programmes they watch—are they able to follow soap operas and series? Can they answer the questions on quiz shows?

What someone does day to day depends both on their capacity to do tasks and the physical and social environment in which they do them. It also depends on opportunity, restriction (e.g. family concerns about safety, risk, or falls), and the use of aids and appliances. In assessing function, you must also assess the environment and levels of help available and used. Do they live with someone? If so, who? What sort of accommodation do they have (house with stairs, ground-floor flat, care home)? Do they have help from family, or paid carers? Make sure also to ask after the health of an elderly spouse or co-resident.

Functional improvement will often be the metric by which the success of a treatment, progress towards a goal, or by which treatment failure, recurrence, complications, or the approach of the end of life are judged.

Physical assessment

Third-party history

Most older people are able to give a full account of themselves and their symptoms. If the person has mental capacity, it is technically a breach of confidentiality to involve anyone else without their permission. It is always courteous to ask permission to consult others, although in many cases the consent will be implicit, and need not be explicit. If someone cannot give an account of themselves, best practice, best interests, and (in the UK) the law requires that others be consulted. The opportunity to explain problems or educate key carers in a joint consultation can be invaluable.

Information from an informant is usually required in cases of cognitive impairment, aphasia, or other communication difficulties, non-specific 'not coping', loss of consciousness, and falls. Thirty per cent of people experiencing syncope have no recall of losing consciousness; epilepsy is a diagnosis made primarily on third-party history; the deathly pallor of cardiovascular syncope or presyncope can be a helpful diagnostic pointer.

Retake the history from the informant, ascertain the baseline level of health and function, and the nature and time-course of decline. Identify and characterize prior ADL, as in the 'functional history', and current problems. Also find out about cognition, especially time-course of deterioration, severity, and impact on behaviour. This may be done together with or separately from the patient, by telephone if necessary. Carers may wish to ensure that you fully understand what they are experiencing, especially where there is fluctuation, and this may include information upsetting to the patient.

Family members or others with caring responsibilities often bear physical and psychological consequences—so-called carer strain—which can result in inadequate care or breakdown in care. This should be ascertained if appropriate.

There can be a tendency for a carer to want to advocate for or speak over a person with cognitive or communication problems; we must guard against failure to listen to the patient's opinions. Inclusion is important, and the impression that information is being passed on 'behind the back' of the patient must be avoided.

Others may also have useful information. Consider phoning the general practitioner, or social care providers (home care, or wardens of assisted living facilities). Look out for visitors like neighbours who may have been providing substantial help but who are not recorded in medical or nursing records. Professionals working in care homes or the community can help by ensuring that key items of health, personal, and social information are available during episodes of emergency or respite care. Hospitals can reciprocate on discharge.

Physical assessment

Anticipating hospital discharge

In hospitals, 'discharge planning begins on day one' is a slogan that may or may not be applicable in complex cases (NB: the answer will often be 'it depends'). It is important to keep options open (such as returning back home) before a full assessment and decision-making process has been undertaken.

When completing admission paperwork (including emergency MH admissions), make life as easy as possible for colleagues who look after the patient later by recording basic aspects of social and functional history, and sources of support, especially if there is a relative present who may not be available later. If strong opinions about the future are expressed early on ('she's not coming home'), record them, but try to keep all options open for as long as possible.

Discharge home with support isn't always possible, but is usually preferable, and quicker, than care home placement. Moreover, it may be that, despite severe disability and dependency, someone already well supported at home can be discharged quickly after resolution of a minor crisis even when you would have anticipated a long and difficult admission. However, only follow this route if you know the support arrangements that are in place.

End-of-life planning

Sometimes you need to identify quickly that terminal care is appropriate, and plan accordingly. This may include information about advance decisions to refuse treatment, prior discussions or decisions, priorities, preferences, fears and values, attitudes to risk, and available informal support and professional care. End-of-life planning will include ascertaining problems and distressing symptoms, identifying who should be involved in discussions, and consideration of spiritual needs.

Physical examination

The procedure for examining each physical system is no different from those used in any other adult. Often this will be targeted at the particular problem being addressed, but at least once during a hospital admission, someone should do a full physical examination. It is important to ensure that this is followed up on if it was not possible at the point of admission. We must pay careful attention that all parts of the physical examination are performed.

General appearance

An acutely ill patient is often disengaged, lethargic, and may be drowsy; these features may represent a hypoactive delirium. Weight loss, cachexia, or loss of muscle mass may indicate severe illness such as cancer, malnutrition, long-standing inactivity, chronic disease including dementia, or a treatable condition such as thyrotoxicosis or tuberculosis.

Physical assessment

Unkempt appearance may be a warning sign, indicating impairment of function.

A patient prone to agitation, restiveness, or described as noncooperative should be approached carefully. Establish a rapport by introducing yourself and friendly small talk. Try to avoid anything that might be interpreted as a threat. Do not rush. Hand holding and smiling may help. Talk calmly and in a friendly tone, and explain everything that you are doing before and as you do it, so-called 'talking-through', as you examine or perform a procedure, to try to reduce fear. Adopt a nonthreatening body posture (sitting or squatting), but ensure your personal safety. Prioritize what is most important to examine. If the person objects or resists, and cannot be persuaded otherwise, do not persist. Use observation, examine what you can, document your attempt, and come back another time if necessary ('leave and return' strategy).

Communication

Assessing communication is part of both neurological and mental state examinations, but many physicians neglect to examine or describe it formally. Interpreting the history, mental state, distress, insight, mental capacity, and engagement with and adherence to treatment all depend on communication.

Initial assessment is informal and occurs during conversation. Sensory impairment (deafness, visual impairment) should be noted and mitigated as much as possible, and a translator sought if needed. Dysphonia is a disorder of voice production ('hoarse' or whispery), which implies vocal cord paralysis or pathology. Dysarthria leads to problems with word production, and may be due to face or tongue weakness, or incoordination ('cerebellar-type' dysarthria). Aphasia is inability to understand (receptive) or express. Understanding can be tested by asking the person to follow motor commands, initially simple ('close your eyes') but also more difficult (three-stage or complex instructions such as during neurological examination). Word-finding difficulties may be evident in spontaneous speech, and can be tested through object naming or picture description. Other tests include sequences (days of the week), multiple choice or yes/no answers, and listening for crying, swear words, or unformed sounds.

Communication may be affected by physical health (pain or breathlessness), other aspects of cognition (memory, reasoning, or insight), mood, thought content (delusions), intelligence, and world view.

Postural blood pressure

Blood pressure varies with circumstances, and in older people may vary dramatically throughout the day, especially in people with delirium and dementia. Drugs or autonomic failure make postural hypotension quite common (25% of those over 65 years). When investigating dizziness or falls, measure blood pressure after five minutes lying, then after 40

Physical assessment

seconds, one minute, and three minutes standing (an automated sphygmomanometer takes about 20 seconds to make a reading). Record if the patient felt dizzy or lightheaded on standing, and if the pulse rate increases (as it should). A systolic drop of 20mmHg, or diastolic drop of 10mmHg is significant. Blood pressure falls that have not reversed within 40 seconds of standing are associated with increased risk of falls (Bhangu et al., 2017).

Mouth and dentition

Oral health is an important consideration, and is of increasing relevance with a greater proportion of people retaining their natural teeth into old age. Poor dentition can cause dysarthria and swallowing difficulties, as well as being a risk for infective endocarditis. Dental pain or abscess may be a source of distress in someone who cannot communicate. Be very careful to prevent dentures getting lost, especially in hospital.

Vision

Distinguish between uniocular loss (a problem anterior to the optic chiasm, broadly ophthalmology) and homonymous loss (a problem posterior to optic chiasm, broadly neurology). Sudden vision loss is an emergency that requires immediate explanation (do fundoscopy, and/or refer to an eye emergency department). Ensure that an adequate explanation has been reached for any visual loss; refer on to ophthalmology if this is not clear, although optometrists and orthoptists can also examine the eye. Any sudden change in function might represent sudden visual (or hearing) loss in someone who cannot communicate well.

Musculoskeletal system

Joint disease is very common in older people (50% of 80-year-olds have knee arthritis), and may contribute to immobility, falls, dizziness, and pain. Examination requires observation, testing range of movement in all directions, and during function, noting pain and deformity. Examine the shoulders and hands if symptoms dictate. Look at the knees and hips, and the bulk of quadriceps muscles. Record if the knees can be fully extended (they should go into a few degrees of hyperextension), and the extent of any fixed flexion deformity. Test flexion/extension and internal/external rotation of the hips. If painful, think about the shortened externally rotated leg in hip fracture. An apparently painful hip, with a normal X-ray, may be due to a pelvic fracture. Joint pain may be referred from the joints above or below. Small joint arthritis of the hands and feet may be distressing and disabling. Neck arthritis may be associated with dizziness on standing when the neck is extended (due to disordered proprioception, not vertebrobasilar ischaemia). Kyphosis indicates vertebral shape changes due to osteoporosis. A vertebral compression fracture or a rib fracture produces pain and severe localized tenderness.

Physical assessment

Feet

The feet should always be examined, especially in people with diabetes. Look for ulcers, deformities, signs of ischaemia, sensory loss (e.g. neuropathy in diabetes), and neglected nails (onychogryphosis).

Neurological examination

Many doctors consider this the most difficult part of physical examination, and thus do a brief version of little value, neglect it entirely, or say that examination was impossible. Mental illnesses are (usually) diseases of the brain, so neurological examination is as important for the psychiatrist as the geriatrician.

Examining the nervous system can be lengthy, which is both time-consuming and often beyond the stamina of a frail or ill patient. Musculoskeletal problems may make neurological function difficult to interpret. Skilled observation alone can provide many clues, e.g. a patient walking into a consultation displays involuntary movements, cannot follow what you are asking, or is agitated or uncooperative. Examining the nervous system properly takes practice, and some signs are subtle (such as fasciculation, bradykinesia, or incoordination).

The key is to be clear about the purpose of the exam. The 'nervous system' is a collection of several systems: higher thought and consciousness, vision, brain stem, hearing and balance, speech, pyramidal motor, extrapyramidal motor, coordination, sensory, and autonomic. An old adage states that the purpose of neurological examination is to ask: '*where* is the lesion?' followed by '*what* is the lesion?' (i.e. what pathologies might occur at that location?), to which we might add '*so what about* the lesion?' (i.e. what are the functional consequences?). We use knowledge of neuroanatomy to determine where the lesion is. Where we look is determined by the nature of the problem and the symptoms revealed in the history. If we are investigating falls, we need to examine vision, vestibular, and pyramidal function, coordination, feet tactile sensation, and proprioception. If the person has cognitive impairment, we are interested in alertness and attention, extrapyramidal or parkinsonian symptoms (bradykinesia, increased tone, tremor, postural instability), or pyramidal motor symptoms (weakness, increased tone, hyperreflexia, up-going plantar response).

If you expect the examination to be normal, in the absence of specific neurological symptoms, or 'red flag' features (focal onset epilepsy, or indicators of raised intracranial pressure, e.g. headache, vomiting, drowsiness) a minimum examination should reassure you that a structural brain lesion is unlikely (Donaghy, 2005). It takes about five minutes to perform and comprises: gross visual acuity and visual fields; eye, face, palate, and tongue movements; speech; arm tone; pronator drift (ask the patient to hold their arms out in front with their eyes closed, as if holding up a parcel, for 20 seconds), power in shoulder abduction and first dorsal interosseous (index finger abduction); finger-nose coordination,

Physical assessment

dysdiadochokinesis; hand and foot sensation; and standing balance/Romberg's test and gait.

If cooperation is lacking, observe and use ingenuity. You may be able to detect spatial inattention and visual field loss, facial asymmetry, speech and swallowing problems, abnormal limb movements, symmetry of limb movement and co-ordination, ability to stand from sitting, gait, and possibly limb tone, and hand grip (via a hand shake).

Be aware that physiotherapists also perform a sophisticated neurological examination, albeit subtly different from that done by doctors. It is functionally (rather than diagnostically) orientated, and includes items unfamiliar to doctors, e.g. muscle activation in standing. Speech and language therapists examine the lower cranial nerves as part of swallowing assessment as well as communication. Occupational therapists work through 'activity analysis', which is based on neuropsychological understanding, including assessment of spatial neglect, apraxia, sequencing, or executive function problems.

Nowadays, access to CT or MRI scanning is generally easy, but in the absence of 'red flag' symptoms, a normal, competently performed neurological examination almost excludes significant structural brain pathology.

Skin

New pressure sores on specialist wards are rare, but may occur on surgical wards and in nursing homes. All patients should be assessed for risk of pressure sores on admission to hospital; increasing age, impaired mobility and poor nutrition are risk factors for pressure damage. The sacrum, greater trochanters, and heels are most vulnerable. A sore can appear in as little as 30 minutes if a sufficiently immobile patient (e.g. after a hip fracture) is lying on a sufficiently hard surface. Shearing (from dragging across bedding) or maceration (usually from incontinence) are further mechanisms of skin damage. Specifically look at pressure areas, know the warning signs (non-blanching erythema or blisters), and how to stage a pressure sore (1: non-blanching erythema; 2: skin break; 3: full-skin thickness or subcutaneous tissue loss; 4: muscle cavity). Describe the extent and nature of dead tissue or slough, the state of the ulcer border (when healing, 'granulation tissue' looks moist and purple), and look for signs of infection.

Leg ulcers can be described similarly (but you have to take the bandages off first, and if you take them off be sure to have the means to dress them again).

Beware the cold, pale, numb, painful, acutely ischaemic limb, which needs urgent vascular surgical assessment.

Physical assessment

Pain

'Pain is what the patient says it is' (McCaffery, 1968). However, in someone with impaired cognition or communication, they may not be able to say, and pain may manifest as non-specific distress or a difficult behaviour, such as resistance to care, apathy, aggression, or calling out. We often use very abstract terms to describe pain (burning, stabbing, crushing, aching, and so on), which can be difficult for a person living with dementia. If the patient cannot localize or describe a pain, or if there is unexplained distress or agitation, it is necessary to look for it. A general survey of likely sites includes mouth, neck, joints, back, abdomen, constipation, urinary retention, skin, and genitals. Also observe the patient during transfers or walking, and discuss with family, carers, or nurses about pain during personal care. It is all too easy to miss fractures, including of the hips, pelvis, or neck of humerus.

Continence assessment

The commonest diagnoses will be unstable or overactive bladder and incomplete bladder emptying. A post-void bladder ultrasound scan and urine dipstick test provide the 'quick wins', but more involved assessment may include a neurological examination of the legs, inspection of the vulva for atrophy or prolapse, and a rectal examination for prostate enlargement and constipation.

Functional assessment

In someone who is fairly well, doctors can assess sit-to-stand, bed transfers, and gait. Anything more difficult is associated with risk, both to the patient (falling) and practitioner (back injury). Always be sure to follow your organization's manual handling policy. Nurses usually have good judgment about what someone can do, but you may require formal physiotherapy and occupational therapy assessments. Do not try to supervise a difficult transfer (e.g. to get someone on a bed) if you are not confident, or have not been trained. The golden rule is: if in doubt, use the safest transfer, using a hoist if necessary.

Investigations

Some people believe that frail older people are over-investigated. Others argue that age discrimination denies older people access to the best modern imaging technology. Rather than focusing on investigating more or investigating less, the most important thing is to investigate with a clear purpose. Older people with severe mental illness are particularly vulnerable to health inequality and suboptimal access to investigations and treatment for physical health problems.

Investigation is important in such cases since diagnosis may be more difficult due to non-specific and atypical presentation, multiple pathologies, and uncertain information, especially if history-taking is

Physical assessment

compromised by cognitive impairment or communication difficulties. This can mean that older people need more, not less, access to high-tech tests.

However, some tests are unpleasant, and most carry a cost, if only in terms of time, travel to hospital or the scanner, and inconvenience ('investigation burden'). For a frail, cognitively impaired or bewildered older person this can be a major trial. Tests done for defensive or academic reasons alone cannot be justified.

Tests provide information, which is valuable, but some argue that a test is only justified if it is going to change management. However, a test can be useful regardless of whether it leads to therapeutic intervention. A test result can inform prognosis, including reassurance when it is normal, or can help you decide to stop investigating further (for example, a scan reporting widespread cancer). If there is doubt about the wisdom of investigation, discuss with the patient and family and use the principles of shared decision-making to decide (options, pros and cons, how to weigh up the information) (Coulter and Collins, 2011). Clinical judgment is important, as is offering an opinion; it is unfair to put this professional responsibility onto individuals or families alone.

The practicality of tests must be considered and discussed. For example, retaining barium in the colon may be impossible, in which case colonoscopy is preferable. All bowel investigations are impossible without fully evacuating the bowel, which is unpleasant, and may itself require hospital admission. An MRI scan is impossible if there is a pacemaker or metallic implants (the scanning department will complete a safety questionnaire, and some implants are MRI-compatible), or if the person is too claustrophobic (up to 10%). If a test is judged to be absolutely necessary, sedation (usually with lorazepam) or a general anaesthetic may be justified if the patient is too agitated or fearful to allow it otherwise. No one benefits from an uninterpretable MRI scan degraded by movement artefacts.

Blood tests are less burdensome. Make sure there is a recent blood count, renal, liver and thyroid function, and calcium. Anaemia, neurological, and psychiatric symptoms in addition need vitamin B12 and folate measurement. C-reactive protein (CRP) is a useful screen for sepsis but (like temperature and the white cell count) is not 100% sensitive (there can be false negatives), nor specific (there are other causes), and sometimes the rise in CRP with infection is delayed up to 48 hours.

Dipstick urinalysis virtually excludes urinary infection when it is negative. Urinalysis positive for nitrites (suggesting presence of bacterial urease) and leucocyte esterase (suggesting presence of white blood cells) needs culture to confirm infection. Thirty per cent of elderly women, and anyone with a urethral catheter, will have asymptomatic bacteriuria, so the test must be interpreted in the light of circumstances and symptoms (which are unreliable in older people) (Ninan et al., 2014). If someone is non-

Physical assessment

specifically unwell and there is no other explanation, treating the urinary tract infection (UTI) is unavoidable.

Don't repeat tests unnecessarily. B₁₂ and thyroid function will not change over six months or a year. Don't measure vitamin D in someone on supplements (unless you suspect malabsorption).

Direct functional assessment

Doctors may watch someone walking or dressing, but allied health professionals routinely use a combination of self-report, informant information, and direct observation. This often comprises a combination of 'assessment' (ongoing or re-assessment) and 'therapy' (practice and intervention).

For example:

- A physiotherapist might assess transfers, walking, use of mobility aids, or ability to climb stairs.
- An occupational therapist may assess dressing, kitchen skills, or do a home visit to assess function in the home environment.
- A speech and language therapist will directly assess swallowing and communication, and use of communication aids.
- An audiologist will assess for and then teach and review use of a hearing aid.

Nurses use observations of physiological vital signs (alertness, pulse, blood pressure, temperature, oxygen saturation) to monitor physiology, and 'observation' of wellbeing, distress, ADL, oral intake, and behaviour. This often includes describing varying degrees of assistance. This represents valuable, if informal, 'assessment' and should be discussed in handover and multi-disciplinary team meetings.

Problem lists

A problem list is a way of assembling complex, disparate information to give an overview of concerns and where work needs to be done. It is usually a working tool, rather than a formal document.

Problems can be symptoms or impairments (e.g. breathlessness, weakness, spasticity, pain), diagnoses, disabilities (eating, mobility, continence, behaviours), social or environmental issues, abnormal test results, risks, or predispositions.

Use a problem list as part of the 'history of the presenting complaint', especially where there are many different symptoms. In sub-acute or long-term care settings (e.g. medical, MH, or rehabilitation wards, intermediate care or a care home) where more information has emerged from tests and assessments, and as issues develop over time, the problem list becomes a reassessment of 'where we have got to'. You may also use

Physical assessment

it at a ward round or weekly review. It is a way of making sure that things do not get overlooked.

Common problems

Immobility

Immobility is one of the 'geriatric giants' that comprise non-specific presentations of acute illness. It represents an 'activity limitation' or 'disability', and is often the consequence of multiple pathologies and other factors, such as volition and environment, although a single cause may be identified (Table 11.4). A common crisis occurs when someone has suddenly become more immobile ('gone off their legs') due to acute illness. Immobility also results from chronic illness, including musculoskeletal, neurological, or cardiorespiratory disease and dementia.

Table 11.4 Assessing immobility.		
System	Problem	Investigation
<i>Musculoskeletal</i>	Arthritis, especially knees, hips, back	Mainly clinical; X-ray may help
	Covert fractures (pelvis, hip, tibial plateau)	X-ray
	Limb loss	Clinical
	Foot deformities (toenails, ulcers, hallux valgus)	Clinical
	Myopathy	Vitamin D status, thyroid function, CK ^a , ESR ^b ; steroids
<i>Neurological</i>	Hemiparesis (usually stroke)	Clinical, CT ^c /MRI ^d brain
	Paraparesis (including spinal cord compression or ischaemia, cervical myelopathy)	MRI ^d spine, B ₁₂
	Parkinson's disease	Clinical

Physical assessment

	Peripheral neuropathy	Nerve conduction studies, glucose, B ₁₂ , ESR ^b , autoantibodies
<i>Vision</i>	Blindness	Clinical
	Hemianopia and inattention	Clinical, CT ^c brain
	Refractive error	Optician, glasses
<i>Cardiovascular</i>	Heart failure (breathlessness, oedema)	Clinical, chest X-ray, ECG ^e , echocardiography,
	Chest pain	Clinical, ECG ^e , chest X-ray, angiography
	Postural hypotension	Clinical, lying, and standing blood pressure
	Intermittent claudication	Clinical, duplex ultrasound, angiography
<i>Respiratory</i>	Breathlessness (COPD ^f , pulmonary embolism, fibrosis, effusion, pneumonia, cancer)	Chest X-ray, spirometry, blood gases, CT ^c thorax
<i>Skin</i>	Leg or foot ulcers	Clinical
	Oedema (dependency, heart failure, hypoalbuminaemia, venous or lymphatic obstruction)	Clinical, albumin, as for heart failure
<i>Psychological</i>	Anxiety, loss of confidence	Clinical
	Depression with psychomotor retardation	Clinical

Physical assessment

	Dementia (apraxia, executive failure)	Clinical
aCK: creatine kinase; bESR: erythrocyte sedimentation rate; cCT: computed tomography; dMRI: magnetic resonance imaging; eECG: electrocardiogram; fCOPD: chronic obstructive pulmonary disease.		

An important additional contributor to immobility is 'deconditioning': the loss of muscular strength and stamina, and cardiorespiratory fitness following a period of illness, immobility, or under-activity, sometimes over months or years. Loss of muscle mass and function is sometimes termed 'sarcopenia'. This is a particular problem during hospital admissions, when walking or other activity is not possible due to illness, discouraged or prevented due to fear of falls, or pointless due to lack of purpose or opportunity. Fortunately, deconditioning is reversible with sustained and progressive exercise (that is, exercise getting more difficult over time), and, along with restoration of confidence, probably accounts for a large part of what is achieved in general geriatric rehabilitation.

Gross mobility can be approximately quantified as a hierarchy of levels, from sitting balance, to transfers, through indoor mobility, stairs, outdoor mobility, and crossing roads or rough ground.

Further qualification can be in terms of:

- human help (number of persons, hands-on, or supervision)
- aids required (wheelchair, wheeled Zimmer frame, pulpit frame, gutter frame, three-wheeled delta frame, crutches, sticks)
- degree of difficulty experienced
- distance or speed achieved, e.g. timed walk or Timed Up and Go (TUG) test (Podsiadlo and Richardson, 1991).

A report may, for example, describe someone as being able to walk 15 metres with a Zimmer frame and the assistance of one person.

The medical role is to assess and identify causes, intervene to reverse treatable causes, palliate outstanding symptoms, and initiate rehabilitation to improve motor function and other functional abilities. Assessment will identify symptoms and signs causing the problem, which must then be explained by diagnoses. This requires history-taking and thorough examination of the neurological and musculoskeletal systems, heart, and chest. Reports from nurses and therapists can help to identify the immediate reasons why someone cannot walk. When mobility declines suddenly, consider an acute medical illness (infection, fracture, metabolic disturbance, new stroke, drug side-effect).

Immobility may not always be 'curable', but as a minimum we should not miss a treatable cause. If part, at least, of a progressive decline is due to deconditioning, this is eminently reversible. After an acute illness, the

Physical assessment

ambition should always be a return to pre-morbid mobility. Most direct restorative intervention will be directed and supervised by physiotherapists, nurses and care/healthcare assistants, or family.

Falls

Falls, and fear of falling, are common, and limiting. A third of older people fall each year, as do up to 60% of people living with dementia. Falls are inevitable if activity and mobility are encouraged; a complete absence of falls suggests inactivity or restraint. A fall can result in injury, which must be identified or excluded.

To assess someone who has fallen or who is at risk of falls, we must understand the balance system. Four mechanisms detect postural instability:

- vision
- the vestibular system
- proprioception in the neck, ankles, knees, and hips
- tactile sensation in the feet.

The motor and musculoskeletal systems provide the effector mechanism for adjusting to balance disturbances. The processor integrating sensory input and motor response is the central nervous system, acting through both reflex and intentional mechanisms. Balance is rarely static (e.g. standing still); posture must be maintained during walking, climbing stairs, and other activities, when we deliberately make ourselves unstable by moving our centre of gravity outside the base of support, and then react and compensate to maintain control. Anticipation, navigation, sequencing, planning, and judgment are required (visuospatial and executive functions). Abnormalities of any of these components increase the tendency to fall.

Falls may be classified in several ways.

By main cause (about a third each):

- Acute illness: falling is a non-specific presentation of any illness in an older person, so be vigilant for acute illness, such as pneumonia, adverse drug effect, arrhythmia, stroke, gastrointestinal bleed, metabolic or electrolyte disturbance.
- Chronic illness: especially neurological disease, including Parkinson's disease, stroke, and dementia, arthritis, cardiovascular problems, and visual problems.
- Environmental challenge (accidents, tripping, lighting).

Physical assessment

Pre-disposition and precipitation:

- Anyone can fall. What varies is the risks people take in order to do things, and the probability that any given activity, trauma, or insult will result in failure to maintain balance. People will also vary in the likelihood of a resulting injury.
- A long list of factors has been described that increase the risk of falls, including previous falls, chronic neurological disease, lower limb arthritis and proximal muscle weakness, abnormal gait, history of heart disease, postural hypotension, taking four or more prescription drugs (especially sedative, neuroleptic, and antidepressant medication), poor vision, and foot problems. The more risk factors, the greater the chance of falling, so interventions tend to be multifactorial to remove or reduce as many risk factors as possible.
- The precipitant may or may not be obvious. A single adequate explanation (seizure, syncope, acute stroke, heart attack, pulmonary embolus, trauma, tripping, misjudgment) should be sought, but will often be uncertain.

Syncopal or nonsyncopal, or association with dizziness:

- Syncope (loss of consciousness) has particular diagnostic implications (possible head trauma, cardiovascular, epileptic, hypoglycaemic causes; see Table 11.5)
- Syncope is associated with amnesia for the event in 30% of cases.
- Type of dizziness may give diagnostic clues. There are three main types, but dizziness is hard to describe, and precise classification may not be easy:
 - *presyncope* is 'light-headedness, as if about to faint', a 'swimming' sensation with blurred or darkened vision, and possibly tinnitus, and generally implies a cardiovascular cause.
 - *vertigo* is a spinning sensation, and implies vestibular or brainstem dysfunction.
 - *dysequilibrium* is a perception of unsteadiness, or staggering, 'as if drunk', which may be neurological or musculoskeletal in origin. Brief (few seconds) dysequilibrium occurs when the (arthritic) neck is extended during standing (NB: ENT surgeons sometimes use the term 'disequilibrium' to mean vertigo!).

Table 11.5 Causes of syncope and pre-syncope.

Factor	Comment	Investigation
<i>Head trauma</i>	Usually obvious. Look for lacerations.	CT ^a brain if intracranial bleeding suspected (drowsy, features of

Physical assessment

	Beware cervical spine injury	raised intracranial pressure, focal neurology) or on anticoagulants.
<i>Epilepsy</i>	Generalized seizures are defined by loss of consciousness. Get an eye-witness description. Ask about ictal and post-ictal features.	CT ^a brain, glucose, electrolytes, EEG ^b .
<i>Intracranial bleeding</i>	Primary or subarachnoid haemorrhage. Highly unlikely to be transient, unless it precipitates a seizure	CT ^a brain, +/- angiography.
<i>Hypoglycaemia</i>	Loss of consciousness only if severe, unless it precipitates a seizure	Capillary blood glucose
<i>Vasovagal syncope</i>	3Ps: provocation, posture, prodrome.	Clinical diagnosis, exclusion of other causes
<i>Postural hypotension</i>	Due to drugs, autonomic neuropathy, e.g. in diabetes, or age- or dementia-related autonomic dysfunction	Lying and standing BP, or head-up tilt test; Autonomic function tests
<i>Carotid sinus hypersensitivity</i>	Cardioinhibitory and vasodepressor types	Head-up tilt test.
<i>Other provoked syncopes</i>	Micturition, defaecation, cough	Clinical diagnosis
<i>Bradyarrhythmias</i>	Heart block, Stokes-Adams attacks, sick sinus syndrome	ECG ^c , 24h ECG ^c

Physical assessment

<i>Tachy-arrhythmias</i>	Sustained or paroxysmal, AF ^d , SVT ^e , VT ^f	ECG ^c , 24h ECG ^c
<i>Tight aortic stenosis</i>	Typically exertional syncope (but uncommon)	Echocardiography
<i>Acute myocardial infarction</i>	Temporary or permanent myocardial damage and pump failure; provoked transient arrhythmia; vasovagal secondary to pain.	ECG ^c , troponins, cardiac enzymes

^aCT computed tomography;

^bEEG electroencephalogram;

^cECG electrocardiogram;

^dAF atrial fibrillation;

^eSVT supraventricular tachycardia;

^fVT ventricular tachycardia

Falls assessment needs to be multi-disciplinary:

- The predisposition and precipitant model is most helpful. First, explain the fall, what happened, and why? Then identify what risk factors make the person prone to falling.
- A history from a witness is required if there was syncope, an unexplained fall, or no recall.
- Identify the circumstances of the fall. What was the person doing? Was there a clear and sufficient cause (tripping, being pushed, falling out of bed, standing without habitually required supervision)?
- Was there any warning? Did the person complain of feeling dizzy? Was there time to sit down? Or did the patient drop to the ground?
- What did they look like? Cardiovascular causes often cause a 'deathly pallor'. Generalized epilepsy causes transient respiratory arrest, and the patient may go blue. Convulsion (shaking), tongue biting, or incontinence may be evident.
- Were there associated symptoms such as chest pain, palpitation, or breathlessness?

Physical assessment

- Did anyone take the pulse during the episode?
- Enquire if it has happened before. If so, how often? Were there obvious precipitants?
- Ask if acute or chronic alcohol excess involved?
- Assess general function, including transfers, walking, stairs, outdoor mobility, dressing, and bladder function (hurrying to the toilet can lead to lapses of judgment; nocturia is another occasion of risk).
- Examination during a syncopal episode is invaluable, especially for features of a seizure; take pulse, blood pressure, ECG rhythm strip if available, respiratory rate, or neurological signs
- Between attacks a thorough cardiovascular, neurological, musculoskeletal, and ear examination is required.
- Check postural blood pressure.
- Examine for heart murmurs, suggesting aortic stenosis or other structural abnormalities, e.g. hypertrophic cardiomyopathy. Get an echocardiogram if suspicious.
- Test visual acuity (separately in each eye) and examine for cataracts. Are the spectacles up to date? Bifocal or varifocal lenses increase the risk of falling.
- Test visual fields, and for visual inattention. Examine for Parkinsonism (cogwheel rigidity, best felt at the wrist), bradykinesia (touch the thumb on each finger in turn), and tremor. Examine for pyramidal (upper motor neurone) lesions—weakness, increased tone and reflexes, up-going plantar response (Babinski's sign). Pronator drift is a sensitive test for subtle weakness. Also test proximal muscle power (shoulder abduction, hip flexion) and for lower limb sensation loss (pin prick, vibration, proprioception).
- Test cerebellar function (finger–nose ataxia, dysdiadochokinesia).
- Examine the neck for cervical spondylosis, hips and knees for arthritis (unsteadiness either due to mechanical instability or 'nociceptive inhibition', giving sudden loss of supporting muscle tone around an acutely painful joint).
- Examine the feet for overgrown toenails (onychogryphosis), corns, calluses, ulcers, and other deformities.

There are some important caveats in assessing falls:

- Transient ischaemic attacks (TIA) do not cause syncope or presyncope.
- Isolated vertigo (with no other associated neurological features) is usually due to vestibular dysfunction.
- Hyperventilation can cause dizziness (symptoms are reproduced by hyperventilating).

Physical assessment

- Vasovagal syncope always occurs standing up, and there is a clear precipitant (pain, fear, smell) and some presyncopal warning symptoms before the loss of consciousness.

The choice of tests will be guided by prior assessment (Table 11.5):

- The diagnostic yield of echocardiography and 24-hour ECG is low, and these tests should not be used indiscriminately in the absence of appropriate findings from the history, clinical examination, or 12-lead ECG. A 24-hour ECG recording can be difficult to interpret, as they often show minor abnormalities of no particular diagnostic value, or there may be false negatives. If the clinical features are sufficiently suspicious, 48- or 72-hour recordings can be done, or an implantable loop recorder inserted (like a pacemaker that can be remotely interrogated)
- CT or MRI scanning is only required when specifically indicated. Fits require neuroimaging. Possible bony injury resulting from falls requires appropriate imaging.

Environmental assessment and modification, usually by an occupational therapist, to reduce hazards, optimize equipment and appliances, and review lighting, are commonly employed in falls prevention programmes.

Bony injury is painful, and fractures are usually severely painful, although this can be difficult to assess if the patient has communication impairment. The only way to exclude a fracture is an X-ray (or other imaging), which involves a disruptive trip to hospital and the possibility of an escalating cascade of assessment and precautionary admission. Someone who can weight bear through a limb is unlikely to have fractured it, and although a pelvic or vertebral fracture is possible, management of these is usually conservative. Arthritic joints hurt more after trauma, and this usually persists for several weeks. Muscle or ligamentous injuries are also possible, and recover over four to six weeks with analgesia and progressive return to normal activity.

Head injury is worrying because of the possibility of intracerebral haemorrhage. Subdural haematoma can occur after minimal or unnoticed trauma, and if significant will result in fluctuating drowsiness, focal neurological signs, or increased confusion. Subdurals are potentially operable but, as a general rule, frail patients over 80 do not tolerate neurosurgery well. Other haemorrhagic conditions, including cerebral contusion or traumatic subarachnoid haemorrhage, can result from falls, but are managed conservatively. The only way to tell for sure is to do a CT head scan. It is also possible that an intracerebral haemorrhage or aneurysmal subarachnoid haemorrhage caused the fall. Risks are greater, and the threshold for CT scanning reduced, in those on anticoagulants.

Prolonged lying after a fall may result in pressure sores, rhabdomyolysis (with greatly raised CK), which can lead to acute kidney injury and hypothermia and indicates cognitive impairment or social vulnerability.

Physical assessment

Incontinence and lower urinary tract symptoms (LUTS)

Like other non-specific presentations of acute illness, new incontinence can be caused by any acute illness, and is not necessarily confined to those affecting the urinary tract. To determine if the incontinence is new requires a history of what went before. So-called 'transient' urinary incontinence should resolve with the underlying illness.

To diagnose a UTI requires evidence of systemic infection (temperature, raised CRP or white cell count), and some evidence of involvement of the urinary tract (dysuria or frequency, or a positive urine culture). Heavy pyuria is suggestive. A negative dipstick test for leucocytes, nitrites, blood, and protein more or less rules out UTI. A positive dipstick test is insufficient by itself to diagnose UTI; follow-up with culture is required. About 30% of older women have asymptomatic bacteriuria, which does not require antibiotic treatment. Defining what is truly 'asymptomatic' can be difficult, if the clinical presentation is non-specific (such as a fall or delirium), in which case treatment is unavoidable. Not all incontinence or delirium is caused by UTI, but a dipstick test, and culture if positive, is mandatory. Over-diagnosing UTI leads to other things being missed (Ninan et al., 2014).

'Functional incontinence' is wetting caused because of immobility, communication difficulties, disorientation, or inability to find a toilet (especially after stroke or for a person living with dementia in a new environment or strange hospital ward), rather than because the bladder is abnormal.

The majority of longer-term bladder problems among older people is caused by detrusor instability (overactive bladder), followed by incomplete bladder emptying (retention). Urgency and nocturia can be almost as troublesome as incontinence itself. Urologists have a saying that 'the bladder is an unreliable witness', meaning that it is difficult to make accurate diagnoses from symptoms alone. The cardinal feature of an overactive bladder is urinary urgency (inability to postpone the need to void). Urgency may be brought on by trigger factors: arriving home (the 'key in the door phenomenon'), bumpy rides, or the sound of running water. Other symptoms include urinary frequency and nocturia. Many cases represent primary detrusor instability (no evident precipitating cause), but other causes include any neurological disease (including stroke, dementia, and multiple sclerosis, and in which case it may be called 'hyperreflexia'), prostatic hyperplasia, bladder infections, cancers and stones, and oestrogen deficiency. Fast filling also provokes unstable bladder contractions, such as after drinking several cups of caffeinated drinks or alcohol, or taking loop diuretics.

Examination has a limited role, apart from excluding neurological disease and feeling for an enlarged bladder and prostate gland per rectum (but these are poor guides). Women may be examined for atrophic urethritis, but essentially all older women are oestrogen deficient. The gold

Physical assessment

standard for diagnosis is cystometry (bladder pressure studies), which is invasive and unpleasant, but may be useful if an enlarged prostate is responsible. A frequency-volume chart over three days gives a lot of information, including functional bladder capacity (normal is 350–600ml), which is likely to be low (150–250ml) in detrusor instability, frequency (less than seven times by day and once at night is normal), and the day/night split of urine production.

Some people with incontinence, especially in dementia, will not be cured, and a routine of prompted voiding (about every two hours), along with adequate containment is the best that can be achieved. However, in assessment, it is important not to miss infection, the effects of drugs, or retention.

Nocturia is a troublesome problem for older people, resulting in disturbed sleep and falls. About half of women over 70 pass urine two or more times at night. There are many 'medical causes', including diabetes, heart failure, especially with leg oedema, hypercalcaemia, alcohol or tea drunk in the evening, and taking lithium drugs that must be identified. Many are due to age-related nocturnal polyuria, due to a combination of loss of diurnal production of antidiuretic hormone and renal insensitivity to it. A day/night split with more than a third produced at night is diagnostic (in younger adults, urine production halves during sleep).

Incomplete emptying is easy to assess with the use of portable ultrasound scanners. These must be used post-void. Anything less than 100ml is normal, although symptoms are unlikely with volumes less than 300mls residual. A residual volume over 100ml precludes the use of anticholinergic bladder-stabilizing drugs, however. Causes include anticholinergic drugs, prostatic enlargement, faecal impaction, spinal cord disease and detrusor failure. Check renal function and prostate specific antigen, and do a rectal exam (or abdominal X-ray) to assess for faecal loading (as well as examining the prostate).

'Obstructive' urinary symptoms may be reported by men including poor stream, hesitancy (slowness to get started), intermittency (stop-start flow) and terminal dribbling. A urine flow rate (the urology clinic will have a machine), cystoscopy, or cystometry are used to make the diagnosis formally.

Faecal incontinence may be due to diarrhoea, which requires investigation in its own right. Describe the stool type using the Bristol Stool Scale (Lewis and Heaton, 1997). Do not miss cases caused by drugs or laxatives. Such is the desire among healthcare professionals to avoid constipation that laxatives are now the commonest cause of faecal incontinence in care homes. Faecal incontinence can be due to constipation with overflow; the rectum produces mucus, which gets stained with faeces and passed as 'spurious diarrhoea'. More commonly, a disinhibited 'neurogenic' colon (equivalent to the unstable bladder) can be caused by neurological disease or dementia (Box 11.1). This is a

Physical assessment

diagnosis of exclusion. For the most part, toileting while trying to predict bowel movements and containment are all that can be done, apart from a 'bowel regime' (constipate with loperamide and electively evacuate with an enema, which is unpleasant and generally disliked by patients unless it is the only way to remain at home). Using a diary may help to identify patterns.

Box 11.1 Causes of faecal incontinence

- Diarrhoea
- Laxatives or other drugs
- Disinhibited 'neurogenic' colon
- Constipation with overflow incontinence
- Anorectal sphincter damage (usually childbirth or surgery)
- Immobility
- Diminished level of consciousness or unawareness

Stroke

Stroke is a syndrome of sudden onset (or rapidly progressive over 24h) focal neurological deficit of presumed vascular origin. A newer, pathologically based definition is 'focal brain injury caused by sudden interruption of blood flow'. TIA is a stroke that gets better quickly, usually within the hour, by definition within 24 hours. The importance of TIA (and other minor stroke) lies in its propensity to recur (8% within a week, 17% within three months), necessitating rapid investigation and institution of secondary prevention measures.

The clinical manifestations depend on the site of the injury and include hemiparesis, hemisensory loss or hemi-neglect, visual field loss, speech and swallowing disorders, cranial nerve palsies, incoordination, and cognitive impairment.

Stroke is a syndrome: a collection of signs and symptoms. The first diagnostic task is to exclude mimics (including hypoglycaemia, fits, migraines, tumours, old stroke made worse by intercurrent illness). The next task is to distinguish an infarct from a bleed, which requires early brain imaging (preferably immediately, certainly within 24 hours). This has assumed a new urgency with the availability of thrombolytic therapy for use within 4.5 hours of onset for infarcts ('brain attack').

Stroke diagnosis requires a mechanism or explanation to be defined, although no convincing cause is found in up to half of fully investigated cases. Defining stroke subtypes (e.g. using the Oxford clinical system:

Physical assessment

total anterior circulation (TACS), partial anterior circulation (PACS), lacunar (LACS) and posterior circulation (POCS)) can help define both cause and prognosis. A TACS is due to an occlusion of the middle cerebral artery (MCA), and so damages cortical and subcortical structures, including hemiparesis, visual field loss, and higher cortical function (and often drowsiness). A PACS is due to an MCA branch occlusion, comprises fewer than the full set of TACS features, and is often embolic (from the heart or a carotid plaque). Lacunar strokes (pure motor or sensory hemi-symptoms) involve small end arteries to the internal capsule, typically in hypertension, diabetes, and smoking. Posterior circulation strokes involve the occipital cortex (isolated hemianopia), cerebellum (isolated cerebellar syndrome), or brain stem (sometimes damaging cranial nerve nuclei with contralateral hemiparesis).

Investigation requires assessing cardiac rhythm and looking for evidence of ischaemic damage to the heart (ECG), examining the carotid or vertebr basilar arteries for occlusion, stenosis, or dissection (duplex ultrasound or MR/CT angiography), and assessing other vascular risk factors. In younger patients with no obvious cause, a bubble contrast or trans-oesophageal echocardiography study can identify patent foramen ovale and atrial septal aneurysms. Rare, but diagnostically important, causes include endocarditis (clinical signs, temperature, inflammatory markers, blood cultures, echocardiography), and arteritis (specifically temporal arteritis, with headache and high ESR).

Intracerebral bleeds may need investigation with MR or CT angiography (for aneurysms or vascular malformations) or interval rescanning (for tumours or vascular malformations), although in older people many deep bleeds are put down to hypertension, while superficial (lobar) bleeds are attributed to amyloid angiopathy (especially common in Alzheimer's disease). Bleeds may also occur into areas of old infarction. Watch for patients on anticoagulants; anyone on warfarin or newer anticoagulants with new neurological signs or a persisting headache needs urgent CT head scanning; if there is bleeding, the anticoagulation should be reversed immediately.

Parkinson's disease

Parkinson's disease is one of a group of 'akinetic rigid' syndromes, and one cause of extrapyramidal motor symptoms. Other diagnoses include multi-system atrophy, progressive supranuclear palsy, cerebrovascular disease, dementia with Lewy bodies, corticobasal degeneration, and the adverse effects of antipsychotic and some other drugs. All have prominent associations with cognitive and neuropsychiatric features.

The key feature is bradykinesia, or slowness of movement: you cannot diagnose Parkinson's disease without this sign. It is assessed in repeated movements such as touching each finger to the thumb in turn. Other core features are: increased muscle tone, usually with a 'cogwheel' pattern; a 4–6 Hertz 'pill-rolling' tremor, evident at rest and suppressed by activity

Physical assessment

(but re-emerging on sustained posture such as holding up the arms); and postural instability. Onset is unilateral, but progresses to both sides. Mask-like face, a quiet mumbling dysarthria, seborrhoea, stooped 'festinant' gait with problems initiating a step, and swallowing problems are also seen. In idiopathic Parkinson's disease, 70–100% of patients respond to treatment with L-dopa drugs or dopamine agonists.

In the initial stages, treatment can be very successful, but as time goes by problems emerge, including fluctuation or end-of-dose effects, dyskinesias (writhing movements), and freezing episodes (suddenly stopping and not being able to restart). Functional assessment (occupational therapy and physiotherapy) are required with a view to optimizing mobility and adapting to emerging problems.

Cognitive disorders are very common, especially executive dysfunction, and often progress on to dementia. 'Parkinson's disease dementia' and DLB behave similarly, and probably represent a continuum. In addition, delusions or hallucinations may emerge or be precipitated by drugs (especially the dopamine agonists such as ropinirole and pramipexole, which must be used with extreme caution, or not at all, in people with dementia).

Hip fracture

A hip fracture results from an interplay of three things:

- Trauma, usually a fall (only 1% of hip fractures are spontaneous)
- Sufficient impact (and 'correct' geometry) to break the bone
- Bone that is weak enough to break, usually due to osteoporosis, but sometimes due to a metastasis.

The incidence of hip fracture increases exponentially with age. A third of victims are dead within a year of a hip fracture. Only half of survivors regain their previous mobility. Half of people with a hip fracture have a history of dementia. Fifteen per cent have delirium at presentation and up to half develop it after surgery. Proactive management by a geriatrician alongside the orthopaedic surgeon ('orthogeriatrics') dramatically reduces the risk of delirium (Marcantonio et al., 2001), and complications or distress among people living with dementia (Smith et al., 2015). Comorbidity and acute medical complications are very common, and are associated with mortality.

Assessment should include:

- Identifying why the patient fell, and whether intervention is required to prevent further falls.
- Identifying and optimizing comorbidities, and rationalizing medications.

Physical assessment

- Assessment of osteoporosis—it is safe to assume that all older people with a hip fracture are osteoporotic. Seek a secondary cause: post-menopausal women, hypogonadism in men, steroid drugs or Cushing's syndrome, thyrotoxicosis, smoking, alcoholism, myeloma, hyperparathyroidism, check vitamin D status. Consider drug treatment options (single dose intravenous zoledronic acid is convenient for very frail patients; oral bisphosphonates are difficult to take and prone to cause adverse effects).

Polymyalgia rheumatica (PMR)

Polymyalgia rheumatica (PMR) is almost unheard of under the age of 50, and is one of a small number of pure disorders of ageing. It presents with pain and stiffness around the shoulders or hips and buttocks, worse in the morning, sometimes quite disabling. It may be undiagnosed for months as it is ascribed to arthritis, age, or other comorbidity. In those with appropriate symptoms, the diagnosis is confirmed by a greatly raised ESR, and a rapid response (within 48 hours) to high-dose prednisolone (30mg/d, but rheumatoid arthritis may also rapidly respond to steroids). Thirty per cent also have temporal arteritis, where the urgency is greater, as optic ischaemia or stroke can occur. Ask about headache (possibly unilateral) and palpate the temporal arteries. Arrange for temporal artery biopsy if there is doubt.

Osteoarthritis

Osteoarthritis is the commonest disabling physical condition in Western populations, is evident in most very elderly people, and often ignored by their doctors. Arthritis contributes to immobility, falls, depression, and deconditioning. Examine the joints, exclude inflammatory arthropathies, assess function, and consider therapy options, starting with analgesia (paracetamol and work upwards, using low doses of strong opioids if necessary) and joint-stabilizing muscle strengthening. Involve a physiotherapist and occupational therapist. Assess for aids and appliances, and consider arthroplasty.

The end of life

If someone is about to die, it is useful to know, so that plans can be made, families forewarned, and treatment reprioritized.

Twenty-eight per cent of deaths are associated with cancer, and are relatively predictable once the cancer is disseminated, and functional performance ('performance status' or Karnofsky score) starts to deteriorate. Otherwise, many deaths are associated with dementia or organ failure, including heart, lung, or renal failure; making predictions is much less reliable in these conditions. Comorbidities are as likely to impact on function as the primary condition leading to death. Care is required: delirium or impairment in function associated with acute illness

Physical assessment

can look like impending death, and in some cases survival and worthwhile functional recovery occurs.

Diagnosing dying in chronic conditions is far from easy. A person with heart or respiratory failure who is breathless at rest or on minimal exertion, or who has frequent hospital admissions with exacerbations, is likely in the last year of life. Someone with dementia who is mute, immobile, incontinent, struggling to eat, or whose appetite has failed is usually dying. In dementia, loss of appetite and aspiration during swallowing are particularly poor prognostic signs (but assess for potentially treatable causes such as drug adverse effects, mouth problems, including candidiasis and poor dentition, intercurrent infection, and constipation). Half of people with MH conditions admitted to an acute hospital are dead within a year.

There are some scales that attempt to provide guidance for clinicians, including the Minimum Data Set Mortality risk index (Porock et al., 2010) and the eFI (Clegg et al., 2016). None of these is sufficiently valid to guide individual cases. The difficulty is in identifying exactly who is about to die, but the principles of palliative care are applicable to many frail or disabled older people, and show considerable overlap with person-centred care and CGA models, and the best way to manage a 'problem' will often be to treat the underlying medical diagnosis causing it. Care will necessarily remain eclectic or 'twin' (or 'multi') track. Bronchopneumonia is the most frequently cited cause of death in people with Alzheimer's disease (Duthie et al., 2011).

However, there may be treatable causes that can mislead the unwary. One study investigating why end-of-life care models were less successful in non-malignant conditions found that practitioners had so often 'had their fingers burnt' in making prognoses that turned out not to be true, that they rapidly became cautious or reluctant (Elliott and Nicholson, 2017).

Principles of palliative care include:

- Open communication, including about likely approach of the end of life and uncertainties in making predictions.
- Setting of priorities ('what matters?'), often around relieving distress and maximizing function, the avoidance of burden on family, and maintenance of dignity.
- Identification of problems and symptoms, identifying causes or likely mechanisms of the problems, and using medical or therapy interventions to overcome them.
- Shared decision-making.
- Minimizing treatment, investigation, and healthcare burden (such as attending multiple clinics or appointments, or adverse treatment effects).

Physical assessment

- Identifying and addressing psychological, social, and spiritual problems, including engaging families and other stakeholders.
- Making plans for the future, including preferred place of care, and times when hospital admission may or may not be appropriate.

Typical problems include symptoms, such as pain, difficulties with appetite and swallowing, incontinence, loss of mobility and function, dependency on others, polypharmacy and deprescribing, the burden of delivery of 'routine' care (such as pressure area care and observations), and dealing with mental distress and behaviours. Assessment (and ongoing re-assessment) is central to this. It may be family or professionally led, and will often include care home staff.

Advance care planning in dementia should be supported, particularly while the person with dementia is able to take part. This may be associated with more positive experiences at the end of life, and can reduce the decision-making burden faced by carers (Barker et al., 2017; Dixon et al., 2018).

Conclusion

1. Older people may present with non-specific or atypical symptoms. They often have multiple pathologies, tend to lose functional abilities relatively quickly, and are prone to complications. Their care needs explicit rehabilitation and consideration of their environment.
2. The medical goal in assessing an older person is to explain (all) their problems in terms of diagnoses. This needs patience, commitment, thoroughness, and time. Medical history often requires review or expansion, and examination may have to be spread over more than one session and combined with observations from families, nurses and therapists.
3. There are many practical problems to history-taking. Practitioners require skills to facilitate the process for aphasic, cognitively impaired, deaf, or non-English-speaking patients.
4. Third-party history (or histories) will be required for many patients, especially those presenting with a debilitating episode of mental illness, or where there is cognitive impairment, aphasia, syncope, or unexplained falls.
5. Drug history is crucial and may need some effort to obtain.
6. Full social and functional histories are required, in particular, living arrangements, accommodation type, and help available or used. Function is summarized in eating, mobility, continence, and behaviour, but a very wide range of activities should be considered, tailored to the individual being assessed.
7. Aspects of physical examination that are often neglected include postural blood pressure, joints, vision, and nervous system.
8. Investigations should be used with discretion, but difficulties and complexities in diagnosis make access to high-tech tests more, rather than less, necessary for older people.

Physical assessment

-
9. Doctors must support multiprofessional working, taking account of other professionals' assessments and observations, providing help in terms of diagnostic explanation and assessment of problems or complications identified by nurses or therapists, and respecting other professionals' expertise.
 10. Problem lists help catalogue multiple problems and map areas of uncertainty.
 11. Immobility, falls, confusion, and incontinence are all syndromes or disabilities that require explanation, diagnosis, and assessment of where intervention might help.
 12. Identifying the approach of the end of life can be difficult, but is useful in making plans and reprioritizing the goals of medical care. There is considerable overlap between end-of-life care, comprehensive geriatric assessment, and person-centred dementia care.

Introduction

With dramatic developments in imaging technology over the past few decades, there has been a surge of neuroimaging research studies, particularly in old age psychiatry. Age-related brain changes, together with specific pathological abnormalities, have generated a host of case-control studies that illuminate the aetiology and pathophysiology of brain disease. However, little has as yet been translated into clinical practice. While cutting-edge imaging protocols have the potential to be translated into the clinical domain, they still lack a realistic estimation of sensitivity, specificity, and predictive power that typically comes from studying large-scale representative groups with a validated diagnosis. To cover this division of neuroimaging into scientific clinical enquiry and clinical routine, the first section of this chapter aims to provide a brief overview of the theory behind neuroimaging techniques and outline commonly

Neuroimaging

used analysis methods. The second section covers the current and future clinical applications of neuroimaging. Particular focus is given to the role of neuroimaging in making a diagnosis, predicting outcome, and understanding illness mechanisms.

Theory

Computed X-ray tomography

Computed tomography (CT) is based upon the degree of attenuation of X-rays in neural tissue, i.e. their electron density. Attenuation is greater in hyperdense tissues such as bone, which consist of calcium, phosphate, and carbonate minerals and appear white in a CT image, compared with hypodense tissues, e.g. cerebrospinal fluid (CSF), which primarily consists of water and appears dark. Compared with magnetic resonance imaging (MRI), soft tissue contrast is low, and dense bony structure can obscure underlying soft tissue signals (e.g. in posterior fossa). The development of spiral CT scanners has provided significantly improved resolution and speed of scanning, also resulting in a reduced radiation dose.

Magnetic resonance imaging (MRI)

MRI is a non-invasive technique that can provide high resolution in vivo images of the brain. Different MRI sequences allow various aspects of the brain's structure and function to be investigated. Grey matter is most commonly studied using T₁-weighted MRI (Fig. **12.1a**), white matter hyperintensities (WMH) using T₂-weighted MRI or fluid attenuated inversion recovery (FLAIR) images (Fig. **12.1b,c**), neuronal activation patterns using functional MRI (fMRI) (Fig. **12.1d**), white matter microstructure using diffusion tensor imaging (DTI) (Fig. **12.1e**), cerebral perfusion using arterial spin labelling (ASL) (Fig. **12.1f**) and biochemical profiles using MR spectroscopy (Fig. **12.7**).

Neuroimaging

The physical principles of MRI are generally based upon the nuclear MR of protons present in water within the tissue. Protons possess magnetic spins that, in the absence of a magnetic field, are randomly oriented. An

Neuroimaging

MRI scanner consists of a large magnet that exerts a powerful external magnetic field (B_0) in which spins align to create net magnetization along B_0 . During an MRI scan, a second magnetic field called the radiofrequency pulse is applied, causing the net magnetization to tilt away from B_0 and along the direction of the transverse radiofrequency field. The subsequent removal of the radiofrequency pulse causes the protons to realign themselves such that their net magnetic moment is again parallel to B_0 . The return to equilibrium is called *relaxation*, during which the protons lose energy by emitting their own radiofrequency signal. This is the signal that is reconstructed to produce an MR image, and can be detected with a radiofrequency-tuned coil.

The intensity of the MR signal depends on several factors, including proton density, the relative timing of external radiofrequency pulses, the rate of recovery of magnetization along the longitudinal axis (defined by the relaxation time constant T_1), and the loss of magnetization in the transverse plane (defined by the relaxation time constant T_2). Since proton density, T_1 , and T_2 are tissue-specific properties, they can be manipulated by varying the timing of radiofrequency pulses (repetition time, TR) and the time between transmitting a radiofrequency pulse and measuring a signal (echo time, TE) in order to differentiate between grey matter, white matter and CSF on an MR image. The spatial location of the MR signal is encoded by imposing magnetic gradients on B_0 so that each part of the brain is subjected to a slightly different field strength and therefore has its own resonance radiofrequency. Thus, in addition to differentiating between the *types* of tissues, the intensity of the signal at each frequency also carries information about the *position* of the tissue within the scanner and can be used to define spatial localization.

T₁-weighted MRI

The strength of the T_1 -weighted signal is determined by the amount of magnetization that is restored along B_0 after the radiofrequency pulse is applied. T_1 relaxation time varies depending on the type of tissue in the brain and how freely protons can move within the tissue. CSF has the longest T_1 relaxation time, followed by grey matter, and then white matter, which has the shortest T_1 . This difference in T_1 relaxation between tissues means that when the external radiofrequency pulse is removed, magnetization is restored slowest in CSF (high T_1) and fastest in white matter (short T_1) before the next pulse is applied. T_1 -weighted images typically have a short TR (repeat time) between radiofrequency pulses. With a short TR, there is limited time for all tissues to fully restore net magnetization along B_0 before their magnetization is flipped again. This creates a significant discrepancy in the amount of restored magnetization in each tissue type. CSF, which restores the least magnetization along B_0 before the next pulse, has the lowest MR signal intensity and appears black on a T_1 -weighted image. By comparison, white matter, which is able to quickly restore more magnetization along

B_0 before the next pulse, has the highest MR signal intensity and appears bright on the image.

T_1 -weighted MRI is the preferred modality to isolate and examine grey matter. The most common research analysis techniques use region-of-interest (ROI) and voxel-based morphometry (VBM). ROI analysis of grey matter volumes can be used to test a specific hypothesis about a particular brain region and has advanced from tracing brain regions by hand to employing fully automated segmentation methods (Babalola et al., 2009). Furthermore, shape analysis techniques can provide greater detail of the location of structural changes in subcortical structures (Styner et al., 2003; Patenaude et al., 2011).

VBM provides an assessment of grey matter across the whole brain and can be used for exploratory analyses with no a priori information about the location of potential grey matter differences. VBM typically involves: segmentation of T_1 -weighted images into grey matter, white matter, and CSF; registration of each subject's scans into a standard template to make them comparable between different subjects; optional intensity modulation of images to compensate for the amount of expansion or contraction of each image; and spatial smoothing of images (Ashburner and Friston, 2000; Good et al., 2001). These preprocessing steps allow for standardization of the images and mean that a voxel-by-voxel whole-brain statistical comparison of grey matter can then be made between subjects, between diagnostic groups, and along dimensions, e.g. age or cognitive function. However, as a consequence, VBM is limited by the quality of between-participant image registration and the amount of spatial smoothing of data (Bookstein, 2001).

T_2 -weighted MRI/FLAIR

T_2 -weighted images are obtained by exploiting tissue-specific differences in T_2 -relaxation times. As discussed, T_2 -relaxation time relates to the decay of the transverse magnetization produced by the radiofrequency pulse (T_2 in ms: CSF > grey matter > white matter). In T_2 -weighted images, white matter, which has the shortest T_2 time, loses signal the fastest and therefore appears dark grey, whereas CSF appears white and grey matter appears light grey. Pathological changes often stand out as bright white signals (hyperintensities).

Periventricular and deep WMH were traditionally assessed using visual rating scales on T_2 -weighted scans, although it can be difficult to differentiate between periventricular WMH and CSF on T_2 -weighted images. Fluid attenuated inversion recovery (FLAIR) scans are typically used alongside, or instead of, T_2 -weighted images in the assessment of WMH (Wardlaw et al. 2013). FLAIR sequences increase the contrast between CSF and WMH by nulling the signal from CSF and make it appear black on the MR image, therefore improving the recognition of periventricular WMH (Fig. **12.1c**). Recent advances in automatic segmentation tools allow reliable objective quantifications of total WMH

volumes and the ability to distinguish between deep and periventricular WMH without the need for manually tracing the lesions or relying on subjective visual ratings (Griffanti et al., 2018; Griffanti et al., 2016).

Functional magnetic resonance imaging

Functional MRI (fMRI) provides an indirect measure of neural function by measuring the haemodynamic response to neuronal activity. During neuronal activation, there is an increase in the extraction of oxygen from the blood vessels into the neuron, and a heightened rate of oxygen metabolism within the neuron. This triggers an increase in local cerebral blood flow that far exceeds the rate of oxygen metabolism, resulting in an abundance of oxygenated blood in the vessels surrounding the active tissue. The intensity of an fMRI image is derived from this local change in blood oxygenation, which creates the blood oxygen level-dependent (BOLD) signal.

Oxygenated (oxy)haemoglobin is diamagnetic (i.e. has a stronger BOLD MR signal), whereas deoxygenated (deoxy)haemoglobin is paramagnetic (i.e. has a weaker BOLD MR signal). The higher oxy-to-deoxyhaemoglobin ratio that results from neuronal activity leads to a decrease in magnetic susceptibility and an increase in the BOLD signal (Matthews and Jezzard, 2004).

The majority of fMRI studies have compared the BOLD signal between a baseline and an activation condition. Particularly relevant to psychiatric research are fMRI experiments that assess activation during cognitive tasks or exposure to emotional stimuli, such as happy, sad, angry, fearful, and neutral faces. Stimuli can be presented in a variety of ways. Block, event-related, mixed, and self-driven experimental designs are commonly employed (Amaro and Barker, 2006). Analysis of task-based fMRI typically involves correlating the observed time course of BOLD signal change in each voxel with a model time course based on the expected neural response. A good fit between the two would suggest that the observed BOLD response can be attributed to the task stimulus (Brown et al., 2007).

Even in the absence of a task, there are spontaneous low-frequency fluctuations in the BOLD signal, which give rise to 'resting-state' activity within the brain (resting state functional magnetic resonance; rs-fMRI). The so-called 'resting brain' is organized into networks composed of several brain regions that have temporally correlated resting-state activity. Commonly identified networks include: visual, auditory, sensorimotor, default mode, executive control, and frontoparietal networks. The amplitude of the BOLD signal at rest is comparable with that displayed in task-related experiments (Damoiseaux et al., 2006). Furthermore, there is close correspondence between the major brain networks identified at rest and those identified during task-related fMRI experiments (Smith et al., 2009).

Two of the most widely used methods that explore how remote brain areas work together within the resting brain are independent component analysis (ICA), which examines whole networks, and single seed region analysis, which estimates the functional connectivity of a specific region (or seed) with the rest of the brain. Single seed region analyses assess the temporal correlation between the BOLD time course of a predefined seed region and that of either a priori defined target regions or the whole brain on a voxel-wise basis. Single seed region analysis can only isolate a single network based upon the predefined seed. For example, a seed in posterior cingulate cortex/precuneus is often used to investigate the default mode network, i.e. a network that is active when subjects are resting in the scanner and not engaged in a task (Fig. 12.2).

Fig. 12.2

Seed-based analysis of the posterior cingulate cortex. The blood oxygen level dependent (BOLD) signal time course of a small seed placed in the posterior cingulate cortex (A) is correlated with that of the default mode network (B). Images derived from resting-state fMRI scans in the Whitehall II Imaging sub-study.

ICA, in contrast, decomposes the whole dataset into a set of statistically independent spatial component maps and associated time courses without a pre-specified model. Voxel values reflect the correlation between the voxel's time series and the mean time series of that particular network (Beckmann and Smith, 2004; Beckmann et al., 2005). As with other data reduction component analyses, the spatial pattern of networks generated using ICA varies according to the dimensionality, i.e. the number of components to be investigated. Low-dimensionality ICA can detect and separate several whole networks at once. Moreover, if ICA is performed for each participant separately, it can be difficult to identify the same network consistently across participants. An alternative approach is to perform ICA across all participants, and then, based upon the group-level components identified, generate individualized networks using both spatial and temporal regression (Filippini et al., 2009; Zuo et al., 2010). Networks identified in this fashion are remarkably robust across thousands of resting scans (Smith et al., 2009) (Fig. 12.3).

Neuroimaging

Fig. 12.3

Resting-state networks derived from low-dimensionality independent component analysis (ICA) of 500 resting-state fMRI scans from the Whitehall II Imaging Sub-study. These networks represent auditory, sensorimotor, and visual activity (top row), as well as higher cognitive processes like memory, introspection, and executive function (bottom row).

Both single seed and whole network analyses have provided valuable insights into the organization of the brain at rest, but they are limited in their scope. Seed analyses provide information about the connectivity of a small, selected region, but are vulnerable to seed-selection biases. On the other hand, studying whole networks, each represented by a single time-course, restricts our understanding of whether and how the individual brain regions that make up the networks may be affected by outcome measures like age, cognition, or disease state. Recently emerging 'connectomics'-based approaches use graph-theory or high-dimensionality ICA to expand on traditional single seed or single network analyses and study intra- and internetwork connections across in more detail (Cole et al., 2010; Smith et al., 2013). Such network modelling methods map the 'functional connectome' by splitting the resting state fMRI scans into a large number of small distinct brain regions (nodes) and estimating the functional connectivity (edges) as the temporal correlations of node activity. Variations of the 'nodes & edges' method have been adopted to examine brain-behaviour interactions in big data neuroimaging studies like the Whitehall-II Imaging sub-study (Suri et al., 2017), the Human Connectome Project (Smith et al., 2013) and UK Biobank (Elliott et al., 2017) (Fig. 12.4).

Fig. 12.4

Functional connectome derived from high-dimensionality independent component analysis (ICA) and network modelling performed on 500 resting-state fMRI scans from the Whitehall II Imaging Sub-study. The nodes and edges approach was used to parcellate the brain into 58 distinct spatial nodes (top row) and compute the correlations in time courses between the nodes (matrix). Warmer colours in the matrix represent strong positive correlations and cooler colours represent strong negative correlations in BOLD time courses between the respective nodes. The nodes are reordered according to a hierarchical clustering and are organized into five large-scale resting networks that correspond with the networks typically observed using low-dimensionality ICA.

Blood flow MRI (arterial spin labelling)

The BOLD signal provides an indirect measure of brain function by relating the level of oxygenation in the blood of a given brain region to neural activity within that region. While it assumes that neural activity demands an increase in local blood flow, the BOLD signal does not provide a *quantifiable* measure of this increased blood flow. The most commonly used MR techniques to image perfusion, that is, the rate at which nutrient-supplying blood passes through neural tissue, are dynamic susceptibility contrast MRI (DSC-MRI) and arterial spin labelling (ASL).

DSC-MRI is a relatively quick technique that uses gadolinium (Gd) as an exogenous contrast agent in order to provide several haemodynamic measures. For example, the signal-time curve generated from the passage of the Gd-bolus through tissue can be used to calculate measures of cerebral blood volume, mean transit time, and cerebral blood flow. However, there are relative contraindications for Gd injection, including

renal failure (stage 4 or 5; GFR < 30ml/min per 1.73m²), where there is a dose-dependent risk of nephrogenic systemic fibrosis, and only a limited number of Gd injections are permissible.

In contrast, ASL uses magnetically labelled water molecules in the blood as an endogenous contrast agent to provide a measure of cerebral blood flow. In this method, arterial blood water flowing up to the brain is magnetically tagged with a brief pulse while it is still in the neck. Thus, the protons in blood destined for the brain are now inverted, making it possible to trace their path through the cerebral vasculature. An image of the brain is then acquired after a brief time delay during which the labelled blood flows from the neck into the brain. This image, called the tag image, is subtracted from a control image, in which inflowing blood is not labelled. The difference between control and tag images yields maps of cerebral blood flow, expressed in units of ml per 100 g of tissue per min. The rapid evolution of ASL methodology in the last decade has facilitated the collection of highly accurate perfusion measurements with improved signal-to-noise, which are already seeing clinical applications in acute stroke and vascular dementia (VD). Promising new ASL sequences that can measure venous oxygenation and identify selective perfusion contributions from individual arteries feeding the brain have been developed, but require further technical optimization before being translated into the clinical domain (Wong, 2013).

Diffusion tensor imaging

DTI is an MRI technique that can identify the main orientation of white matter tracts and determine their integrity in vivo. DTI is sensitive to the directional diffusion of water within neural tissues. Water molecules diffuse differently depending on the type and structural integrity of the tissue, and on their interaction with barriers like cell membranes, which restrict diffusion. For instance, diffusion in CSF is unrestricted in all directions (i.e. isotropic), whereas that in white matter is unrestricted in directions parallel to the axon but hindered orthogonally due to the presence of the myelin sheath and other longitudinal axonal structures (i.e. anisotropic) (Beaulieu, 2002) (Fig. 12.5).

Fig. 12.5

Diffusion ellipsoids. In panel (A) isotropic diffusion is modelled as a sphere. In panel (b) anisotropic diffusion is modelled as an ellipsoid.

In diffusion-weighted imaging, the magnitude and direction of water diffusion in each voxel is measured in the x-, y- and z-dimensions. The three dimensions of diffusion can be modelled as an ellipsoid, whose shape is characterized by the three eigenvalues (λ_1 , λ_2 , λ_3). If diffusion is isotropic, diffusion in all three main axes is equal ($\lambda_1 = \lambda_2 = \lambda_3$) and the diffusion ellipsoid becomes a sphere. If diffusion is anisotropic ($\lambda_1 > \lambda_2$, λ_3), the major eigenvector reflects the direction of maximum diffusivity, which, in turn, is assumed to reflect the orientation of fibre tracts (axial diffusivity, Fig. 12.6). DTI can therefore be used to study the orientation and integrity of white matter tracts by deriving metrics that estimate the overall *direction* of diffusion (fractional anisotropy, FA), the overall *magnitude* of diffusivity (mean diffusivity, MD; apparent diffusion coefficient), axial diffusivity (diffusivity parallel to the white matter tract), and radial diffusivity (diffusivity perpendicular to the white matter tract). Such measurements can be extracted locally in previously defined ROI analysis or by tractography, or they can be measured globally, using VBA or tract-based spatial statistics (TBSS); the detail of these approaches is described below. FA and MD are considered sensitive measures of disease-related changes in white matter; axon degeneration and myelin damage are typically characterized by an increase in MD and a decrease in FA.

Measure	Formula
Fractional anisotropy	$\frac{\sqrt{1}{\sqrt{2}} \sqrt{\frac{[(\lambda_1 - \lambda_2)^2 + (\lambda_2 - \lambda_3)^2 + (\lambda_3 - \lambda_1)^2]}{(\lambda_1^2 + \lambda_2^2 + \lambda_3^2)}}}$
Mean diffusivity	$\frac{\lambda_1 + \lambda_2 + \lambda_3}{3}$
Axial diffusivity	λ_1
Radial diffusivity	$\frac{\lambda_2 + \lambda_3}{2}$

Fig. 12.6
Formulae for DTI measures.

ROI analyses are used to examine small predefined portions of white matter tracts, and are insensitive to differences occurring outside of the ROI. *Tractography* can be used to reconstruct entire white matter tracts by predefining a starting point and automatically moving from voxel to voxel via the major direction of diffusion. However, the possibility of type II (false negative) errors remain (Mori and van Zijl, 2002) meaning some white matter tracts can be missed. *Voxel-based analysis (VBA)* involves spatial registration of each scan to a common space and performing a voxel-by-voxel whole-brain statistical comparison of white matter between groups. While VBA can provide a global assessment of white matter, it is limited by the quality of between-participant image registration (Smith et al., 2006). *TBSS* projects all participants' FA data onto an average FA tract skeleton before applying voxelwise statistics. TBSS minimizes the effects of between-participant misalignment and is more robust and sensitive than VBA (Smith et al., 2007). However, as the TBSS skeleton

consists of peak (i.e. most normal) FA values, assumed to be at the centre of the tract, TBSS may be insensitive to differences that are not uniform throughout the width of the tract, leading to conservative results.

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) is an MRI technique used to quantify levels of metabolites in localized brain regions and can be used together with structural MRI to diagnose and track disease progress. For instance, while structural MRI can provide anatomical information about the size and location of a brain tumour, MRS can expand on its underlying biochemical profile.

Data from MRS are not illustrated as an image but as a frequency spectrum. The spectrum is a collection of peaks, each corresponding to a specific metabolite, and it serves as a biochemical fingerprint of the tissue; it can vary depending on the region of the brain studied, and if there is any structural damage to that region. The MR spectrum is a two-dimensional plot of metabolite frequency in parts per million (horizontal axis) versus its signal intensity (vertical axis). The exact frequency of a particular metabolite depends on its molecular structure, i.e. the number and positioning of the hydrogen atoms within the molecule (Fig. 12.7). However, because water is the most abundant hydrogen-containing molecule within tissues, its signal in the ^1H -MRS spectrum is several orders of magnitude higher than that of other metabolites (ratio of water to metabolite: 10000: 1). In order to be able to resolve weaker metabolite signals, the signal from water must be suppressed when the metabolite spectra are being acquired. This is achieved by using a water-suppressing pulse sequence during the MRS scan. MRS measurements are typically obtained in single ROI (often quite large such as several cm^3 voxels), or across a slice of the brain, but it is also possible to employ MRS across the whole brain, although this is time-consuming to do.

The most frequently employed MRS methods within old age psychiatry research are based on proton MRS (^1H -MRS) and phosphorous MRS (^{31}P -MRS). Metabolites studied using ^1H -MRS include N-acetyl aspartate (NAA), a marker of neuronal integrity; choline (Cho) (which includes free choline, phosphocholine, and glycerophosphocholine), a marker of membrane integrity and myelination; myoinositol (MI), a marker of glial integrity; and the neurotransmitters glutamate and glutamine (Glx).

Metabolites studied using ^{31}P -MRS include phosphomonoester (PME) and phosphodiester (PDE), markers of the synthesis and breakdown of membrane phospholipids, respectively; α -, β -, and γ -nucleoside triphosphate (NTP), markers of ATP; phosphocreatine (PCr), which acts as a buffer of ATP; and inorganic phosphate (Pi), which can be used to estimate intracellular pH.

As there are several experimental factors that can influence the signal amplitude, for example, the type of MRI scanner system and the brain

location being evaluated, metabolite concentration is normally measured with respect to a reference signal of known concentration, in most cases water or creatine (Cre), a marker of total cellular creatine stores and thus is often expressed as a ratio.

Emission computed tomography

Single photon emission computed tomography (SPECT)

SPECT exploits the fact that high energy radiation (γ -radiation), like X-rays, penetrates human tissue, so that the three-dimensional distribution of a molecule labelled with a γ -emitter can be reconstructed from the activity maps recorded from outside the head. Gamma-radiation is measured with γ -cameras that translate γ -photons, via scintillation counters and crystals, into electrical signals, which can then be amplified and analysed in a quantitative fashion. The 'direction of view' of the camera is determined by collimators, which admit photons only from a specific direction (see Fig. 12.8a).

Fig. 12.8

Methods of determining site of radiation in SPECT (A) and PET (b).

However much of the radiation is absorbed within the collimator's walls, thereby reducing the sensitivity of SPECT (compare with positron emission tomography (PET); see next section and Fig. 12.8b). Common nuclei used for labelling are iodine-123 and technetium-99m. Both generate γ -radiation, with a half-life of 13.2 h (^{123}I) and 6 h ($^{99\text{m}}\text{Tc}$), respectively. Particularly ^{123}I , therefore, allows for synthesis of the tracer in a commercial laboratory and transport to the scanner. While $^{99\text{m}}\text{Tc}$ is widely generated and available locally, its use is only practicable if the labelling can be done without special skills and radio-chemical equipment, quickly, and to a high standard, as for example with $^{99\text{m}}\text{Tc}$ -HMPAO ($^{99\text{m}}\text{Tc}$ -hexamethylpropyleneamine oxime), where both components ($^{99\text{m}}\text{Tc}$ and HMPAO) are simply mixed in a vial.

A variety of biologically relevant molecules have been employed in brain imaging with SPECT, from lipophilic compounds that mark cerebral perfusion (e.g. $^{99\text{m}}\text{Tc}$ -HMPAO; $^{99\text{m}}\text{Tc}$ -ethylcysteinate dimer = $^{99\text{m}}\text{Tc}$ -ECD; n-isopropyl- ^{123}I -P- iodoamphetamine = ^{123}I -IMP) to those which radiolabel receptor ligands, for example dopamine-, serotonin-, muscarinic-, nicotinic-, and transporter-binding sites (Table 12.1). Of practical clinical importance today are some of the SPECT perfusion markers ($^{99\text{m}}\text{Tc}$ -

Neuroimaging

HMPAO and ^{99m}Tc -ECD) mentioned in this section, and the dopamine transporter ligand ^{123}I -labelled N-(3-fluoropropyl)-2 β -carbomethoxy-3 β -(4-iodophenyl) nortropane (FP-CIT).

Table 12.1 Biologically relevant molecules used in SPECT and PET studies.

Tracer	Isotope-imaging mode	Clinical use	Measure
ECD	^{99m}Tc -SPECT	Yes	Perfusion
HMPAO	^{99m}Tc -SPECT	Yes	Perfusion
5-I-A-85380	^{123}I -SPECT	No	Nicotinic receptor
FP-CIT	^{123}I -SPECT	Yes	Dopamine transporter
Iodobenzamide	^{123}I -SPECT	No	Dopamine D ₂ receptor
Iodo-QNB	^{123}I -SPECT	No	Muscarinic receptor
Iomazenil	^{123}I -SPECT	No	Benzodiazepine receptor
FDG	^{18}F -PET	Yes	Glucose uptake (aerobic + anaerobic)
Glucose	^{11}C -PET	No	Glucose uptake (aerobic)
Oxygen	^{15}O -PET	No	Oxygen uptake
Water	^{15}O -PET	Yes	Blood flow
MP4A	^{11}C -PET	No	AChE activity
Nicotine	^{11}C -PET	No	Nicotinic receptor

Neuroimaging

Pittsburgh compound B (PiB)	^{11}C -PET	No	Insoluble fibrillary amyloid (A β plaques)
Florbetaben	^{18}F -PET	Yes	A β plaques
Florbetapir	^{18}F -PET	Yes	A β plaques
Flutemetamol	^{18}F -PET	Yes	A β plaques
FDDNP	^{18}F -PET	No	Neurofibrillary Tangles (NFTs) and A β plaques
THK5117 and THK5351	^{18}F -PET	No	NFTs
Flortaucipir (AV-1451)	^{18}F -PET	No	NFTs
PBB3	^{11}C -PET	No	NFTs
(R)-PK11195	^{11}C -PET	No	Microglia (inflammation)
FEDAA1106 and DPA714	^{18}F -PET	No	Microglia (inflammation)
Altanserin	^{18}F -PET	No	5-HT $_2\text{A}$ receptor
WAY-100635	^{18}F -PET	No	5-HT $_{1\text{A}}$ receptor

(R)-PK11195: 1-[2-chlorophenyl]-N-methyl-N-[1-methyl-propyl]-3-isoquinoline carboxamide; 5-I-A-85380: [(123)I]-5-iodo-3-[2(S)-azetidinylmethoxy]pyridine; DPA714: N,N-diethyl-2-[4-(2-fluoroethoxy)phenyl]-5,7-dimethylpyrazolo[1,5-a]pyrimidine-3-acetamide; ECD: Ethylcysteinyl dimer; FDDNP: 2-(1-{6-[(2-[fluorine-18]fluoroethyl)(methyl)amino]-2-naphthyl}-ethylidene)malononitrile; FDG: Fluorodeoxyglucose; FEDAA1106: N-(5-fluoro-2-phenoxyphenyl)-N-(2-[(18)F]fluoroethyl-5-methoxybenzyl)acetamide; FP-CIT: N-(3-fluoropropyl)-2 β -carbomethoxy-3 β -(4-iodophenyl) nortropane; HMPAO: Hexamethylpropyleneamine oxime; Iodo-QNB: Iodo-quinuclidinylbenzilate; MP4A: N-[(11)C]methylpiperidin-4-yl acetate; PET: Positron emission tomography; PiB: Pittsburgh Compound B;

SPECT: *Single photon emission computed tomography*; THK5117: 6-(3-¹⁸Fluoro-2-hydroxypropoxy)-2-(4-methylaminophenyl)quinoline; THK5351: (S)-6-(3-¹⁸Fluoro-2-hydroxypropoxy)-2-(N-methyl-2-aminopyridin-5-yl)quinoline; WAY-100635: N-[2-[4-(2-Methoxyphenyl)-1-piperazinyl]ethyl]-N-(2-pyridyl)cyclohexanecarboxamide.

SPECT perfusion ligands are injected and taken up into brain cells on first pass. This means that once the tracer is injected, the patient can be imaged at any time afterwards, as long as the isotope is still active. An additional advantage is that the tracer remains in a pattern representing a snapshot of brain perfusion within two minutes of injection, so that any later interventions, sedation, or even anaesthetic do not change the image and can be used to optimize the quality of the scan.

Positron emission tomography (PET)

In contrast to this, convenient positron emitters are available in the form of ¹¹C (radioactive half-life approximately 20 min), ¹⁵O (approximately 2 min), and ¹⁸F (approximately 110 min), all substituted for the equivalent nonradioactive isotope. The short half-life implies that any synthesis of labelled tracer has to be done in-house, which increases the price of such ligands to a level that can only be afforded in specialist centres. In addition to this, the short half-life of positron emitters such as ¹¹C and ¹⁵O requires the tracer injection to be done in the scanner, which makes the procedure potentially difficult for certain patient groups.

Exceptions to this are ¹⁸F-fluoro-deoxyglucose and ¹⁸F-labelled amyloid ligands (Herholz and Ebmeier, 2011), which can be imported from within a few hundred kilometres and are injected well before the imaging session. For this reason, we will limit our discussion to such potentially clinically useful substances, although there are rapid advances in the development of novel PET tracers providing powerful insights into brain mechanisms and pharmacology in both health and disease.

The central concept in PET is that positrons emitted from the radioisotopes are annihilated within seconds and millimetres of their origin, and generate two photons of defined energy that travel in opposite directions. An instrument that can detect such coincident photons is able to locate their source on the line between the activated detectors (Fig. **12.8b**). Any photon that is not matched by a coincident partner or is of a lower energy than the predicted one is likely to be due to scatter and can be ignored. Thus, PET is generally more sensitive than SPECT, where, in the latter, much of the potentially available radiation is absorbed by the collimator walls.

In common with SPECT is the exposure to radioactive isotopes, which may be trivial in the single case, but adds to the overall population exposure to ionizing radiation. For this reason, BOLD fMRI and arterial spin labelling MRI have taken over virtually all experimental research

applications of ^{15}O -water PET for blood flow. An exception is ^{18}F -FDG PET in dementia research, where the logistics of scanning (injection at rest 30–45 minutes before the scan), its availability in oncology/specialist centres, its quantitative nature, and the age group of the patients involved (where radiation risk is minimized) make it the preferred method of imaging current brain function (Herholz et al., 2002). In addition, ^{18}F -FDG PET provides a more direct ‘window’ on brain function as it measures brain metabolism rather than perfusion.

Abnormal aggregation of amyloid plaques and hyperphosphorylated tau are the hallmarks of Alzheimer’s disease (AD) pathology. It is, therefore, not surprising that efforts have been made to label amyloid and more recently, to characterize tau in vivo (Saint-Aubert et al., 2017; Herholz and Ebmeier, 2011). As amyloid deposition is found in healthy older people’s brains especially over the age of 80, the diagnostic accuracy of amyloid PET scanning for AD in this group is limited. Current efforts focus on the predictive validity of increased amyloid binding in mild cognitive impairment (MCI), as some people in this diagnostic category have normal scans, and others have abnormal amyloid scans. A potential shortcoming of the ligands in development is non-specific white matter binding, but this may be overcome in practice (Herholz and Ebmeier, 2011). If future therapeutic agents were to remove amyloid deposits, an in vivo amyloid ligand would provide a way to monitor treatment success directly.

Unlike amyloid, tau deposits are present intracellularly, and until recently these pathological lesions could only be studied using immunohistochemistry in post-mortem brain tissue.

Over the last five years, there has been an emergence of promising tau-specific PET tracers to study the spatial patterns of tau deposition in AD and other tauopathies, and monitor the spread of tau during disease progression (Saint-Aubert et al., 2017; Bischof et al., 2017). However, currently, a number of caveats have to be considered. In vitro, the available tracers have shown different affinities towards subtypes of tau. ^{18}F -AV-1451 demonstrated stronger binding to combined 3+4 repeat tau (characteristic of AD) compared to exclusive 3-repeat (e.g. behavioural variant-FTD) or 4-repeat tau, such as corticobasal degeneration (CBD) and progressive supranuclear palsy (PSP). When directly compared to ^{18}F -AV-1451, the tracer ^{11}C -PBB3 showed stronger binding to tau aggregates in 3-repeat and 4-repeat pathologies (Ono et al., 2017).

In addition, tau tracers have demonstrated non-specific binding (e.g. to neuromelanin), mainly to subcortical structures, especially in the striatum and in the choroid plexus. Of particular concern is the fact that some of the regions showing off-target binding in vivo are regions where specific binding would be expected in some tauopathies, e.g. the basal ganglia in CBD and PSP. The available tau tracers have differential properties to off-target binding, limiting their comparability. Further standardization of the tracers is required before tau PET can be used as a biomarker; their

potential in the differential diagnosis of different tauopathies is discussed in more detail further on.

PET molecular imaging techniques are also used to study inflammation in neurodegeneration. The great majority of these ligands target the overexpression of the 18-kDa translocator protein (TSPO). TSPO is an outer mitochondrial membrane translocator protein, expressed mostly by microglia. Its levels in the brain of healthy controls are low, while they rise in neurodegenerative diseases. ^{11}C -(R)-PK11195 is the first and best validated TSPO ligand. Second-generation ligands have been subsequently introduced, but it was found that a single-nucleotide polymorphism (rs6971) in the TSPO gene can significantly influence their uptake, making genetic testing mandatory for research studies using this ligand. Other limitations of TSPO as PET imaging molecular target exist, such as multicellular expression, low brain density even in disease states, similar expression in microglia regardless of its phenotype (pro-inflammatory or anti-inflammatory), as well as lack of a specific brain region of negative control (Tronel et al., 2017). Alternative targets are under evaluation. They include receptors (purinergic P2X7, cannabinoid CB2R, adenosine 2A) and enzymes (cyclooxygenase, nitric oxide synthase, matrix metalloproteinases), with a particular focus on their selectivity for microglial expression and polarization (Tronel et al., 2017).

Electromagnetic fields

Electroencephalography

Electroencephalography (EEG) is a non-invasive functional technique that records electrical fields along the scalp using electrodes placed in a cap over the head. The recorded electric potentials are generated by populations of thousands of neurons that have a similar orientation and fire synchronously. The pyramidal neurons of the cortex have these properties and therefore their activity is thought to underlie EEG signals. While the temporal resolution is much higher compared with fMRI—signals can be recorded only milliseconds after the presentation of a stimulus—the spatial resolution is greatly reduced (Fig. 12.9). One reason is that the strength of the electric potential that is measured by EEG falls off with the square of the distance, which impairs the detection of subcortical neuronal activity. Additionally, the skull and scalp cause distortions of the signal, which makes exact localization of neural activity difficult.

Fig. 12.9
Spatial and temporal resolution of different neuroimaging techniques.

Magnetoencephalography

In contrast to EEG, magnetoencephalography (MEG) is used to measure magnetic fields that are induced by the electric activity of neurons. These magnetic fields are measured using superconducting quantum interference devices (SQUIDs) as sensors that are arranged in a helmet placed over the head.

A disadvantage of MEG is that it can only record signals from neuronal pathways that run in parallel to the skull. Therefore, the main contribution to MEG signals comes from neurons located within cortical sulci and deeper sources of activity are less visible to MEG. However, the advantage of MEG is that the magnetic field is less influenced by changes of conductivity between brain, skull, and scalp, which improves localization of neuronal activity particularly, if the activity is superficial.

There are several ways of analysing EEG and MEG data. One might be interested in the electrophysiological response with respect to the onset of a specific stimulus. This response is called an event-related potential (ERP) in EEG and an event-related field (ERF) in MEG, and occurs phase-locked to stimulus onset. Averaging many synchronized EEG traces removes noise and emphasizes any regular responses to the stimulus. Similarly, EEG/MEG can be phase-locked to the subject's response, if the main interest is in processes leading up to a motor response. It is alternatively possible to study changes in the power of oscillations in electric activity in specific frequency bands. More synchronized neuronal firing is thought to underlie increased power of oscillations. Typical frequency bands of interest are delta (less than 4 Hz), theta (4–7 Hz), alpha (8–13 Hz), beta (14–30 Hz), and gamma (30–100 Hz). The power of oscillations can be measured with respect to a stimulus onset (induced activity), which is called event-related synchronization (ERS) or desynchronization (ERD). It can also be measured independently of a

stimulus (spontaneous activity) when subjects are resting during the measurement and not engaged in a specific task.

Several techniques can be used to reconstruct the source of neuronal activity, e.g. equivalent current dipole modelling and beam-former approaches. All of these techniques use specific constraints to locate neuronal activity because theoretically there are an infinite number of solutions to explain the MEG/EEG signal. This is known as the inverse problem.

Clinical Applications

What is involved for the patient?

A structural MRI scan with sequences sensitive to pathological changes typically lasts less than 30 minutes, but in research settings, multimodal MRI acquisition can take up to one hour. A major limitation to scan length is participant comfort and compliance, which also has an effect on image quality (e.g. movement artefacts). There are a number of contraindications to MRI, including pacemakers, certain metallic implants, and severe claustrophobia. CT has several advantages over MRI as it is cheap, widely available, and often suitable for patients with contraindications to MRI. While MRI typically requires lying in a narrow scanner, the more open design of CT, and also of emission tomography scanners, makes them more acceptable for some patients. However, most research is now conducted using MRI techniques as it provides higher resolution images, greater soft tissue contrast, and does not involve ionizing radiation.

PET and SPECT scans are used in various centres, according to their availability. With a trend for PET to become more widely available, PET-CT scanners are being acquired by many services for oncological examinations, although their availability for psychiatric patients is likely to remain limited. Both PET and SPECT are likely to fulfil the requirements of diagnosis and differential diagnosis and can be used interchangeably (Ebmeier, 2010), except in cases where appropriate ligands are not available in a modality (e.g. dopamine transporter ligands are not commercially available for PET, and amyloid ligands for SPECT are not on the horizon). Both scan modalities are relatively user friendly, with an open gantry and little noise. Their main limitation is the radiation dose administered parenterally, both in terms of the necessity of an injection and the (usually very small) risk to the patient from ionizing radiation.

EEG and ERPs are no longer commonly used in clinical psychiatric practice, except in the differential diagnosis of epilepsy and multiple sclerosis, although they have several advantages compared with MRI. EEG equipment is user friendly, cheaper, and more mobile, and recordings do not require a strong magnetic field. Patients merely have to sit still, or engage in simple tasks, usually attentional auditory or visual

Neuroimaging

tasks. Nevertheless, analysis of EEG data is not straightforward, requires special neurophysiological skills, and is strongly affected by current mental state and by medication, which may be one explanation why it is not generally used in the clinic. Computational and advanced analytics are helping improve the diagnostic specificity of EEG in terms of dementia diagnosis, but these approaches still remain primarily within research domain (see Potential diagnostic use).

MEG is not generally available and is predominantly used for research, where it is well tolerated even by the very young and old, as well as cognitively impaired patients.

Making a diagnosis

Current clinical practice

CT and MRI are commonly used in the evaluation of patients with cognitive impairment and other psychiatric syndromes (see Table 12.2). CT is used in the diagnosis of stroke (haemorrhagic or old ischaemic), large tumours, intra- and extracranial bleeding, atrophy, (communicating) hydrocephalus, and trauma. MRI is preferred for the investigation of conditions only detectable with higher resolution and greater soft tissue contrast, such as temporal lobe epilepsy (medial temporal gliosis), multiple sclerosis, certain tumours (e.g. pituitary adenomas), and certain vascular changes.

Table 12.2 Magnetic Resonance Imaging (MRI) used in the diagnostic criteria of some dementias.

Disease	Diagnostic criteria	MRI marker	Use
Alzheimer's dementia	NINDS-ADRDA (McKhann et al., 1984) NIA-AA (McKhann et al., 2011)	'Normal MRI' Medial temporal atrophy	Exclusion Most validated structural topographical marker
Creutzfeldt-Jacob disease	(Collie et al., 2001; Tschampa et al., 2005)	Cortical diffusion changes, pulvinar sign	Diagnostic (included in the criteria for a diagnosis of CJD)
Dementia with Lewy bodies	(McKeith, 2006;	Preserved medial temporal	Supportive*

Neuroimaging

	McKeith et al., 2017)	lobes, relative to Alzheimer's dementia	
Frontotemporal degeneration	(Neary et al., 1998; Rascovsky et al., 2011; Gorno-Tempini et al., 2011)	Focal frontal or temporal atrophy	Supportive*
Multiple system atrophy	(Gilman et al., 2008)	Atrophy of putamen, middle cerebellar peduncle, pons, and/or cerebellum	Supportive*
Progressive supranuclear palsy	(Boxer et al., 2017)	Atrophy of midbrain, 'hummingbird sign'	Supportive*
Vascular dementia	NINDS-AIREN (Roman et al., 1993)	Strategic infarction, extensive white matter changes	Mandatory**
CADASIL	(Zhu and Nahas, 2016)	Confluent white matter hyperintensities, lacunar infarcts, involvement of the anterior temporal lobes	Mandatory**

*Supportive features: consistent with the diagnosis, but without clear diagnostic specificity;

**Mandatory features: required for a diagnosis; NINDS-ARDA: National Institute of Neurological and Communicative Diseases and Stroke/Alzheimer's Disease and Related Disorders Association; NINDS-AIREN: National Institute of Neurological Disorders and Stroke and Association Internationale pour la Recherche et l'Enseignement en Neurosciences; CJD: Creutzfeldt-Jakob Disease; CADASIL: cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy.

Although the exclusion of surgical or non-degenerative causes of cognitive impairment remains an important justification for imaging, there is an increasing focus on identifying biomarkers that help to support a clinical diagnosis of the underlying cause of the dementia. While no imaging feature has perfect sensitivity and specificity for any given diagnosis, there are a number that help to narrow the differential diagnosis. Further validation of these biomarkers is required before they can be implemented in routine clinical practice.

Potential diagnostic use

Dementia of Alzheimer type (AD)

The MRI technique that is arguably closest to translation to the clinic is T₁-weighted MRI in the diagnosis of AD (Dubois et al., 2010; McKhann et al., 2011). A key feature of AD is early, localized atrophy of the medial temporal lobe (MTL), including the hippocampus and entorhinal cortex (Fig. 12.10), which is followed by generalized neocortical volume loss. Hippocampal atrophy is thought to occur early, and three years prior to diagnosis hippocampal volumes are already reduced by 10% (Johnson et al., 2012). T₁-weighted MRI is an ideal tool to examine such patterns of atrophy in vivo, with volumetric measures found to correlate well with both neuropathological disease progression (Gosche et al., 2002; Jack et al., 2002; Vemuri et al., 2008), and the degree of cognitive impairment (Hua et al., 2008; Vemuri et al., 2009). Moreover, T₁-weighted MRI studies of AD have progressed from reporting case-control group differences to automatic classification of individual scans. A multisite study involving 98 AD and 109 control participants obtained a specificity rate of 95% (controls correctly identified as controls, i.e. correct negative rate) and a sensitivity rate of 71% (patients correctly identified as patients, i.e. correct positive rate) (Vemuri et al., 2009). Smaller studies have also reported success in discriminating between AD and other dementias (Kloppel et al., 2008).

Medial temporal atrophy (MTA) is highly sensitive for AD and has been incorporated into diagnostic criteria as a topographical marker of downstream neuronal injury (Dubois et al., 2010; McKhann et al., 2011). However, MTA is found in other dementia subtypes, e.g. frontotemporal dementia (FTD) and VD (Johnson et al., 2012), and its specificity decreases with age due to age-related atrophy (van de Pol et al., 2006). In atypical or early-onset AD it is possible to have greater atrophy of the parietal lobes and less MTA (Galton et al., 2000; Frisoni et al., 2007; Karas et al., 2007).

Other structural neuroimaging markers of AD have not yet been tested in large-scale classification studies, but may have potential to reach that stage. AD has traditionally been conceptualized as a disorder of the grey matter, and white matter damage has been thought to occur secondary to grey matter atrophy. It has now been suggested that white matter damage occurs independently of, and perhaps even before, grey matter

damage (Suri et al., 2014). For example, DTI studies of AD have typically detected a pattern of decreased FA and increased MD values in AD compared with controls. A meta-analysis of 33 case-control studies of AD found that AD was associated with reduced FA and elevated MD values in widespread regions, including within frontal and temporal white matter, the posterior cingulum, corpus callosum, superior longitudinal fasciculus, and uncinate fasciculus (Sexton et al., 2011). Furthermore, several studies have reported a significant association between decreased MMSE in AD and reduced FA, or increased MD (Bozzali et al., 2002; Duan et al., 2006), indicating that DTI metrics may be sensitive markers of disease progression. A meta-analysis demonstrated that DTI measurements of limbic regions yielded moderate to large effect sizes (Hedge's g 0.73–0.97) that were similar to those of hippocampus atrophy (Hedge's g 0.61–1.98), when discriminating between controls and patients with AD or MCI (Clerx et al., 2012).

Rs-fMRI studies in AD have shown that disconnection of the default mode network happens early in the disease course (Barkhof et al., 2014), but evidence from larger studies is required to confirm this. There is an extensive literature on regional cerebral blood flow and regional glucose metabolism studies in dementia (Ebmeier, 2010; Herholz, 2011), so that recent proposals for diagnostic criteria for AD suggest ^{18}F -FDG-PET as a topographical diagnostic marker (Dubois et al., 2010; McKhann et al., 2011). Notably, functional changes precede atrophy detectable by structural imaging. The characteristic AD patterns of abnormal brain perfusion or metabolism are found in the association cortex, while primary sensory-motor cortex is relatively preserved (Ebmeier, 2010), with a ratio of association cortex activity over primary sensory-motor cortex activity being suggested as a diagnostic index for AD (Herholz et al., 1999). Early in the disease course, SPECT and FDG-PET show reduction in posterior cingulate and precuneus perfusion or metabolism, followed by bilateral posterior temporoparietal reductions and involvement of the frontal areas in advanced disease (Mosconi et al., 2008; Ebmeier, 2010; Herholz, 2011). The findings in functional scans correlate with CSF biomarkers (Ceravolo et al., 2008), as well as with cognitive measures (Arlt et al., 2009). PET is more sensitive than clinical assessment in detecting AD (90% vs 81%), while both SPECT and PET are more specific than AD clinical criteria (85% and 89% vs 70%) (McKhann et al., 2011).

In addition, the use of amyloid tracer uptake has been suggested as a pathophysiological marker of AD (McKhann et al., 2011), although there are a number of caveats extending from the lack of availability of ^{11}C -labelled compounds (Pittsburgh compound B, PiB) to the relative lack of specificity of the available ligands which can show abnormalities in both MCI and healthy volunteers (Herholz and Ebmeier, 2011) (Fig. 12.11). There are, however a number of ^{18}F -labelled tracers (flutemetamol, florbetapir, and florbetaben) that will at least make amyloid imaging

available away from specialist radiochemistry laboratories (Herholz and Ebmeier, 2011).

Amyloid imaging provides direct evidence of the presence of Alzheimer's type pathology with A β plaques markers becoming positive years before clinical symptoms and reaching a plateau by the time clinical symptoms appear (Jack et al., 2010). Amyloid PET tracers bind with high affinity to fibrillary amyloid. More than 90% of patients with AD show increased cortical binding (Rabinovici and Jagust, 2009) and false-negative cases are reported only rarely (Cairns et al., 2009). Up to 35% of cognitively normal older people, however, have positive amyloid-PET results, and therefore amyloid imaging has low positive predictive value (Rice and Bisdas, 2017). The relative frequency of positive amyloid scans increases with age and is higher in ApoE4 carriers, compared to non-carriers, as well as in people with maternal familial history of AD (Morris et al., 2010; Rowe et al., 2010; Mosconi et al., 2010).

Amyloid imaging is useful in differentiating AD from non-amyloid dementias such as FTD (Rabinovici et al., 2011; Rowe et al., 2007), particularly in early-onset dementia, when the prevalence of AD equals to that of FTD and the frequency of amyloid deposition in controls is low. There is no uptake in most cases with Parkinson's disease (PD) dementia (Maetzler et al., 2008), but positive scans are common in dementia with Lewy bodies (DLB) (Rowe et al., 2007; Villemagne et al., 2011), which is consistent with pathological findings (Harding and Halliday, 2001). In patients with VD, a positive scan can confirm the presence of mixed pathology which has implications for treatment.

As noted previously, more recent advance in molecular PET imaging is the evaluation of cerebral tau burden. Unlike amyloid pathologies, which do not reflect disease progression, cortical tau pathology correlates with the degree of cognitive impairment and neurodegeneration (Johnson et al., 2016; Cho et al., 2016). Tau tracer retention patterns are also consistent with the expected distribution of tau pathology according to neuropathology findings, including in atypical forms like posterior cortical atrophy and the logopenic variant of primary progressive aphasia (Warren et al., 2012). While this is an encouraging breakthrough in AD research, extensive work is still needed in this field to fully characterize the binding properties of tau PET tracers and relate it to amyloid deposition as well as disease severity.

In regard to PET in vivo measurements of neuroinflammation, several studies demonstrated an increased ¹¹C-PK11195 uptake in AD compared to controls, with the largest effect in the temporoparietal cortex (Cerami et al., 2017). Cortical microglial activation was significantly correlated with cognitive status and negatively correlated with glucose metabolism and hippocampal volumes in AD (Fan et al., 2015; Femminella et al., 2016). A longitudinal study showed an increase of microglial activation in

Neuroimaging

the MTL over 16 months, paralleling the observed reduction in MTL volumes (Fan et al., 2015).

Positive TSPO PET has been found in other neurodegenerative diseases, including FTD, DLB, atypical parkinsonism, and in prion diseases, which supports the hypothesis that glial activation reflects a generic pathological response to neurodegeneration, rather than a specific reaction to a given toxic protein (Cerami et al., 2017).

Although EEG has been shown to be useful in AD research for the last 30 years, there has not been a proper translation into the clinic. One reason might be that there are no large-scale studies investigating the clinical use of EEG to discriminate between AD patients and healthy controls. This is surprising given the good results of resting-state EEG studies. AD is characterized by slowing of cortical rhythms. Early stages of AD are associated with increased theta and delta band activity and decreased

beta band activity, followed by a decrease in alpha activity. Additionally, dementia severity correlates with the mean frequency of power spectra (Jeong, 2004). This could be used for diagnostic purposes. For example, a specificity rate of 83% and sensitivity of 87% was achieved comparing global amplitudes of power in the alpha and theta frequency range between 38 AD patients and 24 healthy controls (Huang et al., 2000). Differences in amplitude and latency of several ERP components have also been reported when comparing AD patients with healthy controls (Jackson and Snyder, 2008).

EEG may aid the differential diagnosis of other dementia syndromes. In sporadic CJD (sCJD) the EEG is characterized by diffuse slowing and FIRDA (frontal intermittent rhythmic delta activity) in early stages, and the typical periodic sharp wave complexes (PSWC) that develop with disease progression. Lateralized or generalized PSWC occurs in about two-thirds of patients with sCJD and has a positive predictive value of 95%; it rarely, if at all, occurs in vCJD. EEG recording is included in the World Health Organization diagnostic classification criteria for CJD (Malek et al., 2017).

In a study comparing patients with different dementia subtypes, focal abnormalities, local 'irritative' phenomena (spikes and/or sharp waves), and slow wave paroxysms were more common in patients with VD than in those with AD (Erkinjuntti et al., 1988). Another study compared patients with AD, FTD, and controls and found that in FTD, there was no increase in slow wave activity and a decrease in fast wave activities (Lindau et al., 2003). A normal EEG in a patient with a clinical diagnosis of dementia should be a cause for reconsidering the diagnosis; one possibility is (untreated) depression, in which the amount of slow wave activity is near normal (Malek et al., 2017).

Latterly, advanced EEG analysis methods have become available, e.g. functional connectivity and network analysis. Especially in the higher frequency bands, AD patients have lower functional connectivity than healthy controls. The changes in connectivity are not equally distributed across brain regions, and at the regional level, connectivity increases have been described as well. The EEG-based functional brain networks of AD patients have been found to differ from those of healthy controls, but the interpretation of the results is constrained by methodological limitations (van Straaten et al., 2014).

MEG studies in AD consistently show that MEG oscillations are slower in AD patients than in controls. A review of 31 studies concluded that, compared to controls, AD patients had slower brain activity, which was reflected in a higher power in the lower frequency bands and lower power in the higher frequency bands consistent with EEG studies in AD. The most affected brain regions were left parietal and left temporal, followed by left occipital, with the central region being less affected. In addition, brain signals in AD were more regular, less complex, and more predictable than in controls; these results are in line with the EEG

findings (Engels et al., 2017). To date, there are only a few MEG-based connectivity and network studies, but largely they support the concept of AD as a 'disconnection syndrome' (Engels et al., 2017). For instance, in a study of resting-state MEG, 22 AD patients showed reduced mean frequency of power spectra, compared with 21 healthy controls (Fernandez et al., 2006a). Further analysis of the same subject group showed that relative power in the 16- to 28-Hz frequency band can differentiate between AD patients and healthy controls with 80% specificity and 81% sensitivity, respectively (Fernandez et al., 2006b). There are only a few MEG studies in other types of dementia and they largely support the EEG findings.

Fig. 12.11

^{18}F -FDG (^{18}F -Fludeoxyglucose) and ^{11}C -PiB (11C-Pittsburgh compound B) scans in healthy controls and patients with mild cognitive impairment (MCI) and Alzheimer's disease (AD). (a) Amyloid scan with florbetapir in a normal control (NC) and an AD patient. Note tracer uptake in white matter of the healthy volunteer brain. (b) FDG scan in a patient with MCI and two years later, when he had progressed to AD. The left column highlights the abnormal areas in black (association cortex).

Vascular dementia (VD)

Evidence from structural neuroimaging is mandatory for diagnosing VD. VD can result from large artery (cortical) ischaemic disease, small vessel (subcortical) disease (SVD), or bilateral thalamic/fornix infarcts (strategic infarcts) leading to severe memory deficits.

SVD is the most common cause of VD. It results from damage to the cerebral microcirculation and is defined as lesions involving > 25% of the white matter (Pantoni, 2010). Radiologically, SVD is characterized on MRI by WMH, recent small subcortical infarcts, lacunae, prominent perivascular spaces, cerebral microbleeds, and atrophy (Wardlaw et al., 2013) (see Table 12.3). These signs are present in up to 10% of patients in their seventh decade, increasing to above 85% of those in their ninth decade (Blair et al., 2017). They are present in healthy elderly, but are

strongly associated with vascular risk factors and cognitive impairment (Pernecky et al., 2016).

Table 12.3 Neuroimaging (MRI) features of small vessel disease.

Neuroimaging

	Recent small subcortical infarct	Lacuna	White matter hyperintensity	Perivascular space	Cerebral microbleed
Definition	Neuroimaging evidence of recent infarction in the territory of one perforating arteriole, with imaging features or clinical symptoms consistent with a lesion occurring in the previous few weeks	A subcortical, fluid-filled cavity consistent with a previous acute small subcortical infarct or haemorrhage in the territory of one perforating arteriole	Signal abnormality characterized by hyperintensity on T ₂ -weighted images without cavitation	Fluid-filled spaces that follow the typical course of a vessel as it goes through grey or white matter	Small areas of signal void with associated blooming
Best sequence	DWI	FLAIR	FLAIR	T ₁ /T ₂ /FLAIR	T ₂ */SWI
Diameter	≤ 20mm	3-15mm	variable	≤ 2mm	≤ 10mm
Comment		Round or ovoid, usually with hyperintense rim	Located in the white matter	Most linear without hyperintense rim	Round or ovoid, well defined, blooming

White matter lesions appear as bilateral, mostly symmetrical hyperintensities on T₂-weighted MRI. WMH are clinically and pathologically heterogeneous (Gouw et al., 2011; DeBette and Markus, 2010); they are not specific to VD and can be found in other conditions including leukodystrophies, leukoencephalopathies, inflammatory conditions, and infections (Harper et al., 2014). WMH in AD might be a marker for Wallerian degeneration triggered by cortical AD-pathology; in this case they have a posterior predominance (McAleese et al., 2017). Currently it is not known why some individuals are symptomatic at early stages of SVD, while others have significant radiological findings and no apparent symptoms. However, as WMH become more extensive they are more likely to be clinically significant (Dufouil et al., 2009), with confluent deep and large irregular WMH being typical of VD.

SVD shares common risk factors with large vessel atherosclerotic vascular disease, e.g. age, hypertension, hypercholesterolemia, diabetes, and smoking, but it is now understood to be a distinct, endothelial disease, likely to require different treatments than traditional plaque-targeted vascular therapies. Recent advances in imaging SVD include quantifying the total SVD burden, imaging brain microstructural integrity, and assessing vascular malfunction. These methods have the potential to identify early disease stages and tissues at risk of progression to more established brain damage. They may be used in the future to stratify patients entering trials and to identify new treatment targets (Blair et al., 2017).

Although still in development, DTI can detect subtle microstructural changes that precede brain atrophy and may be missed by volumetric methods. Using voxel-wise DTI analyses, patients with vascular cognitive impairment had significantly decreased FA in hemispheric deep white matter and corpus callosum compared to healthy controls (Otsuka et al., 2012). Research suggests that the impairment of white matter integrity is more extensive in VD than in AD. Using TBSS, Zarei and colleagues (2009) found that, relative to controls, patients with VD had more widespread reductions in FA in frontal and parietal areas, whereas patients with AD had reduced FA in the temporal lobes.

Typical findings in VD are multiple small lesions of hypoperfusion or hypometabolism, often asymmetrical in distribution, extending over cortical and subcortical structures.

Frontotemporal dementia (FTD)

Currently validated imaging biomarkers in FTD include grey matter atrophy, brain hypometabolism detected by FDG-PET, and brain hypoperfusion detected by HMPAO-SPECT.

FTD encompasses a heterogeneous group of conditions and can be broadly divided into behavioural variant frontotemporal dementia (bv-FTD) and primary progressive aphasia (PPA) (see Chapter 33 for further

elaboration). The most recently published guidelines include as a criterion for establishing a diagnosis of 'probable' FTD evidence for abnormalities on either structural or functional brain imaging in addition to a clinical diagnosis (Rascovsky et al., 2011; Gorno-Tempini et al., 2011).

Bv-FTD is associated with atrophy in the frontal and temporal lobes, the insula, and the anterior cingulate cortex, with the earliest involvement of frontal paralimbic cortices and insula (Meeter et al., 2017). Cluster analyses identify four anatomical forms of bv-FTD: frontal-dominant, temporal-dominant, frontotemporal, and distributed frontotemporoparietal (Meeter et al., 2017). With the disease progression, subcortical structures such as the hippocampus, amygdala, basal ganglia, and thalamus are involved as well (Meeter et al., 2017).

PPA is itself categorized into three clinical phenotypes: semantic variant PPA (sv-PPA), non-fluent PPA (nv-PPA), and logopenic variant PPA (lv-PPA). In sv-PPA, there is typically anteroinferior temporal lobe atrophy, including the fusiform gyrus, while the nv-PPA is characterized by perisylvian atrophy and involvement of the insula (Rohrer et al., 2009; Seelaar et al., 2011). The lv-PPA is commonly associated with Alzheimer's type pathology and the atrophy involves the posterior temporal cortex and inferior parietal lobule (Gorno-Tempini et al., 2004). In PPA the atrophy is more often asymmetrical, with the left side being more affected (Seelaar et al., 2011); with disease progression, the atrophy involves the opposite hemisphere as well. In addition to distinct patterns of regional atrophy that are associated with each clinical phenotype, the rate of atrophy was found to be doubled in FTD and semantic dementia, compared with AD (Krueger et al., 2010).

When available, functional imaging such as FDG-PET may be more useful because early in the disease course the structural scan can be normal. The patterns seen on functional imaging mirror those seen on structural scans, but they are visible earlier, sometimes a few years before patients fulfil the criteria for probable bv-FTD (Meeter et al., 2017). In patients with suspected FTD, the use of SPECT/PET increased sensitivity of consensus criteria from 36.5% to 90.5%, where clinical diagnosis after two years was used as a gold standard (Mendez et al., 2007). In primary psychiatric disorders that mimic bv-FTD, false positive FDG-PET scan results have been reported, requiring caution if this is the only abnormal investigation (Meeter et al., 2017).

New imaging biomarkers for FTD are in the process of development, but have not yet been tested in large studies. For instance, DTI studies demonstrate that changes in white matter microstructure are more widespread in FTD compared to AD, and whole brain mean FA discriminates between FTD and AD with a sensitivity of 78% and specificity of 68% (Meeter et al., 2017). The key white matter tracts involved in bv-FTD seem to be the uncinate fasciculus, cingulum bundle, and the genu of corpus callosum, although patterns of white matter

damage on DTI significantly overlap between FTD subtypes (Meeter et al., 2017).

Using ASL, hypoperfusion in the insula, the amygdala, and parts of the medial frontal lobes including the anterior cingulate was found in patients with FTD. Comparative studies demonstrated that the regions found on ASL MRI overlapped with those on FDG-PET scans, with the two modalities having similar performance for distinguishing bv-FTD from AD and controls (Verfaillie et al., 2015; Tosun et al., 2016).

The most consistent rs-fMRI finding in FTD is decreased connectivity between the frontoinsula and anterior cingulate cortex, which is a part of the salience network, although normal or increased connectivity has been reported as well (Meeter et al., 2017).

Dementia with Lewy bodies (DLB)

Reduced dopamine transporter (DAT) uptake in basal ganglia demonstrated by SPECT (FP-CIT) or PET imaging is the most reliable imaging biomarker of DLB, and has been incorporated as 'indicative' biomarker in the revised criteria for DLB (McKeith et al., 2017) (Fig. 12.10). It has also been recommended by the United Kingdom National Institute for Health and Care Excellence (NICE) if the diagnosis is uncertain and DLB is suspected (NICE, 2018).

Compared with autopsy results, DAT imaging showed sensitivity and specificity of 88% and 100%, respectively, whereas clinical diagnosis had a sensitivity of 75% and specificity of only 42% (Walker et al., 2007). Normal DAT scan in patients with DLB is not common, but has been reported; it is possible that these patients have exclusive cortical involvement with relative sparing of basal ganglia (Siepel et al., 2013) or a balanced loss across the whole striatum (McKeith et al., 2017).

DAT density is highest in striatum, i.e. caudate and putamen. Age-related nigrostriatal degeneration affects both the putamen and caudate nucleus, and the putamen-to-caudate ratio is preserved (Tatsch and Poepperl, 2013). In PD and DLB, however, there is usually a pronounced reduction in FP-CIT signal, often with greater reduction in activity in the putamen. Because antipsychotic drugs bind to the postsynaptic D₂ receptors and not DAT, drug-induced parkinsonism shows a normal uptake pattern for FP-CIT. DAT imaging is useful in the differential diagnosis of DLB from AD; its utility is well-established, with sensitivity of 78% and specificity of 90% (McKeith et al., 2017). However abnormal DAT binding is less reliable in differentiating DLB from FTD because about 30% of patients with FTD were found to have a positive DAT scan (Morgan et al., 2012). Vascular parkinsonism may show a pronounced lateral asymmetry of striatal binding, but idiopathic PD also often presents with asymmetrical FP-CIT uptake. It is important to recognize that a DAT scan cannot differentiate between other syndromes characterized by dopaminergic

loss, such as the atypical parkinsonian syndromes, e.g. PSP or multiple system atrophy, parkinsonian variant (MSA-P), or CBD.

Relative preservation of MTL on structural imaging (CT/MRI) is supporting a diagnosis of DLB, but is unusual in AD. Other supportive imaging biomarkers include generalized low uptake on perfusion SPECT or metabolic PET with reduced occipital activity, including the primary visual cortices (Minoshima et al., 2001; Sinha et al., 2012; McKeith et al., 2017). Parietotemporal reductions are observed in both AD and DLB, but occipital hypometabolism differentiated between the two conditions with 90% sensitivity and 71–80% specificity (Minoshima et al., 2001).

DLB is also characterized by relative preservation of posterior or mid-cingulate metabolism on FDG-PET, the so-called cingulate island sign. Occipital lobe hypometabolism and the cingulate sign, however, are not specific for DLB, as they can be observed in posterior cortical atrophy, a variant of AD (Bohnen et al., 2017).

On EEG, patients with DLB typically exhibit increased posterior slow wave activity relative to healthy controls and patients with AD (Cromarty et al., 2016). The presence of posterior (temporal) transient slow or sharp waves on EEG is included as a supportive feature of the condition in the diagnostic criteria (McKeith et al., 2017). The increased slow wave activity clinically correlates positively with the presence and severity of cognitive fluctuations (Bonanni et al., 2008). Similar to AD patients, DLB patients show greater coherence in the delta band, but reduced coherence in the alpha band (Malek et al., 2017; Andersson et al., 2008).

Other diagnoses

Neuroimaging is not yet used routinely for the assessment of late life depression (LLD), nor have large-scale classification studies been performed in this patient group. Many research studies have used neuroimaging to identify differences between patient and control groups. There are several reasons that have contributed to difficulties in translating their results into clinically useful diagnostic markers of LLD. First, there is frequently great heterogeneity in the anatomy of results reported. For example, while grey matter volume reductions in LLD have been most frequently reported within the frontal lobe and hippocampus, grey and white matter changes have also been observed in the parietal lobe, amygdala, putamen, and thalamus, particularly in late-onset illness (Sexton et al., 2012). Second, there is often a lack of specificity of results reported for LLD. For example, reduced hippocampal volume has also been reported in many other patient groups, including MCI, AD, FTD, and VD (van de Pol et al., 2006). Third, there is the question of what value a neuroimaging marker would have above and beyond the clinical assessment already used. An ideal marker would not only reliably discriminate between patient groups, but also predict outcome. For example, prediction of treatment response would allow the most likely effective treatment to be administered first, while prediction of first

episodes or relapses would provide an opportunity for preventative measures.

Predicting outcome

Neuroimaging techniques are not currently used in the clinic for predicting outcome, but significant research has been performed in this field. In particular, many studies have been performed that have the long-term aim of predicting conversion to AD from at-risk groups, including MCI and apolipoprotein E (ApoE) $\epsilon 4$ carriers.

MCI is a descriptive diagnosis that identifies patients referred with memory impairment beyond that expected for age and education, who do not display functional deficits, and so do not qualify for a diagnosis of dementia. A recent meta-analysis, however, calculated the annual conversion rate from MCI to AD to be only 5–10% (Mitchell and Shiri-Feshki, 2009).

Several T₁-weighted MRI studies have examined conversion from MCI to AD. Ferreira and colleagues (2011) performed a meta-analysis of six longitudinal VBM studies of MCI, in which 142 of 429 participants converted to AD. Conversion was associated with decreased grey matter in the left hippocampus and parahippocampal gyrus. Specificity and sensitivity rates in predicting conversion for individuals with MCI have also been calculated by some studies. For example, Devanand and colleagues (2008) used a model combining hippocampal and entorhinal volumes with functional and cognitive impairment measures, to predict conversion from MCI to AD with 85% sensitivity and 90% sensitivity. Markers of hippocampal atrophy do not, however, take into account the overall pattern of brain atrophy in AD. More recently, comprehensive quantitative metrics of typical brain atrophy in patients with AD that use composite measures across several brain regions or advance machine learning algorithms have been developed (Teipel et al., 2015). Generally, a major determinant of the prediction accuracy achieved in different MRI-based studies is the time to conversion in the patients analysed. The accuracy is higher in patients with MCI who are closer to developing AD.

Reduced white matter integrity has also been detected in people at higher risk of developing AD, including those with MCI and ApoE $\epsilon 4$ carriers. A meta-analysis of 21 case-control studies of MCI found that differences between MCI and controls paralleled the differences between AD and controls, but fewer regions reached statistical significance (Sexton et al., 2011). As with AD, several studies have reported a significant association between decreased MMSE and reduced FA in MCI (Ukmar et al., 2008; Bai et al., 2009; Mielke et al., 2009). The MMSE scores correlated with the FA in the splenium, the genu, and right frontal white matter (Ukmar et al., 2008). With regard to APOE $\epsilon 4$, a TBSS study identified a widespread pattern of elevated MD in APOE $\epsilon 4$ carriers aged 50–78 years compared with age-matched controls, and reduced FA in

carriers aged 20–35, again compared with age-matched controls (Heise et al., 2011).

Metabolic abnormalities in AD-related regions are found even in cognitively normal individuals at increased risk of AD (Mosconi et al., 2007). A meta-analysis of seven FDG-PET studies showed a sensitivity of 77% and specificity of 85% in predicting conversion from MCI to AD, compared with amyloid PET, for which sensitivity was 93% and specificity was 56% (Zhang et al., 2012). These results highlight that, clinically, the role of amyloid PET is more of an exclusionary one, as amyloid plaques are necessary, but not sufficient, for the development of AD.

Many studies have shown the predictive value of EEG measures for progression of healthy subjects to MCI and AD (Jeong, 2004). A seven-year follow-up study of 44 healthy participants with subjective memory complaints showed that EEG at baseline can predict conversion to MCI with 95% sensitivity and 94.1% specificity, and conversion to dementia with 96.3% sensitivity and 94.1% specificity (Prichep et al., 2006). These high values were achieved with ‘eyes-closed’ resting data. Subjects also had to discontinue any centrally acting medication at least two weeks before the baseline scan, which probably limits the potential clinical use. The authors further did a post-hoc logistic regression analysis based on nine quantitative (Q)EEG baseline variables, and variables with the highest significance in their prediction equation were mean frequency of the total spectrum, mean frequency in the delta band, absolute power across all frequency bands on the right hemisphere, and absolute power in the theta frequency band. Quantitative EEG may also have a role in predicting the progression from MCI to DLB. Bonanni and colleagues (2015) followed up 47 MCI subjects for three years. At the end of the follow up, 20 patients had developed probable DLB and 14 had probable AD, with the other patients remaining stable or developing other types of dementia. All DLB patients showed the typical of early DLB EEG abnormalities at admission, while 93% of the patients who developed probable AD maintained a normal EEG throughout the study (Bonanni et al., 2015).

Several studies have used EEG also to investigate the effect of *ApoE* genotype on brain function. In AD patients and in healthy subjects, differences between *ApoE* $\epsilon 4$ carriers and non-carriers were reported. This affected task-related ERP amplitudes and latencies (Espeseth et al., 2009), as well as resting-state EEG measurements (Babiloni et al., 2006).

Understanding illness mechanisms

Neuroimaging can contribute in different ways to the question how and why diseases develop. Functional and structural measures can be used to evaluate the effects of drug treatment, investigate the effects of lifestyle factors on the brain and disease risk, and provide insights into mechanisms that underlie genetic susceptibility to diseases.

With respect to AD, examples of these approaches are studies looking at the effect of cholinesterase inhibitor (ChEI) treatment on the brain (Venneri, 2007). In healthy subjects and AD patients, ChEI administration modulates brain function, and in AD patients it might slow down hippocampal atrophy. A double-blind randomized controlled trial of Donepezil in individuals with prodromal AD showed a 45% reduction in the rate of hippocampal atrophy in the treatment group compared with the placebo group after one year of treatment (Dubois et al., 2015). A follow-up study found that Donepezil-treated participants showed reduced rate of atrophy in the nucleus basalis of Meynert, the region with high concentration of cholinergic neurons projecting to the cortex (Cavedo et al., 2017). However, longitudinal studies of large patient populations are required to understand the long-term effects of ChEI administration. Given that, overall, only around 50% of patients show a positive response to medication, it is also important to investigate if structural or functional imaging measures can be used to predict the response to drug treatment.

Although there are genetic risk factors for AD development, there are important effects of lifestyle, e.g. diet, on AD risk. For example, several neuroimaging studies have shown effects of homocysteine levels on the brain, and among others plasma homocysteine levels depend on nutrition and vitamin supply. High plasma homocysteine levels increase the risk for AD (Seshadri et al., 2002), which might be due to increased cortical and hippocampal atrophy (den Heijer et al., 2003). Additionally, a recent study has reported that administration of B vitamin supplements can slow the rate of brain atrophy in MCI subjects (Smith et al., 2010). Therefore, neuroimaging markers can be used to identify lifestyle factors affecting AD, which may be important to delay disease onset and study preventative measures.

Illuminating the question as to how *APOE* genotype may affect susceptibility to AD, many studies have shown functional and structural differences between *APOE* $\epsilon 4$ carriers and non-carriers. For instance, activity within the default mode network differs between *APOE* $\epsilon 4$ carriers and non-carriers (Filippini et al., 2009). This resting-state network is of interest because amyloid plaque deposition seems to occur in regions that show high neuronal activity, such as the default mode network (Buckner et al., 2005). An association between neuronal activity and the processing of amyloid precursor protein has also been shown in vitro (Kamenetz et al., 2003), which suggests the hypothesis that genetically based differences in neuronal activity may play a role in AD development.

In LLD, neuroimaging studies have played a key role in the development and assessment of the vascular depression hypothesis. The vascular depression hypothesis proposes that cardiovascular factors may 'predispose, precipitate, or perpetuate' late-onset depression (LOD) (typical age of onset is +60 years) (Alexopoulos et al., 1997). Specifically, vascular factors are hypothesized to cause white matter damage within frontal-subcortical circuits (Alexopoulos et al., 1997; Alexopoulos, 2002).

In support of this hypothesis, LOD has often been found to be associated with more frequent and severe WMH compared with early-onset depression (EOD) (Herrmann et al., 2008). More frequent and severe, WMH have also been linked to poor antidepressant treatment response in LLD (Hickie et al., 1997; Hickie et al., 1995; Simpson et al., 1998). Expanding on this research, Sheline and colleagues (2010) have reported that WMH severity predicted Montgomery-Åsberg Depression Rating Scores (MADRS) over a 12-week course of treatment. Although some studies of WMH have employed automated methods, the majority of studies have used rating scales that can suffer from intra- and interrater reliability and a lack of anatomical specificity, and may also be insensitive to subtle changes in WM integrity. DTI studies of LLD overcome many of these limitations and have also provided support for the vascular hypothesis of depression. For example, Sexton and colleagues (2012) found that later age at onset was significantly associated with reduced FA of widespread tracts, in particular, the anterior thalamic radiation and superior longitudinal fasciculus. Similarly, Framingham Stroke scores predicted greater disruption of white matter connectivity (Allan et al., 2012).

Understanding resilience: Neuronal scaffolding

Ageing is characterized by decreasing grey matter density, reducing white matter integrity, and (somewhat paradoxically) increasing neuronal activity. For example, fMRI studies report increased bilateral activation of frontal and other association cortices in older as opposed to younger subjects, which is associated with better cognitive performance (Cabeza et al., 2002; Cabeza et al., 1997; Grady et al., 1999; Reuter-Lorenz et al., 1999; Rypma et al., 2001; Reuter-Lorenz, 2002; Fera et al., 2005). Hippocampal underactivity in well-functioning older subjects is combined with increased bilateral frontal activation when compared with younger volunteers (Morcom et al., 2003; Cabeza et al., 2004; Gutchess et al., 2005; Persson et al., 2006). This increase in activity has been interpreted as a compensatory process, i.e. the brain has to work harder to achieve the same level of performance. A number of authors have converged on the view that it may delay performance failure and clinical decompensation even in the face of progressive atrophy of critical brain structures (e.g. hippocampus) and it is accompanied by subjective awareness of cognitive problems or increased effort during task performance (Buckner, 2004; van Norden et al., 2008). The concept of neuronal scaffolding is a formulation of this general idea that successful ageing is associated with increased recruitment of additional neuronal resources in the face of deteriorating brain structure (Reuter-Lorenz and Cappell, 2008; Han et al., 2009; Park and Reuter-Lorenz, 2009). Scaffolding is a process that results in changes in brain function through strengthening of existing connections, formation of new connections, and disuse of connections that have become weak or faulty (Park and Reuter-Lorenz, 2009). Consistent with this, a posterior-anterior shift of brain activity can be observed with increasing age, suggesting that frontal lobe

networks are preferentially activated in a compensatory manner and so may provide the necessary secondary scaffold (Davis et al., 2008). Therefore, damage to the primary structure involved in a neurocognitive task (for example, the hippocampus in memory) must exceed a certain threshold to reveal the presence of objective memory impairment. However, a parallel process affecting the compensating networks (typically generalized vascular pathological change) may worsen the impact of the primary pathology or even be necessary to reveal a classical clinical condition (Buckner, 2004). This dual mechanism may explain the biphasic clinical course of initial compensated memory impairment with insight, followed by dementia and loss of function in AD (Buckner, 2004). While hippocampal lesions occur early and are the locus of maximum plaque and tangle formation, older people in general and AD patients in particular show a deterioration in the frontal executive network that is characterized by reduction in fluid intelligence, i.e. abstract thinking and reasoning. Structurally, there may be WMH, reductions in white matter integrity, and frontal atrophy. This putative mechanism may be generally applicable because both whole-brain and hippocampal atrophy trajectories have been related to the onset of cognitive impairment and dementia: in one study hippocampal atrophy preceded dementia by three years and whole-brain atrophy by one year (Ridha et al., 2006). Consistent with this, hippocampal atrophy rates have been shown to predict MCI, while global atrophy rates predicted dementia onset (Henneman et al., 2009). In summary, successful ageing is characterized by more anterior, less lateralized, and more coordinated brain activity. The scaffolding theory of ageing has been proposed to explain the processes behind the differing patterns of activation found in ageing. Individual differences in the brain's ability to scaffold may explain the heterogeneity in ageing.

Conclusion

It has taken half a century to develop methods that allow us to examine brain structure and function in vivo. These secrets have been well guarded by the compact packaging and the complex structure of our brains. While giant strides are being made in unravelling aspects of normal and abnormal brain function, analysing this most complex of all systems will take some time to achieve. Obvious limits are given by ethics and by the absence of credible (animal or computing) models for most human psychiatric disorders. It will take all our ingenuity to develop insights and methods that will be of benefit to our patients. We may, nevertheless, be the last generation of clinicians who can claim with quiet satisfaction that our attentive interview and expert examination are as good as any brain imaging currently available to make a diagnosis and decide on the best management for our patients.

Psychopharmacology

Chapter: Psychopharmacology

Author(s): Delia Bishara

DOI: 10.1093/med/9780198807292.003.0013

Introduction

This chapter examines the factors to consider when prescribing psychotropic drugs in older people. It reviews the major physiological changes that occur in old age and the effects that these changes have on the pharmacokinetics and pharmacodynamics of drugs, in particular psychotropic medication. It discusses the problems associated with polypharmacy and explains the potential mechanisms involved in the occurrence of adverse drug reactions and drug-drug interactions. It also investigates the reasons for non-adherence to medication in elderly patients and highlights the importance of establishing adherence before prescribing medication, especially in this population. In addition, it reviews the evidence for the risks associated with the use of antipsychotic drugs and anticholinergic drugs in older people and provides guidance on prescribing these drugs where necessary.

Complexities associated with medication use in older people

The use of pharmacological agents in older adults is one of the most complex aspects of patient care. Clinicians must display expert knowledge on and careful consideration of the various factors involved. Older people exhibit an unexpected or exaggerated response to drug therapy when compared to their younger counterparts of the same body weight and gender, which can often be explained through pharmacokinetic or pharmacodynamic changes. Understanding the common physiological changes seen in ageing is helpful to anticipate the changes expected in pharmacokinetic parameters. The pharmacodynamic variations seen in older patients may also increase or decrease sensitivity to a drug independently of the pharmacokinetic changes (Hutchison and O'Brien, 2007). In addition, age is known to be associated with increased prevalence of multiple chronic illnesses frequently requiring the use of complex therapeutic regimens. Age-related physiological changes as well as the presence of comorbidity and polypharmacy will complicate drug therapy in older people.

Older adults are conventionally defined by a chronological age of 65 years and older because there are as yet no biological markers to define old age. Several processes are involved in ageing including progressive impairments in the functional reserve of multiple systems and organs and reduced ability to respond to environmental demands. The reduced efficacy of homeostatic mechanisms is a fundamental feature of ageing but the decline in functional reserve varies markedly between elderly individuals (Turnheim, 2003). Very old individuals tend to become frail, a syndrome defined as an excessive reduction of lean body mass, loss of skeletal muscle (sarcopenia), chronic under-nourishment, reduced function, and poor endurance as well as neuroendocrine and immune dysfunctions (Walston and Fried, 1999). The prevalence of diseases increases with advanced age, leading to extensive use of medications. Almost half of people over 65 years of age take at least five regular medicines a day (Gao et al., 2017). Consequently, adverse drug reactions are more frequent and more serious in older people (Doucet and Queneau, 2005; Lavan and Gallagher, 2016) and drug interactions occur more often (Herrlinger and Klotz, 2001).

Age-related changes in pharmacokinetics

Pharmacokinetics is the branch of pharmacology concerned with the movement of drugs within the body. Ageing is generally characterized by changes in all phases of pharmacokinetic processes: absorption, distribution, metabolism, and excretion (see Table 13.1).

Table 13.1 Pharmacokinetic changes due to ageing and effect on dosing of psychotropic drugs.

Psychopharmacology

Age-related physiological changes	Pharmacokinetic parameter	Effect on pharmacokinetic parameters	Impact on psychotropic drug dosing
Reduced gastric acid secretion	Absorption	Slightly decreased absorption	Minimal for most drugs
Decreased gastrointestinal motility			
Slowed intestinal transit time			
Delayed gastric emptying			
Reduced splanchnic blood flow			
Reduced bowel surface area			
Increased body fat	Distribution	Increased volume of distribution and half-life for lipophilic drugs	Moderate for some drugs, e.g. phenytoin, diazepam
Decreased lean body mass			
Decreased total body water		Increased plasma concentration of water-soluble drugs	
Decreased serum albumin concentrations		Increased free-fraction of highly protein-bound acidic drugs	
α_1 -glycoprotein concentrations tend to increase		Decreased free-fraction of basic drugs	

Psychopharmacology

Reduced liver mass Reduced liver blood flow Reduced hepatic metabolic function	Metabolism	Less effective first pass metabolism and phase I metabolism	Moderate for some drugs e.g. nortriptyline
Reduced renal mass Reduced renal blood flow Reduced glomerular filtration rate (GFR) Reduced filtration fraction Reduced tubular secretion	Excretion	Impaired renal elimination of water-soluble drugs	Major for drugs that are extensively eliminated by the kidneys, e.g. lithium, gabapentin

Minimal = no impact on dosing anticipated

Moderate = some drugs may require dosage adjustments and monitoring

Major = accurate dose adjustments and monitoring required
Source: data from Corsonello A., Pedone C., and Incalzi A. (2010). Age-related Pharmacokinetic and Pharmacodynamic Changes and Related Risk of Adverse Drug Reactions. *Current Medicinal Chemistry*, 17, 571-584; data from Hutchison L. and O'Brien C. (2007). Changes in Pharmacokinetics and Pharmacodynamics in the Elderly Patient: *Journal of Pharmacy Practice*, 20(1), 4-12.

Absorption

In the ageing gastrointestinal (GI) tract, several physiological changes have been observed, including reduced gastric acid secretion resulting in increased gastric pH, decreased gastrointestinal motility, slowed intestinal transit time, and delayed gastric emptying, as well as reduced splanchnic blood flow and bowel surface area (Klotz, 2009; Hutchison and O'Brien, 2007; Corsonello et al., 2010). Oral medicines have been extensively studied to determine whether these changes have an effect on their absorption. However, since most drugs undergo passive diffusion in the GI tract, they may experience a delay in absorption; there is no

overall change in the extent of their absorption. Thus, there may be a delay in the time to reach maximum concentration after the first dose of medication and the area under the curve (AUC) graph appears flattened, but not diminished. The area under the plasma drug concentration-time curve reflects the actual exposure of drug in the body after administration of a dose. It is dependent both on the rate of elimination of the drug from the body and the dose administered.

In summary, with long-term medication that reaches steady state, no clinically significant changes in absorption occur. However, important changes do occur for certain agents that require a low pH or that undergo active absorption processes (e.g. glucose, calcium, vitamin B₁₂). For these agents, a reduction in absorption may be seen. In contrast, due to reduced gastric acid secretions seen in older people, enteric coated tablets tend to undergo an increased rate of absorption since the coating breaks down more rapidly in alkaline fluid (McLean and Le Couteur, 2004; Hutchison and O'Brien, 2007).

Absorption of drugs from other routes of administration can also be altered in older people. Although with age there is atrophy of the epidermis and dermis, which can result in a reduction in the skin's barrier function, the rate of transdermal drug absorption may in fact be diminished because of reduced tissue blood perfusion. This is also true for the subcutaneous route of administration. Intramuscular injections can lead to erratic absorption of drugs in older people (Turnheim, 2003).

Distribution

The distribution of drugs around the body can be significantly affected by changes in body composition occurring in advanced age. In general, body fat mass increases by 20–40%, while total body water and lean body mass decrease by 10–15% (Corsonello et al., 2010; Turnheim, 2003). As a result, the volume of distribution of lipophilic drugs (e.g. diazepam and chlordiazepoxide) may increase leading to prolonged half-life and time necessary to reach steady state concentration during repeated drug administration (Hutchison and O'Brien, 2007). For water-soluble drugs, however, the volume of distribution decreases resulting in higher plasma concentrations and lower starting dose requirements (e.g. lithium) (Corsonello et al., 2010; Turnheim, 2003).

In general, the changes seen in plasma protein binding appear to be less important for drug therapy in older people. Drugs circulating in blood may be bound to plasma proteins, with only the unbound fraction being pharmacologically active. Serum albumin concentrations can be slightly decreased or remain unchanged in healthy older people, but are significantly lower in frail or malnourished patients. The decrease in albumin can result in an increase in the free fraction of drugs highly bound to albumin, causing unexpected drug toxicity when they are first administered to a patient, until their steady state equilibrium is established. Phenytoin and warfarin are examples of drugs with high free

serum concentrations, despite having the same total concentration (Hutchison and O'Brien, 2007). Psychotropic drugs with a high percentage of protein binding include diazepam, lorazepam, valproate (Hutchison and O'Brien, 2007), and haloperidol (Koyama et al., 2003). The concentrations of α_1 -glycoprotein, which binds primarily to alkaline drugs, tend to increase with age (Corsonello et al., 2010). Since fewer drugs with a narrow therapeutic index bind to this protein, adverse effects are not generally attributed to this change.

Metabolism

The effect of age on hepatic drug metabolism continues to be a controversial issue. Although the metabolism of drugs occurs primarily in the liver, enzymes in the kidney and GI tract may also be involved. A decrease in mass of the liver and kidney accompanied by a decrease in their function plays an important role in the reduction in drug metabolism in older people. Hepatic volume is known to decrease with ageing by about 20–30% and hepatic blood flow is reduced by about 20–50% (Hutchison and O'Brien, 2007; Klotz, 2009; Corsonello et al., 2010). Despite these changes, routine clinical tests of liver function do not change significantly with advancing age, although the serum albumin concentration may decrease slightly (Turnheim, 2003).

The metabolism of drugs in the liver is influenced by the following: hepatic perfusion, intrinsic clearance (capacity/ activity of metabolising enzymes), uptake clearance, and protein binding (Corsonello et al., 2010). Whether the metabolic clearance of a drug is decreased or unchanged in old age has been attributed to the property of the drug in terms of whether it undergoes high or low intrinsic clearance. Some drugs with high intrinsic clearance are rapidly metabolized in the hepatocytes and the rate of drug loss is limited by hepatic blood flow. Since blood flow to the liver declines with age, drugs exhibiting high extraction therefore display an age-related decrease in metabolic clearance. The term 'flow-limited' metabolism is used in these cases and examples of such drugs include amitriptyline and imipramine. Other drugs with low intrinsic clearance are slowly metabolized by hepatic enzymes and the rate of elimination is mainly dependent on enzyme activity. The metabolic clearance of these drugs is, in most cases, *not* reduced in old age as it is not dependent on hepatic blood flow, but rather on the total tissue content of metabolising enzymes ('intrinsic clearance'). This type of metabolic clearance is called 'capacity limited' and examples of drugs include diazepam and valproate (Turnheim, 2003; Corsonello et al., 2010).

Therefore, age-related changes in the liver have the potential to impact on the presystemic metabolism (first-pass effect) and thus the bioavailability of drugs with high hepatic clearance after oral administration. Although the effect on bioavailability is unpredictable, the age-related changes in the liver have the potential to result in a

significant and variable increase in bioavailability for some drugs after oral administration (McLachlan and Pont, 2012).

Changes in hepatic blood flow and intrinsic clearance, however, do not explain the age-dependent reduction in hepatic metabolism of all drugs. For example, theophylline still experiences reduced metabolism in old age although it undergoes capacity-limited metabolism (Turnheim, 2003).

Before their final excretion, the majority of drugs have to undergo biotransformation to more polar (water-soluble) metabolites by several cytochrome P450 (CYP) enzymes. In general, inter-individual variation in metabolic drug clearance by CYP enzymes exceeds the decline caused by ageing. Phase I metabolism primarily consists of oxidation (through the CYP enzyme system in the liver), reduction, and hydrolysis. Research into whether phase I metabolism is significantly reduced in older people has yielded inconsistent results. The CYP 2C19 shows a reduction with ageing but CYP 2D6 does not. The other isoenzymes (1A2, 2C9, 2E1, and 3A4) show marked variability but only a minor decrease or no change at all. Studies comparing young adults with fit elderly individuals and frail elderly individuals found little difference between the young adults and fit elderly people, but a significant reduction in esterase activity (another phase I pathway) was seen in the frail elderly people. In view of this wide variability, it is safer in older people to reduce the dosages of drugs that undergo phase I metabolism, e.g. chlordiazepoxide, diazepam, zolpidem, amitriptyline, selective serotonin reuptake inhibitors (SSRIs), venlafaxine, and risperidone (Hutchison and O'Brien, 2007).

Phase II metabolism involves conjugation (the attachment of an ionized group to the drug) and includes glucuronidation, acetylation, or sulfation. Conjugation reactions are usually unchanged in old age as the activities of glutathione transferase and UDP glucuronosyltransferase are not altered (Le Couteur and McLean, 1998). Therefore, no dose adjustments are usually required on the basis of age alone. Examples of psychotropic drugs that undergo phase II metabolism include lorazepam, oxazepam, zaleplon, and valproate (Hutchison and O'Brien, 2007). Studies have highlighted, however, that glucuronidation is affected by frailty, with frail older people having significantly reduced metabolic capacity in the formation of conjugated metabolites (McLachlan and Pont, 2012; Hilmer et al., 2005).

Excretion

The ageing process gives rise to important modifications in kidney structure and function. Older people tend to have a reduction in renal mass, renal blood flow, glomerular filtration rate (GFR), filtration fraction, and tubular secretion. At a microscopic level, the ageing kidney is characterized by increased fibrosis, tubular atrophy, and arteriosclerosis. A decrease of about 10% per decade in glomerular filtration rate can generally be expected. A measured creatinine clearance is used as a surrogate for GFR, but can be inaccurate because of the many problems

associated with a 24-hour urine collection, as well as the costs involved. The use of serum creatinine level on its own may lead to misleading estimates of renal function because the daily production of creatinine may be significantly reduced in older people as a result of decreased muscle mass, reduced exercise, and dietary meat intake. Thus, the serum creatinine may remain within the normal range despite a reduction in creatinine clearance (Hutchison and O'Brien, 2007; Corsonello et al., 2010). For these reasons, equations for estimated GFR (eGFR) were developed (Garasto et al., 2014).

The Cockcroft and Gault equation estimates the creatinine clearance which in turn estimates GFR in ml/min. The formula was originally published as (Cockcroft and Gault, 1976):

$$\text{CrCl (ml/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times (0.85 \text{ in women})}{72 \times \text{Serum creatinine (mg/dL)}}$$

When serum creatinine is measured in $\mu\text{mol/L}$:

$$\text{CrCl (ml/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)} \times \text{Constant}}{\text{Serum creatinine } (\mu\text{mol/L})}$$

where *Constant* is 1.23 for men and 1.04 for women. Ideal body weight should be used for patients with extremes of body weight.

One interesting feature of the Cockcroft and Gault equation is that it shows how dependent the estimation of creatinine clearance is based on age.

Various other equations for estimating GFR have been developed, for instance, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula, which is the now-preferred one for assessing renal function in kidney disease (NICE CG182). However, when calculating drug doses, the estimated creatinine clearance from the Cockcroft and Gault equation should be used.

Age-related changes in pharmacodynamics

Pharmacodynamics is the branch of pharmacology concerned with the biochemical and physiological effects of drugs at their site of action. It relates to the concentrations of drug at the receptor site, the interaction between the drug and its receptor, and the homeostatic regulation. Several patient specific factors, e.g. age, gender, ethnicity, genetics, and disease, are all known to influence pharmacodynamics (Bowie and Slattum, 2007; Corsonello et al., 2010).

In general, apart from its concentration at the site of action, the magnitude of a drug's effects also depends on the number of receptors at the target organ, the ability of the cells to respond to receptor occupation (signal transduction), and the counter-regulatory processes that tend to preserve the original functional equilibrium. An increase in drug

sensitivity is assumed when the response to a given serum concentration is enhanced. Age-related changes in pharmacodynamics can occur at any level: the receptor level, signal transduction level, or from the changes in homeostatic mechanisms (Turnheim, 2003).

While pharmacokinetic modifications associated with age are, to some extent, predictable (due to known changes in body composition and function), the convoluted and multiform interaction between altered kinetic and reduced homeostatic response make pharmacodynamic changes with age a very complex process. As a result, there are no set rules to help guide clinicians in this area, and the age-related changes in the pharmacodynamics of a drug must be considered separately for each individual drug (Corsonello et al., 2010).

The central nervous system (CNS) is a particularly vulnerable drug target in older people, since ageing causes neuronal loss in several brain regions and a reduction in brain weight (Turnheim, 2003). As a result, older people are very sensitive to the adverse effects of psychotropic drugs, especially delirium, arrhythmias, and postural hypotension. The number of dopaminergic neurons and dopamine D₂ receptors decreases in older people, leading to extrapyramidal symptoms with antipsychotic drugs when a certain threshold of neuronal loss is reached. The number of cholinergic receptors and neurons is also decreased, which is thought to affect cognitive function. In addition, although the exact mechanism for this is unknown, benzodiazepines induce sedation, ataxia, and confusion at lower doses and plasma concentrations in older adults than in younger people. This is possibly due to age-dependant changes identified in the GABA_A-benzodiazepine receptor complex. Benzodiazepines can also cause short-term memory impairment and contribute to cognitive disturbances in this population (Mangoni and Jackson, 2003; Turnheim, 2003).

Since homeostatic mechanisms are reduced in old age, when a pharmacological disruption of a physiological function occurs, more time is required to regain the original steady state because the counter-regulatory measures are diminished. Thus, despite the reduction in receptor numbers and responsiveness, drug effects are attenuated less in older people, the reactions may be stronger, and the incidence of adverse effects is higher when compared to young people. Examples include drug-induced postural hypotension that can lead to syncope and falls (Turnheim, 2003).

The potential for adverse effects in older people is also increased with anti-epileptic drugs where cognitive impairment and haematological toxicity are observed. In addition, although usually irrelevant in the young, cardiac effects of phenytoin or carbamazepine may be life threatening in older patients. Similarly, tricyclic antidepressants and antipsychotic drugs such as haloperidol may have adverse cardiac effects, e.g. prolongation of QT interval, and cause life-threatening ventricular tachyarrhythmia (torsade de pointe) (Turnheim, 2003).

The blood-brain barrier (BBB)

The structure of the blood brain barrier (BBB) comprises endothelial cells with tight junctions in a collagen matrix allowing only small, lipid-soluble, unpolarized molecules to pass from capillary blood to brain tissue. Thus, molecular size, lipophilicity, and polarity are all factors influencing the extent to which substances can penetrate the CNS under normal conditions. Several conditions, however, can increase the permeability of the BBB, including increasing age, comorbid disorders such as diabetes, Parkinson's disease, and Alzheimer's disease, certain medicines, trauma, and stress (Abbott et al., 2010; Esposito et al., 2001). As a result, the blood brain barrier can become 'leaky', allowing compounds through that would not normally be able to penetrate the CNS. A mechanism known to reduce CNS exposure involves permeability-glycoprotein (P-gp), an active CNS efflux transporter that can actively pump agents moving across the BBB from the cerebral vasculature back into the systemic circulation. Drugs that are recognized by P-gp are referred to as P-gp substrates (van Assema et al., 2012). Nevertheless, age-associated decline in P-gp function also occurs, facilitating the accumulation of toxic substances in the brain and thus increasing the risk of neurodegenerative pathology and exposing the brain of older individuals to excessive levels of drugs (Corsonello et al., 2010). More research into age-related changes in the BBB is required to determine whether the alterations in BBB integrity in older people contributes to the enhanced sensitivity to many psychotropic drugs (including benzodiazepines) experienced in this population (Zeevi et al., 2010).

Adverse drug reactions (ADR)

The prevalence of adverse drug reactions (ADRs) increases with age, with twice as many patients aged 65 years and older being admitted to hospital because of ADR-related problems compared with their younger counterparts. More than 50% of these admissions are preventable (Lavan and Gallagher, 2016). It has been suggested that rather than being an independent risk factor, age may simply be a marker for comorbidities, altered pharmacokinetics, and polypharmacy, all of which increase the risk of ADRs (Hilmer et al., 2005).

ADRs are difficult to recognize in older people as they often present with non-specific symptoms such as falls, cognitive impairment, or constipation, all of which have several aetiologies. The risk of falls is increased by certain chronic conditions such as osteoarthritis, visual impairment, and myopathy, but several medications, including antipsychotics and benzodiazepines, can also independently increase the risk of falls. This can make it very difficult to identify the precise cause of a fall. Nevertheless, potential ADRs should be part of every differential diagnosis in older patients. Failure to recognize an ADR can result in a prescribing cascade whereby a new drug is prescribed to treat the adverse effect of the culprit drug, thus exposing the individual to continued and increased risk of ADRs (Lavan and Gallagher, 2016).

Examples of such practice include the prescribing of an anticholinergic drug to treat extrapyramidal symptoms caused by antipsychotic drugs, or urinary frequency caused by acetylcholinesterase inhibitors.

Anticholinergic drugs in turn can cause cognitive impairment, delirium, blurred vision, constipation, and so on (see Fig. 13.1).

Fig. 13.1

Example of prescribing cascade in older people.

Polypharmacy

Polypharmacy, commonly defined as the use of multiple drugs, or more than are clinically indicated, is strongly predictive of ADRs (Lavan and Gallagher, 2016). Polypharmacy increases the risk of adverse events as a result of both the cumulative effect of ADRs to each drug and drug-drug interactions. Many predictable drug-drug interactions occur through the induction or inhibition of cytochrome p450 pathways of hepatic metabolism (Hilmer et al., 2005). Polypharmacy is common in older people due to the number of comorbidities that occur with increased age. Clinicians are often not aware of all the drugs their elderly patients are taking. Patients might receive prescriptions from several different clinicians and could potentially take them to be filled at different pharmacies. In addition, older people are more likely to be buying over-the-counter products for minor ailments. Mallet and colleagues showed that the risk of receiving inappropriate drug combinations is directly related to the number of clinicians prescribing drugs for an elderly patient (Mallet et al., 2007).

Drug-drug interactions

A drug-drug interaction can be defined as the effect that one drug has on another drug. Drug-drug interactions can be either pharmacokinetic or pharmacodynamic in nature. Pharmacokinetic drug interactions involve the effects of one drug on the absorption, distribution, metabolism, or excretion of another drug. These interactions can result in changes in serum drug concentrations and might therefore change the clinical response. The most frequent pharmacokinetic drug interactions involve several isoenzymes of the hepatic cytochrome P450 (CYP) and drug transporters such as the P-glycoprotein and organic anion transporters. Drugs that are substrates, inhibitors, or inducers of CYP450 isoenzymes (e.g. CYP3A4, CYP2D6) are frequently involved in drug-drug interactions (Mallet et al., 2007) (see Table 13.2).

Table 13.2 Psychotropic drugs and their impact on the cytochrome P450 system.

Psychopharmacology

Substrates		Inhibitors		inducers
CYP1A2				
agomelatine amitriptyline* asenapine bupropion* chlorpromazine clomipramine* clozapine duloxetine fluphenazine	fluvoxamine imipramine* melatonin mirtazapine* olanzapine perphenazine ?pimozide* zolpidem*	fluvoxamine moclobemide perphenazine		'barbiturates' carbamazepine modafinil* phenobarbital phenytoin
CYP2A6				
bupropion*		tranylcypromine		phenobarbital
CPY2B6				
bupropion methadone* nicotine sertraline*		fluoxetine* fluvoxamine memantine paroxetine* sertraline*		carbamazepine* modafinil* phenobarbital phenytoin
CYP2B7				

Psychopharmacology

Drugs highlighted in **bold** indicate:

- predominant metabolic enzyme pathway or;
- predominant enzyme activity (inhibition or induction).

Drugs annotated with * indicate:

- known to be a minor metabolic enzyme pathway or activity (i.e. not demonstrated to be clinically significant).

Drugs in normal font (not bold and without *) indicate:

- metabolic enzyme pathway(s) or activity where significance is unclear or unknown

NB: Information on CYP function derived from individual SPCs and US Labelling (accessed November 2017).

The table does not include details of the effects of non-psychotropic drugs on CYP function. Reproduced with permission from The Maudsley Prescribing Guidelines in Psychiatry 2018. Taylor, Barnes & Young, 13th edition.

As well as the effect of co-administered drugs on CYP function, genetic polymorphisms associated with some enzyme pathways (e.g. 2D6, 2C9, 2C19 enzymes) may also account for the inter-individual variations in the metabolism of certain drugs. The effects of polymorphism and pharmacokinetic interaction are difficult to predict because some drugs are metabolized by more than one enzyme and so an alternative pathway may compensate when one enzyme pathway is inhibited (Taylor et al., 2018).

The P-glycoprotein (P-gp) is a drug transporter protein found in the gut wall and in the BBB. P-gp can eject (active process) drugs that diffuse (passive process) across the gut wall. Drugs that inhibit P-gp are therefore expected to increase the uptake of other drugs (that are substrates for P-gp) and drugs that induce P-gp are expected to reduce the uptake of drugs (that are substrates for P-gp). Many drugs that are substrates for CYP3A4 have also been found to be substrates for P-gp (Taylor et al., 2018).

Pharmacodynamic drug interactions relate to the pharmacological activity of interacting drugs. The outcome is an enhancement or reduction in the therapeutic effects or side-effects of a specific drug by another (Mallet et al., 2007). An example of a pharmacodynamic drug interaction causing an enhancement in effects includes the addition of a benzodiazepine to an antipsychotic drug regime, producing excessive sedation. Conversely, an example of a pharmacodynamic drug interaction causing a reduction in therapeutic effect includes the addition of an anticholinergic drug such as oxybutynin used for urinary frequency to an acetylcholinesterase inhibitor for example donepezil. The anticholinergic drug will negate the effects of donepezil.

Stopping medications can also be associated with adverse drug effects related to withdrawal of the drug, recurrence of the underlying condition, or alterations in pharmacokinetics and pharmacodynamics of the patient's other medications (Hilmer et al., 2005).

Medication adherence in older people

Medication adherence is crucial when treating chronic conditions. Therefore, it is even more so when treating older people. Adherence to medication has always been a major issue in healthcare but more so in the elderly population. Reasons for poor adherence are multifactorial and can be classified into patient factors, medication factors, health care provider or system factors, and socioeconomic factors. Examples of patient factors affecting adherence include poor memory or cognitive deficits, depression, poor dexterity, and visual or hearing impairment. Medication factors include aspects of packaging and formulation, e.g. patients may be unable to open a container or swallow large tablets, or may have to manage complicated drug regimens. Healthcare provider or system factors include poor communication, lack of patient involvement,

lack of patient education or follow up, and socioeconomic factors involve the lack of caregivers or caregiver's burden (Yap et al., 2016).

Establishing preceding adherence upon admission to hospital is crucial in order to prevent the occurrence of ADRs. If poor adherence is not identified and medication is given as prescribed (or dose is increased due to the false assumption of lack of efficacy), patients will be at risk of ADRs, particularly older patients. An important example of this in psychiatry is lamotrigine, where dose titration should be repeated after an interval of more than five days—otherwise serious skin reactions can occur.

Antipsychotic use in older people with dementia

For many years, it has been common practice to use antipsychotic drugs in older people with dementia to manage behavioural and psychological symptoms. However, in the last decade, antipsychotics have been associated with an increased risk of stroke and mortality in this population. The increased risk exists with all antipsychotic drugs, both typical and atypical. While the exact mechanisms for this are still unknown, several theories exist. It is thought that orthostatic hypotension may potentially aggravate the deficit in cerebral perfusion in an individual with cerebrovascular insufficiency or atherosclerosis, thus causing a stroke. Tachycardia may also decrease cerebral perfusion or dislodge a thrombus in a patient with atrial fibrillation. There could be a rebound excess of catecholamines with vasoconstriction after an episode of orthostatic hypotension, thus aggravating cerebral insufficiency. In addition, hyperprolactinaemia could (in theory) accelerate atherosclerosis, in turn increasing the risk of a stroke. Sedation, often experienced in medicated older people, might cause dehydration and then haemoconcentration. Each of these factors are all possible mechanisms for the increased risk of cerebrovascular events in older people (Smith and Beier, 2004).

In view of this, antipsychotic drugs should not be used routinely to treat agitation and aggression in people with dementia (Corbett et al., 2014). Risperidone is the only drug licensed in the UK for the management of non-cognitive symptoms associated with dementia and is therefore the agent of choice. It is specifically indicated for short-term treatment (up to six weeks) of persistent aggression in patients with moderate to severe Alzheimer's disease who are unresponsive to non-pharmacological approaches and when there is a risk of harm to self or others. Risperidone is licensed up to 1mg twice a day, although optimal dose in dementia has been found to be 500mcg twice a day (1mg daily) (BNF, Jan 2018).

Alternative antipsychotic drugs may be used (off-licence) if risperidone is contraindicated or not tolerated, but antipsychotics, in general, should only be prescribed in dementia after careful risk assessment, balancing the cerebrovascular risk (taking into account hypertension, diabetes, smoking, atrial fibrillation, and previous stroke), discussion of possible

risks and benefits with carer (and patient if she/he has capacity), and clear documentation of the above (Corbett et al., 2014).

Anticholinergic drugs and cognitive impairment

Older people with dementia are more susceptible to cognitive side effects of drugs. Drugs may affect cognition through their action on cholinergic, histaminergic, or opioid neurotransmitter pathways or through more complex actions. While anticholinergic drugs have been known to cause adverse effects, e.g. confusion, disorientation, hallucinations, and delirium, in older people, more recently, long-term use of these agents has also been associated with an increased risk of cognitive decline, dementia, and death (Carriere et al., 2009; Fox et al., 2011). In addition, anticholinergic drugs have been shown to directly oppose the action of acetylcholinesterase inhibitors used in dementia, thus reducing or negating any therapeutic effects. Nevertheless, studies have frequently shown that up to half of patients with dementia who are prescribed cholinesterase inhibitors are also taking drugs with anticholinergic activity (Carnahan et al., 2004).

Some drugs such as amitriptyline, clozapine, or promethazine are widely known to have anticholinergic properties, whereas other drugs are less likely to be associated with these effects (e.g. olanzapine, quetiapine, and citalopram). Cognitive impairment, particularly memory dysfunction, results from antagonism of M_1 and to a lesser extent M_2 or M_4 muscarinic receptors, which are particularly abundant in the CNS and are thought to mediate cholinergic effects on cognition. For an anticholinergic drug to significantly affect cognition, it not only needs to act on these specific muscarinic receptors, but also needs to be able to penetrate the BBB. In order to identify those drugs that have anticholinergic effects on cognition and those that are safe in patients with dementia, the anticholinergic effect on cognition (AEC) scale was developed and can be accessed on the web-based application Medicheck (<http://www.medicheck.com/>) (Bishara et al., 2017).

Research in older adults

Information on drug safety in older people is sparse, making it difficult to predict their response to medications. Unfortunately, there is very little clinical trial evidence to guide prescribing in this population since elderly patients with comorbid conditions are frequently excluded from clinical trials (Van Spall et al., 2007). As a result, the evidence coming from these studies may not be applicable to older people. Similarly, clinical practice guidelines may also be biased as they are frequently based on the evidence coming from these clinical trials and older people are a very heterogeneous group. In addition, randomized trials are usually not powered to detect safety-related outcomes and therefore only data from observational studies are usually available (Corsonello et al., 2010).

Conclusion

Older people are particularly susceptible to adverse effects of drugs because of the age-associated changes that occur in pharmacokinetic and pharmacodynamic properties, the large number of drugs used in this population, and the increased risk of comorbid diseases.

When considering the effect of ageing on drug disposition and metabolism in older people, confounding factors such as frailty, comorbidities resulting in the possibility of drug-disease interactions and in the case of polypharmacy drug-drug interactions, impairments in organ function and homeostasis, as well as problems with adherence due to reduced dexterity and memory problems all have to be considered. It is important to recognize the heterogeneity of drug response in this group.

While there are no simple rules for prescribing that can be applied to the entire elderly population, it is important to consider some kind of dosage reductions may be required, as well as careful dosing, slow titration, and monitoring of drug action. The general slogan 'start low and go slow' is often used. Only one new medication should be commenced at any one time so that clinicians are able to recognize potential ADRs more easily. Patients and carers should receive clear and concise information about new medicines, including any potential side effects (Merel and Douglas, 2017) and the time frame in which they are most likely to occur. Clinicians should refrain from treating every symptom with a new drug, particularly since the symptoms in question may be due to an adverse effect of a current medication.

Since very little clinical trial evidence exists for older people, it is very difficult to guide prescribing in this area. Clinical decisions must therefore be made for each individual with vigilant monitoring for efficacy and ADRs.

Neurostimulation therapies

Chapter: Neurostimulation therapies

Author(s): Daniel W. O'Connor, Christos Plakiotis, and Peter Farnbach

DOI: 10.1093/med/9780198807292.003.0014

Electroconvulsive therapy (ECT), transcranial magnetic stimulation (TMS), and deep brain stimulation (DBS) all entail the delivery of electrical energy, either episodically or continuously, to the brain with the object of relieving mental or neurological symptoms. This chapter discusses their indications, application, effectiveness, and safety with respect to depression, and other psychiatric conditions. Because the latter two treatments are relatively novel, the bulk of this chapter is devoted to electroconvulsive therapy.

Electroconvulsive therapy (ECT)

ECT is an effective treatment of severe depression, mania, catatonia, and some cases of schizophrenia. It is important, therefore, that old age psychiatrists have a good understanding of its uses, benefits, and risks. Most researchers have failed to distinguish between older and younger patients in their reports and so much of the evidence presented in this

Neurostimulation therapies

chapter is generic in nature and readers must apply the information as best they can to their own practice.

ECT has a multiplicity of actions on the brain. It potentiates the effects of serotonin, noradrenaline, and dopamine; stimulates neurogenesis in animal studies, and blunts pathological hyper-connectivity within cortical and cortico-limbic circuits (Bolwig, 2014; McCall et al., 2014).

Patterns of use

ECT declined in use in most countries from the 1970s onwards, due to the advent of effective antidepressant and antipsychotic medications and to its depiction in popular media as a tool to control aberrant behaviour. Few countries or regions publish complete datasets, but, judging from the number of research publications, ECT and other brain stimulation therapies are in the ascendancy.

ECT is prescribed more per capita to older people than younger ones in Australia (Plakiotis et al., 2012), Denmark (Hundrup et al., 2017), Scotland (NHS National Services Scotland, 2017), the US (Case et al., 2013), and probably most other countries. In Victoria, Australia, where data from all public and private hospitals are collated systematically, applications rose steeply with age until 85 years (Plakiotis et al., 2012) (Fig. 14.1). Likely reasons include an age-related intolerance of antidepressant and antipsychotic medications coupled with an increase with age in depressive psychomotor retardation and psychosis, both of which predict a good response to ECT. It might also reflect a view by psychiatrists that severely depressed old people benefit more from medically oriented therapies. It is conceivable, therefore, that treatment patterns will change yet again now that medications are safer and the role of psychotherapy is expanding.

Neurostimulation therapies

Does ECT work?

Depression

A series of randomized controlled trials (RCTs) in the 1970s and 1980s established that real ECT was superior to sham ‘treatments’ which entailed an anaesthetic but no electrical stimulation. In a meta-analysis of these studies, depressed patients given real ECT improved faster and scored 9.7 fewer points on the 64-point Hamilton Depression Rating Scale (HDRS) two to four weeks later (UK ECT Review Group, 2003).

ECT also proved superior to a range of older and newer antidepressants over periods of 3–12 weeks in all but two of the 13 studies summarized by the UK ECT Review Group (2003). This difference in response translated to 5.2 fewer points on the HDRS. In one of the largest trials, 66% of patients given ECT had no or few symptoms after four weeks compared with 42% of those on imipramine 200 mg daily (Medical Research Council, 1965).

There are remarkably few RCTs of ECT versus other active treatments in older age groups (placebo controls would not be considered acceptable now for very ill people). In the absence of such evidence, naturalistic and between-trial comparisons have some value. In one such report, 78% of depressed people aged 55 years and over (mean age 73 years) had achieved remission (less than ten points on the Montgomery-Åsberg Depression Rating Scale) after a course of mostly unilateral, brief pulse

Neurostimulation therapies

ECT (Dols et al., 2017). In another report, 64% of older, severely depressed patients enrolled in a six-week trial of brief versus ultrabrief pulse ECT had achieved remission compared with 33% of similar patients enrolled in a 12-week trial of two antidepressants (Spaans et al., 2015).

Response predictors

Older patients responded better to ECT than younger ones in some studies (Wilkinson et al., 1993; O'Connor et al., 2001) but not in others (Hickie et al., 1996; Birkenhäger et al., 2010). Depressive psychosis and melancholia, as reflected by objective signs of psychomotor agitation and retardation, have strong predictive capacity. In one trial, 75% of patients with psychosis were rated as early responders compared with 22% of those without such symptoms (Spaans et al., 2016). In another trial, the combination of psychotic symptoms with observable psychomotor change was especially potent. Deluded-retarded cases lost 34.7 points on the HDRS in contrast to 16.2 in the retarded, non-deluded group and 10.7 in the non-retarded, non-deluded group (Buchan et al., 1992).

Certain factors reduce, but do not preclude, the likelihood of responding to ECT. These include chronicity and resistance to antidepressant medications (Dombrowski et al., 2005); subcortical hyperintensities (Steffens et al., 2001); medial temporal lobe atrophy (Oudega et al., 2011); and personality disorder (Rasmussen, 2015). Alcohol abuse seemed not to impact on responsiveness in one chart review study (Moss and Vaidya, 2014).

Schizophrenia, mania, and catatonia

All major clinical guidelines accept acute schizophrenia, schizoaffective disorder, mania, and catatonia as possible indications for ECT (American Psychiatric Association, 2001; Royal College of Psychiatrists, 2005; Royal Australian and New Zealand College of Psychiatrists, 2007). Studies and case reports concerning older people with these conditions have been reviewed by Liu and colleagues (2014).

The use of ECT in acute schizophrenia plummeted once antipsychotic medications became available in the 1950s. ECT works a little faster than antipsychotics and is just as effective in reducing psychotic symptoms (Abraham and Kulhara, 1987), but medications are simpler to administer on a long-term basis and are preferred by most patients. Despite recent advances, there remain patients who do not respond to medications, cannot tolerate them, or require urgent intervention to preserve life. In an RCT, 50% of clozapine-resistant patients given ECT showed a 40% or greater reduction in scores on the Clinical Global Impressions scale compared with none in the clozapine only group (Petrides et al., 2015). Old age need not be a barrier to recovery. Kramer (1999) described five women aged 58–74 years whose florid schizophrenia or schizoaffective disorders improved dramatically with ECT.

Neurostimulation therapies

In cases of mania, ECT performs as well or better than standard pharmacotherapy (Loo et al., 2011; Versiani et al., 2011). There is little information regarding older patients specifically, but clinical experience suggests that those who cannot tolerate antipsychotic or mood stabilizing medications, or are so manic that they look to be delirious, respond better to ECT. Only small numbers of treatments may be required, even in life-threatening cases of 'delirious mania' (Karmacharya et al., 2008).

Catatonia is now uncommon, but it arises occasionally in schizophrenia, depression, mania, and organic conditions including brain tumour, head trauma, stroke, encephalitis, and metabolic disturbance with any or all of the following signs: mutism, negativism, echolalia, echopraxia, muscle rigidity, posturing, and waxy flexibility. Its severest form, lethal catatonia, is associated with extreme agitation, stupor, fever, sweating, and autonomic instability, leading to dehydration, exhaustion, and death if left untreated. It must be distinguished from neuroleptic malignant syndrome and malignant hyperthermia by means of a reliable medication history. ECT proved effective in 60% of cases after an average of 15 treatments (van Waarde et al., 2010), though maintenance therapy may be required to prevent relapse (Wilkins et al., 2008).

Dementia and other organic mental disorders

ECT is an option when severe depression overlaid on dementia fails to respond to antidepressant medication. Published reports are favourable with improvement rates, however defined, of up to 80% in cases of depression comorbid with Alzheimer's disease, vascular dementia, Lewy body dementia, and frontotemporal dementia (Price and McAllister, 1989; Rao and Lyketsos, 2000; Rasmussen et al., 2003). These reports take the form of small, retrospective case series that are subject to bias: positive reports are more likely to be published than negative ones. To counter this, Nelson and Rosenberg (1991) compared 21 consecutive patients with dementia and comorbid major depression with 84 similarly aged people without dementia. The group with dementia derived almost as much benefit from ECT. While confusion post-ECT was more common and correlated with the degree of dementia, mini-mental state examination (MMSE) scores actually improved on average by 1.6 points. Confusion complicated ECT in half the cases described by Rao and Lyketsos (2000) but it lasted only a few days and treatments continued uneventfully. In one of the few reports to provide follow-up data, relapse rates were high (Rasmussen et al., 2003). With respect to mania in dementia, McDonald and Thompson (2001) described two patients who responded well to ECT in the short term but required ongoing treatment to hold symptoms at bay.

ECT is not a standard treatment of the behavioural symptoms of dementia, e.g. screaming and aggression, that arise in mid- to late-stage dementia, except where patients have comorbid depression and fail to respond to antidepressant medication. Notwithstanding this, 17 case reports with a total of 122 patients described improvement in the

Neurostimulation therapies

majority. Adverse effects where present were mostly mild and transient (van den Berg, 2017). In a single prospective series of 23 patients with dementia complicated by agitation or aggression non-responsive to pharmacotherapy, ECT (mostly unilateral) was associated with significant reductions in agitation scores. Where cognitive testing was possible, scores usually improved. Two people failed to respond to treatment and two developed delirium, in part due to unrelated conditions (Acharya et al., 2015). ECT has been delivered safely and effectively to patients with mental disorders secondary to stroke (Currier et al., 1992), Huntington's disease (Ranen et al., 1994), head injury (Kant et al., 1999), and intellectual disability (van Waarde et al., 2001), though relapse rates tend to be high.

Other conditions

ECT can improve tremor, rigidity, bradykinesia, and gait in Parkinson's disease for periods of several weeks, but is rarely used for this indication (Kennedy et al., 2003). It is of greater benefit in neuroleptic malignant syndrome, a condition that overlaps in form with catatonia and is precipitated by antipsychotic medication. Patients who fail to respond to supportive therapy, benzodiazepines, and dopamine agonists, or whose lives are in danger, may benefit from a brief course of ECT. Care is required, however, since patients are often medically unstable (Troller and Sachdev, 1999).

Relapse and maintenance therapy

Relapse is common in the period following ECT. In a study by Sackeim and colleagues (2001), patients whose major depression remitted successfully with ECT were randomly assigned to receive placebo, nortriptyline, or a combination of nortriptyline and lithium carbonate. Over the ensuing 24 weeks, 84% of those on no continuing medication had relapsed, compared with 60% in the nortriptyline group and 39% of those on combination therapy. Relapse was more common in cases resistant to pharmacotherapy. In a naturalistic outcome study, relapse rates were also higher in cases of psychotic depression (31% versus 22%), comorbid psychiatric disorder (43% versus 27%), and personality disorder (23% versus 14%). Relapses were most frequent within two weeks of follow-up (Prudic et al., 2004).

It is now standard practice to introduce an antidepressant medication, either alone or together with an antipsychotic or mood stabilizer, during the ECT course or soon afterwards (Haskett and Loo, 2010). Where medications are known to be ineffective or unsafe, continuation or maintenance ECT is an option. Continuation therapy (C-ECT) follows directly from an acute course of ECT with the object of preventing relapse. Treatment intervals are typically stretched from weekly to monthly depending on progress. Maintenance ECT (M-ECT) refers arbitrarily to treatments extending beyond six months, and occasionally for years, where the risk of relapse is known to be high. Intervals

Neurostimulation therapies

between treatments are typically extended until breakthrough symptoms provide clues to the optimal schedule. In an RCT of continuation ECT plus an antidepressant and lithium carbonate versus pharmacotherapy alone, 13% of ECT recipients had relapsed within 24 weeks compared with 20% in the medication only group (Kellner et al., 2016). Outcomes look more promising in longer-term studies. In a retrospective chart review of 58 aged patients with severe, medication-resistant depression or psychosis, hospital readmissions fell by 53% in number and 79% in duration in the two years after M-ECT started compared with the previous two years (O'Connor et al., 2010c). Within the actual M-ECT treatment periods, which varied widely, admissions fell by 90% in number and 97% in duration compared with the same period earlier. Similar findings emerged in earlier reviews of adult patients (Petrides et al., 2011). M-ECT has also been used to limit relapse in bipolar disorder and schizophrenia (Vanelle et al., 1994; Chanpattana et al., 1999).

M-ECT looks to be safe and there is no evidence of progressive cognitive impairment (Rami et al., 2004), even in a patient who received 430 treatments over an eight-year period (Barnes et al., 1997).

Since M-ECT is usually delivered on an outpatient basis, patients must be cooperative, medically stable, and conversant with practical requirements. Processes must also be in place to conduct physical and mental state checks at predetermined intervals, to gauge the intervals between treatments, and to decide when treatment ends (O'Connor et al., 2010b).

Treatment

Anaesthesia

The ideal ECT anaesthetic induction agent ensures rapid, painless unconsciousness, an adequate seizure, and speedy recovery with minimal post-treatment confusion. Methohexital has a rapid onset, short duration of action, and no anticonvulsant properties. By contrast, propofol is sometimes painful on injection and raises seizure thresholds. Its major advantage is that pulse rate, blood pressure, and heart rhythm are more stable (Hooten and Rasmussen, 2008). If seizure threshold is unusually high, or rises steeply as treatment proceeds, or seizure quality is uniformly poor, reducing the dose of propofol may prove helpful, for example, by using augmenting agents like alfentanil or remifentanil (Loo et al., 2010). Other induction agents include etomidate, ketamine, and sevoflurane (Bryson et al., 2017).

Muscle relaxants like succinylcholine virtually eliminate the risk of fractures during ECT, though two cases of vertebral compression fractures were reported by Mulsant and colleagues (1991) in patients known to be osteoporotic. Doses of relaxant can be increased if desired in these situations. Anticholinergics (usually atropine or glycopyrrolate) may be administered just prior to treatment to reduce salivation and

Neurostimulation therapies

bradycardia, but only in selected cases given the risks of tachycardia and myocardial ischaemia due to unopposed sympathetic activity (Jadhav et al., 2017).

Seizure threshold

Tonic-clonic seizures are critical to ECT's success (Cronholm and Ottoson, 1960) and the electrical charge must therefore exceed seizure threshold to ensure that a convulsion ensues. Thresholds can vary tenfold or more between patients but lie mostly between 10 and 150 millicoulombs (mC) (Gálvez et al., 2015). Increasing age, male gender, bilateral electrode placement, and propofol anaesthesia all predict higher initial thresholds (Sackeim et al., 1987; Gálvez et al., 2015). Men prescribed bilateral ECT will therefore have higher mean thresholds than women prescribed unilateral ECT.

Electrical charge is not critical in itself. What matters more is that energy levels exceed the threshold by a defined amount. Bilateral ECT is effective at, or just above, seizure threshold. However, unilateral ECT is not, as shown in a critical study by Sackeim and colleagues (2000), in which 'low dose' unilateral treatment (50% above threshold) was much less effective than 'high dose' unilateral treatment (500% above threshold). 'Moderate dose' ECT (150% above threshold) occupied an intermediate position. 'High dose' unilateral ECT worked almost as well as bilateral ECT (50% above threshold) in lifting depressive symptoms.

Stimulus dosing

In former times, the same electrical dose was given to every patient. There is no place for this now: treatments are individualized to maximize efficacy and reduce side effects. There is debate, however, about how best to achieve this. One approach, called stimulus dose titration, entails giving one or more stimulations in the first session to ascertain threshold. A widely used protocol recommends that, for women receiving unilateral ECT, electrical charge is delivered at 32 mC, 48 mC, and then 80 mC until a convulsion is provoked. Once threshold is established, a therapeutic stimulus is delivered at between three times and six times this level (Royal College of Psychiatrists, 1995; American Psychiatric Association, 2001; Mahli et al., 2015). For bilateral ECT, the 'multiplier' is typically one and a half times threshold.

In experienced hands, stimulus titration takes just a few minutes to complete. Inexpert clinicians are less sure-handed, resulting in longer anaesthetics and slower recovery. In earlier decades, repeated subconvulsive stimulations precipitated cardiac arrhythmias but this is rarely seen now. In addition, there is also no evidence that subconvulsive stimulations cause more cognitive impairment (McCall et al., 1994; Prudic et al., 1994).

Neurostimulation therapies

Age-based dosing strategies are simpler, faster, and possibly safer for very old, frail patients. According to one formula for unilateral ECT, doses for patients aged 60, 70, and 80 years are about 300 mC, 350 mC, and 400 mC, respectively. Doses for bilateral ECT are half these. According to Tiller and Ingram (2006), age-based dosing led to only 2% of their women patients and 7% of men receiving subtherapeutic doses. Against this, doses would have been too high, at seven or more times threshold, for 30% of women and 8% of men. In addition, if treatment is not progressing well, it is harder to take sensible corrective action if threshold is not known. It is advisable therefore to establish threshold, unless there are good reasons not to do so.

Seizure monitoring

Threshold levels tend to rise as treatment progresses, more for bilateral than unilateral ECT, and electrical charge must be increased to keep pace if this happens (Sackeim et al., 1987). It is not practicable to recheck patients' thresholds week after week. Instead, clinicians make judgments based on EEG monitoring of seizure duration and morphology. This is an imprecise science. ECT machines now produce measures of seizure duration, amplitude, interhemispheric synchronicity and post-seizure electrical suppression, but none of this information can be interpreted exactly.

Greater seizure intensity, regularity and post-seizure suppression correlate with better outcomes (Plakiotis and O'Connor, 2011), but what is cause and what is effect is unclear: patients who respond well to ECT may possess this sort of profile from the outset (Nobler et al., 1993; Perera et al., 2004). A good 'electrical picture' might therefore predict recovery, not cause it. To complicate matters, older people typically have shorter, weaker, and less synchronous seizures, irrespective of clinical outcome, and their thresholds rise faster as treatment progresses (Nobler et al., 1993). In the absence of clear evidence, it seems reasonable to increase electrical charge by 50 mC at a step if seizures become obviously shorter and weaker.

Treatment variants

Efforts continue to boost treatment efficacy while minimizing adverse effects. One alternative to the standard bitemporal electrode placement is bifrontal ECT in which the electrodes are placed 3–5 cm above the outer angle of both orbits. In a recent trial, bitemporal ECT worked a little faster, but the two placements were otherwise indistinguishable (Dunne and McLoughlin, 2012).

In another approach, the standard electrical square wave stimulus is shortened from a pulse width of 0.5–2 milliseconds (ms) to an 'ultrabrief' pulse of 0.3 ms, with the object of depolarizing neurons and stimulating seizures at lower electrical doses. Unilateral ultrabrief pulse ECT is effective and associated with significantly fewer cognitive sequelae than

Neurostimulation therapies

standard brief pulse unilateral ECT (Sackeim et al., 2008), but response is a little slower and more treatments are required (Tor et al., 2015). Counterintuitively, bilateral ultrabrief stimuli are strikingly less effective than unilateral ultrabrief stimuli (Sackeim et al., 2008). Ultrabrief pulse treatment has a place for older people with pre-existing cognitive impairment as well as those who became confused after previous courses or who fear post-treatment memory loss.

Some patients have very brief or low-amplitude seizures, and poor clinical outcomes, even at maximal electrical stimulation. Efforts to lengthen and optimize seizures have included hyperoxygenation and pre-treatment with oral or intravenous xanthine alkaloids (caffeine, theophylline, aminophylline). None of these strategies has been subject to rigorous study and xanthine alkaloids can lead to prolonged seizures, tachycardia, and cardiac arrhythmias (Loo et al., 2010).

With respect to frequency, ECT is traditionally administered three times a week, but twice weekly treatments are just as effective (Charlson et al., 2012), require no more treatments in total, and cause less cognitive impairment (Shapira et al., 1998). Barring life-threatening cases, there is no benefit in administering ECT more often.

Concomitant medications

Benzodiazepines raise seizure thresholds and should therefore be avoided, reduced, or stopped if possible but modest doses (e.g. lorazepam up to 3 mg daily) have little impact in reality (Boylan et al., 2000) and are permitted in most ECT research trials to lessen anxiety and agitation. Mood stabilizers that are also anticonvulsants (e.g. carbamazepine and valproate) should also be stopped if possible.

Medications with anticholinergic properties have been linked with worsened cognition post-ECT. Mondimore and colleagues (1983) found that eight of their 12 patients with high serum anticholinergic levels lost two or more points on the MMSE after a single ECT compared with only one of eight patients with lower anticholinergic levels. Tricyclic antidepressants, some antipsychotics, and even lithium carbonate all have discernible anticholinergic activity, as do some analgesics, antihistamines, and antispasmodics (Chew et al., 2008).

Lithium might be hazardous too when combined with ECT, given occasional reports of severe confusion, prolonged seizures, and catatonia, even with 'normal' blood levels (Sartorius et al., 2005). By way of confirmation, rates of confusion were higher at 22% in 27 patients given lithium and ECT concurrently, compared with 12% in those whose lithium was stopped just prior to ECT, and 6% in those with no exposure (Penney et al., 1990). Against this, Dolenc and Rasmussen (2005) cite reports in which lithium and ECT were combined safely. Though the risk of serious mishap is slight, lithium should be stopped if possible before starting ECT.

Neurostimulation therapies

Cardiovascular effects

During and immediately after electrical stimulation, an intense parasympathetic surge flows through the vagal nerve to the heart, resulting in a transient sinus bradycardia, with periods of asystole lasting for two seconds on average but occasionally for five seconds or more (Burd and Kettl, 1998). A sympathetic surge then follows, leading to an average rise in blood pressure of 55 mmHg, and in pulse rate of 37 beats per minute, together with clinically benign premature atrial and ventricular contractions. Rare complications at this time include acute myocardial infarction and ventricular fibrillation (Burd and Kettl, 1998). Pulse rates and blood pressure both rise more during bilateral than unilateral ECT, and more with higher than lower energy levels (Gangadhar et al., 2000). Cardiac function usually returns to normal within 15 minutes, but ST changes and arrhythmias (typically bursts of bigeminy or trigeminy) are a little more common than usual in the following 24 hours (Huuhka et al., 2003).

Safety

In an analysis of nearly a million treatments in 32 countries, the mortality rate associated with ECT was 2.1 per 100,000 treatments, with a decline in the last decade (Tørring et al., 2017), placing the risk at the bottom of the range for procedures requiring general anaesthesia (Watts et al., 2011). This is not because treatment is reserved for physically fit patients. ECT is given quite commonly to patients with serious medical comorbidities compounded by dehydration, inanition, and exhaustion secondary to depression or psychosis. It might actually be safer than psychotropic medications in such circumstances. In a chart review by Zielinski and colleagues (1993), 11 of 21 patients with cardiac disease were forced to discontinue treatment with tricyclic antidepressants because of cardiovascular complications compared with only two of 40 comparable patients given ECT. Similarly, cardiovascular and gastrointestinal (GI) complaints were more common in 39 very old, pharmacologically treated depressives compared with 39 carefully matched patients treated with ECT (Manly et al., 2000). There are risks, however, as the following sections make clear.

Aged patients are at higher risk of adverse events. In a report by Burke and colleagues (1987), 15% of patients aged 60 years and over experienced a cardiorespiratory complication (mostly changes in blood pressure) compared with 3% of younger patients, and 15% sustained a fall versus none in the younger group. Rates of post-ECT confusion were 18% and 13%, respectively. Altogether, 35% of older patients had a complication, but most were transient and settled spontaneously. Side effects also rose with age in a chart review by Alexopoulos and colleagues (1984). Cardiovascular complications arose in 19% of patients aged 65 years and over versus 1% of younger patients, and 14% had neurological complications (mostly confusion) compared with 12%. Apart from an 87-

Neurostimulation therapies

year-old man who died of a myocardial infarction 48 hours after his second treatment, most patients went on to complete their course.

Cattan and colleagues (1990) found that octogenarians had adverse events roughly twice as often as 'younger old' patients. Cardiovascular complications and falls were more frequent in very old patients than younger ones at 36% versus 12%, and 36% versus 14%, respectively. Confusion was the commonest problem, arising in 59% and 45% of the two groups. Outcomes were more benign in the patients aged 75 years and over described by Gormley and colleagues (1998), of whom 7% suffered prolonged confusion and 4% became manic. All problems resolved within two weeks. Similarly, Tomac and colleagues (1997) reported that 32% of the patients aged 85 years and over experienced prolonged confusion and 10% fell. One of the 34 patients sustained a fracture between treatments and six died of causes unrelated to ECT within 45 days after the last treatment, attesting to their very high rates of physical comorbidity.

Other uncommon side effects include dental injury, fractures secondary to falls (de Carle and Kohn, 2001), and vertebral compression fractures due to poorly modified seizures (Mulsant et al., 1991). Very rare sequelae include stroke (Bruce et al., 2006) and status epilepticus (Srzych and Turbott, 2000). Neurological asymmetries are common after ECT but generally resolve within 20 minutes (Kriss et al., 1978).

Prevention and management

Contraindications to ECT include recent myocardial infarction and stroke, severe valvular heart disease, clinically significant arrhythmias, unstable angina, uncompensated cardiac failure, and cardiac and arterial aneurysms, but these rules are not absolute. ECT has been applied safely and effectively in patients with recent myocardial infarction (Magid et al., 2005), cardiomyopathy (Adabag et al., 2008), aortic aneurysm (Mueller et al., 2009), pulmonary embolism (Suzuki et al., 2008), cerebral aneurysms and angiomas (Kang and Passmore, 2004), and a wide range of neurological conditions (Ducharme et al., 2015).

Examples of the strategies required to minimize risk in medically compromised patients are described by Tess and Smetana (2009). These include pre-treatment with atropine or glycopyrrolate to prevent bradycardia (though atropine may worsen post-ECT confusion); pre-treatment with betablockers to limit hypertension and tachycardia (though unopposed parasympathetic activity can worsen bradycardia); reductions in anticoagulant therapy for patients with an intracranial mass or aneurysm; and additional muscle relaxation for those with fractures or marked osteoporosis. A careful physical examination, ECG, measures of renal function, and discussions with medical and anaesthetic colleagues are vital. Other laboratory and imaging results add little extra information

Neurostimulation therapies

(Lafferty et al., 2001). Implanted cardiac pacemakers present no special risk (Dolenc et al., 2004).

Cognition

Objective changes

No evidence has emerged from numerous anatomical and imaging studies that ECT causes altered brain structure, neuronal death, or cerebral atrophy (Devanand et al., 1994; Ende et al., 2000). There is no doubt, however, that ECT can result in objective cognitive disruption. Patients are sometimes confused and disoriented on waking from anaesthesia. This typically lasts just for a few minutes but extends occasionally for hours and rarely for several days. Risk factors for emergent confusion include bilateral electrode placement (Sackeim et al., 1993); high electrical dose relative to threshold (Sackeim et al., 1993); a sinusoidal waveform (Daniel and Crovitz, 1986); advanced age (Tomic et al., 1997); pre-existing dementia (Rao and Lyketsos, 2000); and concomitant anticholinergic medications (Mondimore et al., 1983).

Most studies show some reduction in the acquisition and retention of new verbal and nonverbal material (anterograde memory) over the course of a treatment cycle. Improvement starts within a few days of treatment completion, more quickly for information acquisition than retention, and continues for up to six months. Recall of past events (retrograde memory) is also affected, especially for personal or autobiographical memories, and for recent events more than distant ones (Ingram et al., 2008). Autobiographical memory is difficult to measure in a standardized way and so the nature, extent, and duration of lapses is unclear. Knowledge of events in the days or weeks prior to treatment may never be recovered, extending in some cases to a more than a year beforehand (Ingram et al., 2008).

Risk factors for anterograde and retrograde amnesia include bilateral electrode placement (Sackeim et al., 2000), high electrical dose relative to threshold (Sackeim et al., 2000), advanced age (Zervas et al., 1993), and limited education (Legendre et al., 2003). Impaired cognition at baseline and prolonged disorientation after treatment are associated with a heightened risk of retrograde amnesia (Sobin et al., 1995). Other risk factors include substance abuse, cardiac disease, and neurological disorders (Sackeim, 2000).

Remarkably few studies have focused on old people, despite their higher rates of premorbid cognitive impairment, and most were small and of poor quality. Post-treatment confusion is certainly more common and cognition typically declines as treatment progresses, more for bilateral than unilateral ECT (O'Connor et al., 2010a), but recovery is usually rapid (Russ et al., 1990; Rubin et al., 1993). Published reports may not be fully representative of clinical experience, however, since many severely depressed patients cannot participate in cognitive testing or consent to

Neurostimulation therapies

research. The patients who are most vulnerable to cognitive side effects might therefore be excluded from study (Gardner and O'Connor, 2008).

In the longer term, some cases of dementia must be expected in older age groups because of the established links between depression, on the one hand, and incipient cerebrovascular and Alzheimer's diseases, on the other. While rates look high at 14% in the patients aged 65+ years who were followed for three years by Godber and colleagues (1987) and 36% in those aged 75+ years followed for five years by Brodaty and colleagues (2000), there is no reason to believe that ECT plays a causative role.

Clinical guidelines highlight the need for cognitive assessment before, during, and after an ECT course but leave the choice of tests to the clinician (American Psychiatric Association, 2001; Royal College of Psychiatrists, 2005). Porter and colleagues (2008) proposed using the MMSE as a baseline measure; checking time to reorientation in the recovery room after every treatment; a brief test of verbal learning after every third treatment; and an abbreviated autobiographical memory questionnaire after every sixth treatment. All these tests can be administered by a trained nurse.

Cognitive impairment is prevented or minimized by administering ultrabrief pulse unilateral ECT in the first instance, titrating stimulus intensity, prescribing only two treatments each week, and limiting the number of treatments in a course, subject to clinical progress (Prudic, 2008; Mayur et al., 2013). There is some evidence that cholinesterase inhibitors might also prove helpful (Henstra et al., 2017).

Subjective reports

While complaints of poor memory subside as depression remits (McCall et al., 1995; Coleman et al., 1996), between 29% and 88% of patients describe some persistent forgetfulness in coming weeks and months (Brodaty et al., 2001; Rose et al., 2003; Philpot et al., 2004). Gaps in memory of the six months before treatment and the two months afterwards are common and mostly well tolerated (Freeman et al., 1980). Of more concern to patients are 'holes' in past memories and difficulties with remembering faces, names, and lists (Freeman et al., 1980). Risk factors for subjective deficits include bilateral electrode placement and high electrical charge (Squire and Slater, 1983; Coleman et al., 1996).

Mood also plays a role. Patients whose depression persists despite treatment tend to report greater memory difficulties and to perceive ECT more negatively (Freeman and Kendall, 1980; Coleman et al., 1996). This is not surprising: mood correlates strongly with self-rated memory, even in community populations (O'Connor et al., 1990).

Self-perceived cognitive changes, when assessed using standard questionnaires, are only weakly associated with scores on objective tests, perhaps because the questionnaires fail to tap patients' personal memories. In fact, responses to a single, general question about memory

Neurostimulation therapies

changes correlate quite well with objective performance, suggesting that complaints have validity (Brakemeier et al., 2011).

Previously, psychiatrists tended to blame complaints on patients' ongoing psychopathology, their loss of self-efficacy, or excessive concern with normal cognitive changes (Prudic et al., 2000). Others were more circumspect. Freeman and colleagues (1980) noted that ECT 'complainers' were only fractionally more depressed on mood rating scales than 'noncomplainers'. Following from this, and from the observation that the temporal gradient in complaints fitted better with ECT than depression as causative agent, Sackeim (2000) concluded that 'attributing these subjective deficits to ongoing psychopathology or natural disease progression would seem disingenuous and defensive'. An account by one patient is especially compelling. Donahue (2000) wrote that ECT (initially unilateral and then bilateral) saved her from suicide. She felt grateful to be alive and would have ECT again if necessary, but whole chunks of her life had been lost to her—a cost she accepted but could not deny.

Ethical issues

For patients with the capacity to consent, ECT should be administered only with their agreement. Consent must be voluntary, based on an adequate explanation of the nature of ECT, its practical implications and side effects, tailored to individual circumstances. Patients concerned about cardiac symptoms, for example, need more detailed information about cardiovascular sequelae. Verbal discussion is best supplemented by an informational brochure that patients and families can digest at leisure, modelled perhaps on the document prepared by the American Psychiatric Association (2001). Moderately depressed, cognitively intact older patients absorb and retain this sort of information quite adequately (Lapid et al., 2004). A visit to the ECT treatment suite to explain its procedures and equipment can allay patients' and relatives' concerns.

Clinicians will naturally advocate for ECT when its use is warranted. There is a fine line, however, between persuasion and coercion. Patients' apprehension typically settles with appropriate reassurance and factual responses to questions, but doctors and patients sometimes perceive this process differently (McCall, 2006). In a review of 17 reports Rose and colleagues (2003) reported that only half the respondents believed they had been given an adequate explanation of ECT and most had limited knowledge of actual procedures. Patients sometimes recounted giving 'consent' while heavily sedated or threatened by legal compulsion. These recollections might sometimes be inaccurate, but patients are left traumatized as a result. Johnstone (1999) described the perceptions of shame and despair by 20 aggrieved ECT recipients; it is required reading for clinicians.

Neurostimulation therapies

Some of the patients most likely to benefit from ECT are unable to consent by virtue of marked depression or psychosis. Pointers to lack of capacity include difficulty recalling basic information about the nature and consequences of ECT, marked difficulty in decision-making, delusional nihilism about the prospects of recovery, and an inability to speak. Treatment can be applied in most jurisdictions on an involuntary basis with review by a court or tribunal. It is important to document the reasons for mandating ECT; the pros and cons of alternative treatments; patients' mental state and capacity to make informed decisions; and family viewpoints. Except in emergencies, second opinions are encouraged. The limited research conducted to date suggests that nonconsenting patients often rate their outcome as satisfactory (Wheeldon et al., 1999). Patients who accept ECT passively but cannot contribute to the decision-making process are best treated involuntarily to ensure legal oversight and protection (Law-Min and Stephens, 2006).

ECT typically entails a series of treatments over a period of weeks. Mental capacity will often improve as depression or psychosis abate, with the result that noncompetent patients become competent and can participate in the decision to continue with treatment. Conversely, a patient made confused by ECT may lose competence for a period of time. Ethical practice requires a constant monitoring of patients' mental states, attitudes to ECT, and decisional capacity. Repeated explanations of the reasons for administering ECT and its likely benefits and side effects may be required if patients fail to recall initial discussions.

Attitudes to ECT

Patients' views

Fear of ECT is widespread. In a survey of 56 Australian general hospital visitors, none of whom had received ECT, many agreed that it ablated memory and rendered patients 'zombies' (Kerr et al., 1982). Psychiatrists attribute this fear to misinformation spread by popular movies and lobby groups, but, in reality, a dread of electricity is instilled in children from an early age.

Malcolm (1989) detailed the concerns expressed by 100 patients prior to ECT. Their fears included brain damage, memory loss, pain, being seen by strangers while unconscious, having a heart attack, and developing epilepsy. Their knowledge of ECT was rudimentary: only 16% knew that a convulsion was induced and many expected a single treatment. Older people were more stoical: 52% denied fear compared with 30% of younger ones. When the same patients were asked later what aspects most perturbed them, they nominated waiting for treatment, seeing equipment laid out, hearing staff talk in the background, breathing into an anaesthetic mask, and waking up afterwards.

In a retrospective survey, only 6% of 70 British patients who had received ECT rated it as much worse than a visit to the dentist (Benbow and

Neurostimulation therapies

Crentsil, 2004). By contrast, 7% of Australian patients said that they dreaded it and another 12% found it frightening (Kerr et al., 1982). Occasionally patients develop an overwhelming horror of ECT, usually after lengthy or repeated courses (Fox, 1993).

Not all patients are negatively disposed. A psychiatrist who received ECT himself described a lifting of mood after the first treatment. Side effects—nausea, stiffness of the jaw, topographic disorientation, and mild memory loss—were a small price to pay in his view (Vallance, 1965). Another patient, while grateful for treatment, described the stigma and inconvenience of maintenance ECT (Hensley, 2008).

Patients' views are coloured in part by their mental status. Depression brings with it fears of therapeutic nihilism. As these fears remit with treatment, opinions of ECT may become more positive (Chakrabarti et al., 2010). Favourable views post-ECT correlate with the severity of mental disorder and disability pre-ECT, fewer treatment side effects, and a perception of good care while in hospital, but not with legal status (Wheeldon et al., 1999; Philpot et al., 2004; Rosenquist et al., 2006). This suggests that the sickest patients, who stand to derive the greatest benefit from ECT, come to perceive it most favourably.

In a meta-analysis of 16 published reports, positive views of ECT emerged most commonly from studies conducted shortly after ECT by psychiatrists using brief checklists. Studies conducted by independent investigators some time after admission using open-ended questions were less encouraging (Rose et al., 2003). This suggests that structured assessments conducted by doctors in medical environments may fail to tap patients' true perceptions.

Proposed strategies to improve acceptance of ECT include educational videos, use of ECT-experienced peer support workers, minimizing time in the waiting room, and reducing exposure to technical paraphernalia (Westreich et al., 1995; Koopowitz et al., 2003; Parvin et al., 2004). The video deployed in one study made no discernible difference to patients' knowledge, perhaps because they were too depressed to benefit, but it was greatly appreciated by families, whose support is often critical (Westreich et al., 1995).

Families' views

Little research has been conducted of family members' attitudes to ECT, both before and after treatment. This is a deficiency, since an informed, positively disposed family can do much to assist patients through their illness and treatment. In the meantime, two compelling accounts have been published of relatives' battles with sceptical psychiatrists to secure ECT for a father and son respectively whose mental disorders had failed to respond to medications and psychotherapy. Their efforts were rewarded by excellent clinical outcomes (D'Agostino, 1975; A Grateful Parent, 2005).

Neurostimulation therapies

Practice standards and training

Variations in practice

ECT can work quickly and effectively when administered by skilled clinicians to carefully selected patients. In a large, prospective North American study of suprathreshold bilateral ECT, 75% of patients had remitted after seven sessions as shown by HDRS scores of 10 or less (Husain et al., 2004). The same might not apply, though, when patients with complex, chronic conditions are treated in mainstream facilities using suboptimal methods. As an example, in a survey of hospitals in New York state where treatment practices varied widely, HDRS scores fell below 10 points in only 47% of all cases. To make matters worse, 40% of accrued improvement was lost within ten days and relapse rates ranged from 46% to 79% across sites (Prudic et al., 2004).

In a related study the investigators were perturbed to find that 17% of 59 mental health facilities administered the same electrical charge to all patients; 8% of facilities failed to monitor seizure duration; and 20% neglected to check patients' cognitive status. Such a wide variability in how ECT is conducted raises serious public health concerns (Prudic et al., 2001).

Training deficiencies were commonplace until recently. Of 160 junior doctors in England and Wales, 63% had watched an instructional video but only 53% had been supervised by an experienced psychiatrist when giving their first treatment and only 4% were routinely supervised thereafter (Duffett and Lelliott, 1998). Similar findings emerged in New South Wales, Australia, where 20% of doctors were not supervised in their first session by another medical practitioner (Halliday and Johnson, 1995).

Clinical guidelines

Three national professional bodies have since published detailed accounts of ECT's indications and contraindications; proper assessment and treatment procedures; legal and ethical standards; and training and supervision requirements (American Psychiatric Association, 2001; Royal College of Psychiatrists, 2005; Royal Australian and New Zealand College of Psychiatrists, 2007). The American Psychiatric Association stipulates that trainee psychiatrists should complete at least 10 treatments under direct supervision and then attend regular ECT review meetings. 'Privileging' to administer ECT independently requires objective evidence of safe, proficient practice that conforms to local standards. Further education might include attendance at an ECT course, a structured clinical practicum, supervised reading, and participation in quality assurance activities.

A checklist prepared by the Royal College of Psychiatrists' Research Unit (2006) of basic, standard, and ideal policies and procedures covering all aspects of physical facilities, staff training, patient assessment and

Neurostimulation therapies

treatment, consent, and follow-up provides a template for self-appraisal in any ECT service. A curriculum for psychiatry trainees has been proposed by Dolenc and Philbrick (2007) that covers all important areas of theory and clinical application.

Transcranial magnetic stimulation

Repetitive TMS uses a pulsed magnetic field to induce an electrical current in the underlying cerebrum, targeting the neural circuitry implicated in depression and possibly other conditions including auditory hallucinations, obsessive-compulsive disorder (OCD), substance use disorder, and post-traumatic stress disorder.

The magnetic pulses used in TMS are of comparable strength to those used in magnetic resonance imaging. Rapid pulses (5 Hz and above) increase the activity of the underlying cortex while slower pulse rates (1 Hz and below) reduce activity. In a newer development, theta-burst stimulation, very high frequency stimulation is repeated in 'bursts' at a frequency in the theta range (Chung et al., 2015).

During TMS, patients sit in a purpose-built chair with the coil positioned over the scalp. The commonest coil is a figure-of eight design, though other configurations exist. The usual strategy is to administer brief pulses over the primary motor cortex to determine the minimum amount of power required to make the thumb twitch (the motor threshold). For treatment of depression, the coil is typically positioned to deliver high frequency stimulation to the left dorsolateral prefrontal cortex (DLPFC). If this proves ineffective, an option is to direct low frequency stimulation to the right DLPFC. Treatments typically take 20 to 40 minutes on five days per week over four to six weeks depending on clinical progress. As no sedation is required, normal activities can be resumed immediately (George and Aston-Jones, 2010).

Objects affected by magnetic fields (e.g. deep-brain stimulators, cochlear implants, and metal objects in the eye) present an absolute contraindication to TMS as they can move or become heated. Implants such as aneurysm clips that are manufactured to be 'MRI compatible' are considered safe. Advice should be sought if in doubt. TMS is relatively contraindicated in patients with a history of seizures or with conditions that lower the seizure threshold (e.g. disseminated sclerosis or recent cortical bleeds or infarctions).

Side effects are generally transient and mild (Rossi et al., 2009). About 40% of patients experience a degree of local discomfort or headache. Hearing protectors reduce the risk of hearing loss from the coil's noise.

TMS has proven antidepressant effectiveness. A recent review found evidence of definite efficacy for left, high frequency DLPFC stimulation and probable efficacy for right, low frequency DLPFC stimulation (Lefaucher et al., 2014).

Neurostimulation therapies

TMS appears to be as effective in older as in younger adults (Conelea et al., 2017). In an open-label study of left DLPFC TMS in 65 older, treatment-resistant patients, 58% showed a 50% or greater reduction in HDRS scores (Sayar et al., 2013).

In a meta-analysis of 25 studies of major depressive disorder (MDD), Chen and colleagues (2017) reported that the cumulative probabilities of being the most efficacious treatment were: ECT 65%; bilateral DLPFC TMS 25%; right DLPFC TMS 8%; and left DLPFC TMS 2%. The cumulative probabilities of being the best-tolerated treatment were: right DLPFC TMS 52%; bilateral DLPFC TMS 17%; left DLPFC TMS 16%; and ECT 14%. Notwithstanding these findings, the time and expense associated with TMS limits its utility as a first-line treatment.

Preliminary evidence exists that TMS can improve performance on several of the cognitive functions impaired in mild cognitive impairment and Alzheimer's disease (Nardone et al., 2014). Other areas for research include new forms of coils and magnetic field geometry, and better individual tailoring of treatment procedures (Lefaucher et al., 2014).

Deep brain stimulation

DBS has generated interest as a psychiatric treatment modality following its success in treating neurological disorders such as Parkinson's disease, epilepsy, and chronic pain. It involves the precise bilateral implantation of electrodes in deep brain nuclei via stereotactic neurosurgery and their connection to an implantable pulse generator situated in the chest wall. The electrodes deliver continuous high-frequency stimulation to the surgical target using parameters (pulse frequency and width, stimulation intensity, and the size and shape of the stimulation field) that can be adjusted non-invasively (Mosley et al., 2015; Fitzgerald and Segrave, 2015).

The mechanisms of action of DBS remain speculative but, in contrast to psychosurgery, most probably involve functional alterations in brain activity rather than disruption of specific brain regions (Fitzgerald and Segrave, 2015). The neuronal effects of DBS are both inhibitory and excitatory in nature, depending on the location and mix of cell bodies and white matter fibres in the stimulated field, as well as the stimulus parameters themselves (Holtzheimer and Mayberg, 2011). At a systems level, DBS is presumed to act on cortico-striatal-thalamic-cortical neural circuits implicated in conditions like depression and OCD (Ward et al., 2010).

Studies of DBS for psychiatric disorders are limited in size but the results look promising. Naesström and colleagues (2016) systematically reviewed the indications for DBS in treating psychiatric illness, particularly major depressive disorder (nine studies with 100 patients) and OCD (18 studies with 112 patients). In the largest depression study involving 21 patients who received subcallosal cingulate gyrus stimulation, response rates

Neurostimulation therapies

were 57% at one month, 48% at six months, and 29% at 12 months, where response was defined as a 50% or greater reduction in the 17-item HDRS score (Lozano et al., 2012). However, the 12-month response rate increased to 62% when defined as a 40% or greater reduction in the HDRS score. In the largest study of OCD, the long-term results of ventral internal capsule/ventral striatum stimulation showed clinically significant symptom reduction and functional improvement in about two-thirds of the 26 patients. Results improved over time as the target area was moved more posteriorly, to the junction of the anterior capsule, anterior commissure, and posterior ventral striatum, based on outcome appraisal (Greenberg et al., 2010). Other disorders addressed in the systematic review, usually with very small numbers of studies, included Tourette's syndrome, anorexia nervosa, heroin addiction, alcohol addiction, agoraphobia with panic attacks, and autism (Naesström et al., 2016).

DBS is invasive and its adverse effects include perioperative complications (haemorrhage, seizures, and death); hardware-related complications (infection, electrode misplacement, and skin erosion), and target- and patient-specific side effects of stimulation (transient memory impairment, musculoskeletal and GI complaints, agitation, and irritability) (Neumaier et al., 2017). Unlike lesional psychosurgery, however, DBS is reversible, produces minimal tissue destruction, and is easily adjusted or switched off. Clarification of optimal stimulus targets, treatment profiles, patient selection criteria, and long-term outcomes are future research directions (Fitzgerald, 2011). Patients with melancholic depression who respond to ECT but continuously relapse with maintenance psychotherapy, pharmacotherapy, or TMS may be ideal candidates for future DBS trials (Mosley et al., 2015).

Conclusion

- ECT is an effective, accepted treatment of depression. It works faster, and may be safer than pharmacotherapy for frail, older patients but relapse rates are high once treatment stops. Continuing pharmacotherapy is mandatory. ECT works best in depressed patients with psychomotor changes and psychotic symptoms.
- There is a place for ECT in medication-refractory cases of mania, acute schizophrenia, and catatonia.
- Electrical stimulation must always exceed seizure threshold, more for unilateral than bilateral ECT. Stimulus titration ensures that energy charges are individualized. Fixed-dose, high-energy treatments are not acceptable.
- Very old patients have higher rates of cardiovascular complications, confusion, and falls. Twice-weekly ECT is adequate. Benzodiazepines, anticonvulsants, and medications with anticholinergic properties should be stopped if possible.
- Complaints of memory loss abate with time, but gaps in memory may persist.

Neurostimulation therapies

- Capacity to consent to ECT can change as treatment progresses and explanations may need to be repeated. Educational brochures and videos are encouraged.
- ECT is perceived negatively by many patients and families and great efforts must be made to address their concerns accurately and to reduce the risk of poor outcomes.
- Such a complex treatment should never be administered by untrained staff.
- Few published reports focus just on frail, aged patients. Further research is required to ensure that treatment of this vulnerable group is made as safe and effective as possible.
- TMS is better tolerated, but less effective, than ECT as a treatment of major depression.
- DBS requires major surgery and its role is limited to the treatment of severe, chronic, and disabling psychiatric disorders.

Person- and relationship-centred dementia care: Past, present, and future

Author(s): John Keady and Mike Nolan

DOI: 10.1093/med/9780198807292.003.0015

Introduction

It has been recognized for some time that supporting people with dementia and their family carers represents the most significant challenge facing health and social care systems throughout the world over the next 50 years (Jennings, 1999). However, debates as to the best model and care pathway to adopt continue to evolve, with various approaches to the support of people with dementia and their family carers being advocated. For instance, during the last 40 years or so, services and professional attitudes have moved from a largely deficit-based model focusing on the person-with-*dementia* through to a much more personalized, individualized, and self-deterministic approach with an emphasis on the *person-with-dementia* (Kitwood, 1997; 7), a momentum which, in England, culminated in the publication of the

Person- and relationship-centred dementia care: Past, present, and future

National Dementia Declaration (Dementia Action Alliance, 2010). The Declaration involved people with dementia in all stages of its development and composition. Indeed, its goal was to change the experience of living with dementia in England 'for good', a process that was framed through seven 'I-statements' aimed directly at people with dementia, e.g. 'I have personal choice and control or influence over decisions about me' and 'I have a sense of belonging and of being a valued part of family, community and civic life.' More recently, and with the support of the Alzheimer's Society, these seven 'I-statements' were refreshed and relaunched by people with dementia (Dementia Action Alliance, 2017) and now comprise five statements about the collective rights of people living with dementia (Box 15.1).

Box 15.1 The dementia statements

- We have the right to be recognised as who we are, to make choices about our lives including taking risks, and to contribute to society. Our diagnosis should not define us, nor should we be ashamed of it.
- We have the right to continue with day-to-day and family life, without discrimination or unfair cost, to be accepted and included in our communities and not live in isolation or loneliness.
- We have the right to an early and accurate diagnosis, and to receive evidence based, appropriate, compassionate and properly funded care and treatment, from trained people who understand us and how dementia affects us. This must meet our needs, wherever we live.
- We have the right to be respected, and recognised as partners in care, provided with education, support, services, and training which enables us to plan and make decisions about the future.
- We have the right to know about and decide if we want to be involved in research that looks at cause, cure and care for dementia and be supported to take part.

Reproduced with permission from National Dementia Action Alliance (2017). Dementia Statements. Available on line at: <https://nationaldementiaaction.org.uk/dementia-statements/>, accessed 02nd September 2019.

The Dementia Action Alliance suggests that these five new dementia statements replicate the things that people with dementia believe are essential to their quality of life and exist to act as a rallying call to improve the lives of all people with dementia. Changing 'I' to 'We' in this new set of statements also promotes a more inclusive and shared vision/

Person- and relationship-centred dementia care: Past, present, and future

experience of living with a dementia. Arguably, these five new dementia statements also act as a mirror to society to reflect the changes in public and policy perception about the condition in the UK, a change that has been propelled through increased public awareness (e.g. via the Dementia Friends initiative: <https://www.dementiafriends.org.uk/>; accessed 29 January 2018) and embedded in dementia-friendly social policy architecture. This latter change is seen most clearly in the targets and implementation plans attached to the development of dementia-friendly communities in the UK and set out in the Prime Minister's Challenge on Dementia 2020 (see, for example: Department of Health, 2012, 2015, 2016).

Recent times have also seen the emergence of relational and dynamic models that transcend the essentially individualistic approach of person-centred care (Post, 2001) and take a triadic perspective with a focus on the relationships and interactions between people with dementia, their family carers, and formal service systems (Nolan et al., 2002b; 2006). Such trends reflect both advances in thinking about the nature of the 'dementia experience' and the importance now accorded to the active engagement of users, carers, and professionals. This approach recognizes that each of these partners is an 'expert' in their own right and that a complete understanding will only emerge when these differing, but complementary, perspectives are brought together (Nolan et al., 2007). The approach also acknowledges the growing importance attached to enabling people with dementia to be more active in the conduct and practice of research attached to their own lived experience so that the power relationships between users, carers, and professionals are harmonized as far as this is both practical and possible to achieve (for an example of people with dementia acting in a co-research capacity alongside academic researchers, see Swarbrick and Open Doors, 2017). Nowadays, and as highlighted previously in the five new dementia statements, such a push for harmonization is being taken forward by people with dementia themselves as a fundamental right and positioned through the language of equality and equity (Mental Health Foundation, 2015; Dementia Alliance International, 2016; The Race Equality Foundation, 2016). The times are undoubtedly changing.

This chapter presents a historical overview of the above changes and then focuses on a particular approach to working with people with dementia, family carers, and paid carers based on the concept of relationship-centred care (Tresolini and the Pew Fetzner Task Force, 1994) as captured in the 'Senses Framework' (Nolan, 1997; Nolan et al., 2002a,b, 2006). It begins with a brief review of some of the key considerations in dementia before charting the rise of person-centred and relational models. It then presents a more detailed consideration of the conceptual and empirical bases for the 'Senses Framework', followed by a case study that illustrates its practical application. The chapter concludes with a glance towards the future and proposes that relationship-centred care could extend its triadic structure by adding a fourth domain: the informal,

Person- and relationship-centred dementia care: Past, present, and future

community-based social networks of people with dementia and their families as they live their lives 'outside their front door' in the everyday community spaces and resources that exist in the local neighbourhood. Ward and colleagues (2017) recently argued that accounting for, respecting, and authenticating the relationships that people with dementia and their families have with neighbours, the neighbourhood at large, shops, friends, and where 'life is lived everyday' are important social world dimensions now receiving attention in the literature and in policy formation.

Dementia: Key considerations

Currently, there are no restorative cures for any of the dementias and promoting, and adopting a healthy lifestyle is presently advocated as the main option for treatment (Alzheimer's Disease International, 2016). Education and skills training for health and care staff who are engaged in the support and care of people living with dementia are therefore recognized as crucial for high-quality compassionate and culturally competent care to emerge (Department of Health, 2016). A review of psychological interventions for carers of people living with dementia by Elvish and colleagues (2012) found that multicomponent interventions were among the most effective, and interventions underpinned by cognitive/cognitive behavioural models appeared to produce meaningful change. A narrative review by Roach and colleagues (2009) on the experience of living with young-onset dementia highlighted the importance of dedicated service provision for this group. They also found that age, employability, current family composition, and presentation of symptoms related to dementia combine to significantly raise the stress for individuals and their families, especially when teenage children are present in the home. This intergenerational impact of the lived experience of dementia is a timely reminder that 'dementia' extends beyond the traditional 'dyad', however that relationship is defined, and reaches out to other members of the family (Roach et al., 2014; Koo and Pusey, 2017). The impact also extends to the wider neighbourhood and the home where people with dementia live, a space that includes the garden (where there is one) and those spaces around the home that bring people with dementia into contact with the outside world (Ward et al., 2017).

Recognition that dementia is not confined to later life is also a timely reminder of the history of the condition and the work of the German psychiatrist and neuropathologist Dr Alois Alzheimer, from whom the disease takes its name. In November 1901, at the age of 51, Auguste Deter was admitted to the Frankfurt am Main insane asylum at the behest of her husband. The family doctor's admission note from 1901 survives, and it shows that Mrs Deter's condition required 'treatment' from the local asylum as she was experiencing weakening of the memory; persecution mania; sleeplessness; restlessness; and an inability to perform any physical or mental work (Maurer and Maurer, 2003). Dr Alzheimer himself performed various cognitive, psychological, and

Person- and relationship-centred dementia care: Past, present, and future

dexterity tests at the time of Mrs Deter's admission, which included an appraisal of her reading and writing performance. For example, Alzheimer recorded Mrs Deter's performance in the following way (Maurer et al., 1997):

... when she has to write Mrs Auguste Deter, she writes Mrs and we must repeat the other words because she forgets them. The patient is not able to progress in writing and repeats, 'I have lost myself' (p. 1548).

After Auguste Deter's death in the asylum on 8 April 1906, it was the staining techniques applied to her brain by Alzheimer and his colleagues that identified the amyloid plaques and neurofibrillary tangles that, to this day, remain confirmatory biological markers for presence of the disease and gave rise to the description of the 'clinical symptoms' of 'presenile dementia' (Maurer and Maurer, 2003). The search to further understand the biological functioning of the brain, and the death/dysfunction of the responsible neurotransmitters, largely marked Alzheimer's disease as 'medical territory' for much of the twentieth century with its diagnostic classification, and that of 'dementia', written into international mental health disease classifications (e.g. World Health Organization, 1992, 2016).

Arguably, the direct alignment between 'Alzheimer's disease' and 'mental health/illness' promoted a deficit-based model and further exposed those living with the condition to the stigma of mental illness, as well as to the stigma of ageing. Indeed, closer inspection of the quotation above reveals the 'malignant positioning' (Sabat, 2001, 2002) by Alzheimer of Auguste Deter as 'a patient' [rather than as 'a person'] and an inmate of the confining and austere environment of the Frankfurt am Main insane asylum. In such a setting, opportunities for individual expression and self-determination would have been limited, to say the least.

Similarly, the subsequent focus on the 'staining technique' on her deceased brain, rather than attempting to find meaning in Auguste Deter's profoundly self-aware words of 'I have lost myself', effectively closed the door on what is now central to dementia care practice—namely the use of life story work (Kellest et al., 2010; McKeown et al., 2010, 2015; Gridley et al., 2016). Auguste Deter's life story did not emerge until 100 years after her death when Page and Fletcher (2006) pieced together the fragments of her life that they were able to recover from various sources. In the story that emerged, Mrs Deter was not simply 'a patient' whose brain gave life to Alzheimer's disease, but until the time of her death at the age of 56, she remained a married woman who had had a daughter called Thekla. As Page and Fletcher (2006) reveal, Auguste Deter married Karl, a railway clerk, when she was 23 years of age and it was at this time in the young couple's life that they moved to Frankfurt to continue their life from within the protestant religion. It was also reported that after his wife's admission to the asylum in 1901, Karl Deter struggled to pay the fees for his wife's care and he was seen to visit her

Person- and relationship-centred dementia care: Past, present, and future

'frequently'. Rather movingly, Mrs Deter is described in the admission notes as being a 'tall woman with long brown hair, brown eyes and elegantly long fingers' (Page and Fletcher, 2006; 578), and as far as it can be ascertained from the available writings, she was a woman who had a preserved sense of identity—in the eyes of her husband and daughter—as a wife and as a mother.

We would like to think that Auguste Deter had a sense of belonging and significance for those who loved her, but defining people with dementia from within their own relationships, life story, and preserved attributes was not the dominant narrative of the early twentieth century. This discourse was not to change until society began to question the morality and ethical standpoint of institutional and asylum-based care, and influential academics, practitioners, and policy makers began to challenge the long-held assumption that living with dementia equated simply to 'coping with a living death' (Woods, 1989) in which 'the self' had long since vanished (Cohen and Eisdorfer, 1986). We next explore how person-centred care was central to the emergence of a new, more holistic vision of dementia and how responses could be formulated.

Person-centred care

As noted, during significant parts of the twentieth century, dementia had a chequered history with the provision of care being largely institutionally based and task orientated (Keady et al., 2009). Indeed, at the time, the meta-narrative of dementia was largely constructed around challenge, hopelessness, and the loss of self (for a review, see Nolan, 2003) with little, if any, effort made to provide supportive, evidence-based psychosocial interventions to enable people living with the condition to reach their optimum quality of life. This therapeutic nihilism was not to change until the introduction of reality orientation in the early 1980s (Holden and Woods, 1982) and the construction of a more sympathetic, and empathetic, policy architecture that began to value people with dementia. Two reports published one year apart proved particularly influential in challenging the prevailing public and professional attitudes at the time: *Organic Mental Impairment in the Elderly* (Royal College of Physicians, 1981) and *The Rising Tide* (Health Advisory Service, 1982). For the first time, these reports both signposted the importance and human worth of people with dementia and highlighted the need for well-staffed resources in both community and residential settings. In particular, *The Rising Tide* addressed the needs of both the person with dementia and their carers and set out the key components of a comprehensive service that was to include 'support, advice and relief at times of special difficulty to families' (p. 17) with primary health and social services seen as the 'essential ingredients' in providing a successful comprehensive service.

This commitment to improving the lives of people with dementia *and* carers was reinforced by the King's Fund Centre (1984) in a project paper that detailed the tenets of good service practice. This was achieved by

Person- and relationship-centred dementia care: Past, present, and future

outlining five 'key principles' that provided philosophical beliefs about personal empowerment for people with dementia. The five principles (King's Fund Centre, 1984; 7–8, slightly abridged) called for an acknowledgment that:

1. People with dementia have the same human value as anyone else irrespective of their degree of disability or dependence;
2. People with dementia have the same varied human needs as anyone else;
3. People with dementia have the same rights as other citizens;
4. Every person with dementia is an individual; and
5. People with dementia have the right to forms of support which do not exploit family and friends.

While this was a most helpful start, the case for putting the 'self' back into the individual experience of living with dementia was more eloquently articulated by Professor Tom Kitwood and his colleagues at the Bradford Dementia Group. They developed an elegant social theory of personhood in dementia that was, in time, to influence UK public policy and have a global impact. True to the philosophy of a person-centred approach, this model did not emerge from the consideration of data collected from significant numbers of individuals but, as with Alzheimer's work, was built around a single case history, or psychobiography as it was originally named, undertaken by Kitwood himself (Kitwood, 1990b). This psychobiography was conducted by Kitwood with a person called 'Rose', whose struggle to assert her personality through the mask of her confusion triggered Kitwood's thoughts on the need to reconceptualize the experience of dementia. After attempting to agree a meaning to Rose's actions and behaviours with colleagues at the Bradford Dementia Group (see Kitwood, 1990b for a fuller discussion), they constructed a multidimensional theory that identified a range of social and subjective factors that they believed shaped Rose's experiences. While the emerging theory focused predominantly on the more 'advanced' stages of dementia in residential care, mirroring Rose's personal circumstances, it nevertheless placed the person with dementia at its heart. It was from these observations that Kitwood (1988) reconceptualized the experience of living with dementia along the following lines:

$$SD = P + B + H + NI + SP$$

In this equation, SD refers to senile dementia, which is viewed as the product of the complex interactions between the remaining five elements of the equation:

P	Personality, which includes coping styles and defences against anxiety.
B	Biography, and responses to the vicissitudes of later life.

Person- and relationship-centred dementia care: Past, present, and future

H	Health statues, including the acuity of the senses.
NI	Neurological impairment, separated into its location, type, and intensity.
SP	Social psychology, which constitutes the fabric of everyday life.

Kitwood (1988) suggested that the equation accounted for most of the phenomena associated with the range of dementias and explained the unique course of each person's dementia by combining 'structural' and 'conjunctural' means of explanation. This theory reflects Kitwood's (1990a; 1997) critique of the past failings of care environments and approaches to people with dementia, which, for Kitwood (1990a), created a 'malignant social psychology' that inhibited the full expression and selfhood of people with dementia. Crucial to the emerging theory was the acceptance of the construct of 'personhood' and the recognition that a 'malignant social psychology' had been developed which 'bore down powerfully' on those with dementia (Kitwood and Bredin, 1992b). Kitwood (1990a) initially outlined ten components that illustrated the elements of this 'malignant social psychology' but later extended these to 17 by the time of the publication of the now-seminal text *Dementia Reconsidered: The Person Comes First* (Kitwood, 1997; 46-47). Examples of the factors that Kitwood believed created a 'malignant social psychology' include:

- Infantilization: implying that a dementia sufferer has the mentality or capability of a baby or young child.
- Stigmatization: turning a dementia sufferer into an alien, a diseased object, an outcast, especially through verbal labels.
- Outpacing: the delivery of information or instruction at a rate far beyond what can be processed.
- Objectification: treating a person like a lump of dead matter; to be measured, pushed around, drained, filled, and so on.
- Ignoring: carrying on (in conversation or action) in the presence of a person as if they were not there.

Kitwood and his colleagues cogently argued that 'the dementia' is not the main problem, rather it is 'our' (individual, carer, professional, society) inability to accommodate 'their' view of the world. Kitwood and Bredin (1992b) suggested that this 'them' and 'us' divide creates a dialectic tension that is reinforced over the years by the devalued status of someone who is labelled as 'demented' and who is consequently seen to be cognitively incompetent (see also Sabat et al., 2011). Underpinning these observations is the belief that if the elements of a 'malignant social psychology' can be identified, appraised, and overcome, then care (both for family and professional carers) can be improved and that the person with dementia will achieve a greater sense of personal 'wellbeing'. This

Person- and relationship-centred dementia care: Past, present, and future

focus on wellbeing is reflected in Kitwood's (1997) definition of personhood:

It is a standing or status that is bestowed upon one human being, by others, in the context of relationship and social being. It implies recognition, respect and trust. Both the according of personhood, and the failure to do so, have consequences that are empirically testable (p. 8).

To promote the practice of person-centred care, the observational method of Dementia Care Mapping (Kitwood, 1990a; Kitwood and Bredin, 1992a) was devised, with the goal not only of enhancing care in formal settings, but also of capturing it in a measurable way. Kitwood and Bredin (1992a) argued that a positive change to the social environment could cause a reversal of the accepted 'decline' trajectory in dementia (i.e. from mild to moderate to advanced stages) and named this 'reementia'. Such a paradigm shift had implications for the caring professions, as people with dementia were now seen to exert a sense of agency that could only be realized through significant changes in professional attitudes, practices, and cultures.

Following Professor Kitwood's untimely death at the end of the 1990s, the mantle of developing person-centred care was taken up by Professor Dawn Brooker who, at the time, was also working out of the Bradford Dementia Group in the UK. In a subsequent influential paper, Brooker (2004) developed the VIPS model of person-centred care:

- Value of all human lives;
- Individualized approach recognizing uniqueness;
- Seeing the world from the **P**erspective of the service user;
- Social environment that promotes wellbeing.

The VIPS model provides a helpful memory aide highlighting the importance and value of people with dementia as well as reflecting a more holistic appreciation of the relationships that infuse daily life. In a later text, Brooker and Latham (2015) extended the reach of the VIPS model to challenge the prevailing culture of care home attitudes and outlined the importance of 'getting person-centred care into everyday practice' (p. 24).

While Kitwood's work was promoting a new vision of the experience of dementia from the perspective of people who lived with the condition, a parallel stream of work was exploring the carer's perspective.

Dementia: Focusing on family carers

There is no doubt about the enormous impact that Kitwood's work has had on the care of people with dementia, with the previously largely nihilistic approach being replaced by a much more positive and dynamic model centred on the personhood of the individual. However, as noted,

Person- and relationship-centred dementia care: Past, present, and future

Kitwood's initial focus was largely on care provided in an institutional setting and, while the role of staff in creating a positive (or malignant) social psychology was acknowledged, the contribution of family carers was largely overlooked in the construction of person-centred care. This left a considerable gap in our understanding, for then, as now, the majority of people with dementia live in the community supported, as needed, primarily by family carers (Alzheimer's Society, 2014). Studies on the experiences of family carers for people with dementia have a long and distinguished history from early pioneering work conducted in the US by Zarit and colleagues (1980, 1986) and which continues to the present day. However, much of this early work was undertaken in North America and focused almost exclusively on the 'burden' of family care and the negative consequences that caring has on the health and wellbeing of family carers—a perspective that continues to dominate the landscape of dementia care and practice.

As Kitwood was developing his new approach to dementia care, a parallel but separate stream of work was being undertaken at Bangor University in North Wales that sought to provide a more rounded and holistic view of family care. The original focus of this work was on carers of older people and parent carers of people with learning disabilities rather than carers of people with dementia per se. It clearly demonstrated that a view of caring predicated on burden alone was inadequate and that, in reality, caring comprises a complex mix of burdens and rewards, and the balance between the two matters the most (Nolan and Grant, 1989; Nolan et al., 1990; Grant and Nolan, 1993). Several studies showed that carers' subjective interpretations of their situation and the nature and quality of their relationship with the person they were supporting were most influential in determining their levels of stress, rather than the objective circumstances of care, such as the amount of direct practical and instrumental help they provided (Grant et al., 1990; Nolan et al., 1990; Nolan et al., 1994).

This called attention to the dynamic nature of the relationship between carers and cared-for persons that was consistent with the [at the time] recently published and now seminal work of Kahana and Young (1990). These authors were ahead of their time in criticizing the largely unidirectional and unidimensional models of care that then predominated, in which the cared for person was seen only as a source of stress and burden on the carer, with universally negative consequences for the latter. Instead, Kahana and Young (1990) called for the development of more dynamic and relational models, which acknowledged and explored the possibilities of both negative and positive consequences for both the carer and the cared for person. Such 'dyadic' and dynamic models were, they argued, essential if more appropriate and sensitive support was to be developed. In looking to the future, these authors suggested that the dyadic model itself needed to expand to account for triadic interactions that included the perspectives of service providers as well.

Person- and relationship-centred dementia care: Past, present, and future

This work appeared as a book chapter (a source of expertise and inspiration that is sadly all too often overlooked today with the present hegemony of the 'journal'), coinciding with the work being undertaken at Bangor University, and stimulated further exploration into the relational dynamics of caring. In a seemingly serendipitous manner, at virtually the same time, American psychologist John Rolland (1988, 1994) published his model of working with people with disabilities, their family carers, and formal services, which he called the 'therapeutic quadrangle'. Rolland's interest was in the experience of living with and supporting people with long-term conditions, which he argued are far more heterogeneous in their presentation and effects than acute conditions. He postulated that, in order to develop truly responsive interventions, there was a need to look at the interactions between the person with a long-term condition, the family, and the professional system all within the context of living with a particular form of a chronic condition, which varies on several important dimensions, e.g. onset, course, incapacity, and outcome. Thus, he argued, a condition such as a stroke, which usually has a sudden and often unexpected onset, and causes varying degrees of incapacity but which subsequently follows a relatively stable course (in the absence of another episode), makes very different demands than a condition like dementia, with its usually insidious onset, highly variable and unpredictable course, and slowly increasing levels of incapacity. As such, it requires very differing forms of support for all concerned in the process.

The work of Kahana and Young (1990) and Rolland (1988, 1994), coinciding as it did with the newly emerging focus on the dynamics of caring relationship in the UK, exerted a considerable influence on the direction of future studies with Nolan and colleagues (1994) adopting the 'therapeutic quadrangle' as an organizing framework for much of their ongoing work (Fig. 15.1). Subsequently, Keady took the lead on a number of studies with people with dementia and their carers (Keady and Nolan 1994a,b; Nolan et al., 1995, 1996; Keady, 1996, 1997, 1999), and it is to this body of work that we now turn our attention.

Person- and relationship-centred dementia care: Past, present, and future

Developing new understandings on 'caring' and the dementia experience.

Around the time that Rolland (1988, 1994) and Kahana and Young (1990) published their work, some exciting new insights emerged about the meaning of caring in dementia from the perspective of family carers. For example, Motenko (1989) highlighted the potential for carers of people with dementia to experience both gratifications and frustrations, thus reinforcing Hirschfield's (1981, 1983) earlier conclusions on the importance of mutuality in caring relationships, or the extent to which carers find gratification and meaning in their role. Concurrently, Barbara Bowers, an American nurse, was exploring the meanings that caregiving daughters of people with dementia give to their experiences and developed a much more sophisticated and nuanced typology of caring (Bowers, 1987). The next few sections describe briefly the types of care, many of which were deliberately kept 'invisible' from the person with dementia, and some of which occurred a long time before actual hands-on instrumental care was needed.

Anticipatory care

This typically occurs long before any physical care is needed and involves carers anticipating what they would do if ever care was needed in the future. However, while this is a cognitive and speculative activity it can still have a profound effect on people's lives, for example, in the case of an only daughter who may not move overseas in anticipation that her ageing mother might need care in the future.

Person- and relationship-centred dementia care: Past, present, and future

Preventive care

This typically comprises caring at a distance and involves subtle efforts to 'keep an eye' on an ageing parent, for example, to see that they are taking medication or that their diet remains good. This is more overt and purposeful than anticipatory care, but is still nevertheless largely hidden from the older person.

Supervisory care

This type of care is now becoming increasingly obvious and comprises more direct action, such as shopping with/for the older person, directly ensuring they take medications, checking to see that their fridge is adequately stocked, and taking action if it isn't.

Instrumental care

This is the type of activity most usually defined as caring and involves providing direct hands-on assistance usually with a range of activities of daily living or instrumental activities of daily living. It is the primary type of 'caring' activity that is recognized as such by formal services, and often the only type of care for which a carer is likely to be offered help.

Protective care

This again comprises a subtle range of activities which daughters [in the theoretical sample that predominantly comprised the study] undertook to 'protect' their mothers from knowledge of their increasing frailty and cognitive abilities.

Bowers' (1987) data indicated that it is protective care that daughters see as the most stressful and the most important, and instrumental care that they see as the least stressful and important. However, paradoxically, services focused almost exclusively on the latter and did not usually even acknowledge the former. This was often a source of conflict between family and paid carers.

While much taken with this model, at the time we argued that, based on our data collected over a number of years, anticipatory care was not confined to the early stages of caring (as Bowers contended) but occurred throughout the caring trajectory (Nolan et al., 1995, 1996). What changed was the nature of what was being anticipated. Moreover, we also suggested that while it was usually well-meaning, protective care could be potentially paternalistic and that the best caring relationships were characterized by *reciprocal care* in which both parties made a valued contribution. Another important element to the caring dynamic was *reconstructive care*, in which carers helped the person they were supporting to reconstruct a positive view of themselves. It was how such reconstructive and reciprocal care developed over time that was the primary focus of Keady's ongoing work.

Person- and relationship-centred dementia care: Past, present, and future

Building on a temporal model of the dementia caring experience as it unfolds over time (Wilson 1989a,b), Keady (Keady and Nolan 1994a,b; Nolan et al., 1996; Keady, 1996, 1997, 1999; Grant et al., 2003) developed a six-stage model of the caring trajectory that comprised the following phases:

- Building on the past
- Recognizing the need
- Taking it on
- Working through it
- Reaching the end
- A new beginning

'Building on the past' acknowledges that caring relationships do not appear fully formed 'out of the blue', but rather are usually preceded by a long relationship and that the quality of this relationship is very influential on the subsequent caring dynamic. 'Recognizing the need' is a period, either extended (as in dementia) or short (as in stroke), when the carer becomes aware that the nature of their relationship with their loved one is changing and that differences in roles and responsibilities are becoming apparent. 'Taking it on' should be a time when informed decisions about whether or not to 'become a carer' are made, based on as full an understanding of the potential consequences as possible. However, this rarely happens in practice and carers often 'take on' their role uninformed and lacking the skills and knowledge that they need to 'do caring well' (Schumacher et al., 1998). 'Working through it' is often described as the 'long haul' of caring and is the period during which, if they get any support at all, that carers are most likely to be in receipt of formal services. Sadly, they are rarely supported when they 'reach the end' either through the death of the person with dementia or their placement in a care home. At such times, carers often receive no support at all. Of course, for many carers, this is not the end of their support for the person with dementia, as the family will often continue to play an important part in the lives of the person with dementia. It is here where 'A new beginning' enters the life of (ex) family carers and different opportunities open up, which may, or may not, include continuity and exposure to dementia, e.g. taking on a voluntary role with the Alzheimer's Society or taking part in one of the many dementia café initiatives that are in existence across the UK. However, as far as services are concerned, their role as a 'carer' has ended.

Keady originally developed this model following in-depth interviews with carers of people with dementia (Keady and Nolan, 1994a,b; Keady, 1999) and it was subsequently elaborated upon with data from carers of physically frail older people and parent carers of people with learning disability (Nolan et al., 1996). While these studies tended to fit into the existing paradigm of treating people with dementia and carers separately, towards the end of his interviews Keady was able to involve some people with dementia. Consequently, a much more subtle picture began to emerge (Keady, 1999; Keady and Nolan, 2003), which allowed the

Person- and relationship-centred dementia care: Past, present, and future

'dynamics' of dementia to be better understood. Keady was able to describe a delicate and often longstanding dialectic that took place between the person with (as yet undiagnosed) dementia and their carer, in which the former began to notice that something was wrong and made efforts to hide this, and the latter sooner or later 'suspected' that something was wrong and made efforts to try and find out what (Keady and Nolan, 1995a,b; Keady and Gilliard, 1999). This involved 'boxing and coxing' in which both parties 'worked' hard but often towards different ends and sometimes to the detriment of their relationship. In such circumstances some carers and their partner tended to 'work apart' over time (Keady and Nolan, 2003). On the other hand, when couples developed an open stance to the changing behaviour of one partner and were more proactive in discussing potential difficulties and addressing them positively then they 'worked together' far more effectively. As the dementia was diagnosed and progressed over time, it was the carer who increasingly did most of the 'work' and Keady termed their efforts to keep the person with dementia engaged as 'maintaining involvement' (Keady, 1997).

Since that time, several studies have further explored the dynamics of caring relationships in dementia (e.g. Brodaty et al., 2003; Selwood et al., 2007) and our understanding moved closer to addressing Kahana and Young's (1990) prophetic call for the development of much more intricate models of the 'give and take' of caring relationships as they unfold over time. Recent studies have also seen the emergence of 'couplehood' in dementia, capturing, in more nuanced ways, dementia as a shared experience.

From personhood to couplehood

Probably the most extensive of these studies was that undertaken in Sweden (Hellström et al., 2005a,b; Hellström et al., 2007), which involved following 20 couples (where in each, one had dementia) over a five-year period and, wherever possible, interviewing both spouses several times. In total over 150 interviews were completed. This study has, to the best of our knowledge, collected the most extensive data of this type yet available and demonstrated several important points. Firstly, that it is possible to obtain rich and meaningful data from people with dementia over an extended period of time, with 12 of the original 20 people with dementia still being interviewed five years later. Secondly, for most of the spouses the idea of 'couplehood' was far more meaningful than was the idea of 'personhood' in that both parties described themselves primarily in relation to each other, rather than as separate individuals. Thirdly, in the majority of relationships, both spouses adopted a wide range of subtle tactics to ensure that they both experienced the best quality of life possible. Fourthly, until the very late stages, the person with dementia was a very active participant in 'maintaining involvement' and often developed deliberate strategies to 'hand over' responsibilities to their

Person- and relationship-centred dementia care: Past, present, and future

partner when they appreciated that their own capacity was becoming limited.

In describing these interactions Hellström et al. (2007) identified a wide range of processes, some of which reflected well-established patterns of relating, others of which had been developed and evolved in response to the dementia experience. Taken together, these processes created a 'nurturative relational context' (Hellström et al., 2005a,b) in which spouses sought to both 'sustain couplehood' and to 'maintain involvement'. In order to do so, they focused their attention primarily on the present, rather than looking too far into the future, but at the same time they often 'took risks' so that the person with dementia was not unduly constrained in their actions. However, most of their focus was on the dynamics of their relationship and involved:

- 'Talking things through', so that each partner was aware of the thoughts and feelings of the other;
- 'Being appreciative and affectionate', and complimenting each other on their appearance and the efforts they made to keep their relationship 'special';
- 'Making the best of things' by sharing enjoyable activities, seeing the positive things in life, and living for the moment; and
- 'Keeping the peace', which involved being aware of, and seeking to avoid, those activities that triggered a negative response in their partner.

As mentioned, this subtle range of activities were actively practised by both spouses, often over a prolonged period of time. Studies of this kind attest not only to the importance of relationships in understanding the dementia experience, but also to the continued agency of the person with dementia. These findings continue to hold resonance and meaning in the current literature (e.g. Wadham et al., 2016).

Although it had taken over a decade, studies such as these were now beginning to realize the vision of Kahana and Young (1990). The insights provided by such knowledge have implications for the care and support given to people with dementia and their family carers (which we consider shortly). However, before doing so, there is a need to describe an approach that more fully realizes Rolland's (1988, 1994) aspiration of a 'therapeutic quadrangle'.

Squaring the quadrangle: The Senses Framework and relationship-centred care

Following Kitwood's (1997) pioneering work, 'person-centred care' became a watch word for good quality individualized care for people with dementia and his ideas have been further developed by Brooker (2004) and Brooker and Latham (2015). However, the notion of person-centred care has also become the policy 'mantra' of the last decade and the

Person- and relationship-centred dementia care: Past, present, and future

'personalization' agenda still dominates policy pronouncements (e.g. Social Care Institute for Excellence, 2010). Unfortunately, unlike the contribution of Kitwood and, separately, Brooker, whose work has had an undoubted impact, the reality of policy rarely matches the rhetoric and there remains considerable confusion about what 'person-centred' care actually means (McCormack, 2004). Increasingly, at least in policy terms, it has become associated with concepts such as independence and autonomy, with a focus on the 'individual' and their circumstances rather than the nexus of relationships in which we all participate. This reflects the move towards the application of consumerist principles to health care (McCormack, 2004) and the emergence of concepts such as successful ageing, which lionize independence and autonomy (Scheidt et al., 1999). This represents a retrograde step, and overlooks the complexity of the vast majority of real-life situations, especially in conditions such as dementia. Ethicists like Evans (1999) and MacDonald (2002) have become increasingly critical of the 'politics of independence', arguing that such a stance tends to negate the shared responsibility that we all have to provide adequate support for the frailest and most vulnerable members of society.

The tensions apparent in many modern day health and welfare systems, with their goal of promoting independence, were acknowledged a number of years ago by a major 'task force' established in the US to consider creating a health care system fit for the future needs of American society (Tresolini and Pew-Fetzer Task Force, 1994). Following a period of 'intense national debate', it was recognized that the current system did not meet the needs of a population that was increasingly ethnically diverse and also lived primarily with long-term conditions. Such conditions pose the greatest future challenge to health care, but the system in the US, possibly even more so than in the UK, is not geared to address acute care needs. The task force concluded that there was a need to develop an entirely new model of health care, predicated of a different philosophy and they termed this 'relationship-centred care'. They determined that:

... relationships are critical to the care provided by nearly all practitioners and a sense of satisfaction and positive outcomes for patients and practitioners. Although relationships are a prerequisite to effective care and teaching, there has been little formal acknowledgement of their importance and few formal efforts to help students and practitioners learn to develop effective relationships in health care (Tresolini and Pew-Fetzer Task Force, 1994; p. 11).

In promoting a more holistic vision of health care the Task Force focused on several areas including the:

- Social, economic, environmental, cultural, and political contexts of care;

Person- and relationship-centred dementia care: Past, present, and future

- Subjective experience of illness; and
- Reality that relationships develop between practitioners, patients, families, and the wider community over time.

They suggested that it was the interaction of these factors that should lie at the heart of a health care system based on relationship-centred care and that relationships form the 'foundation' of any therapeutic or healing activity. While they went on to outline the basic elements of such a system, they also recognized that the concept of relationship-centred care was still emerging, and that further work was needed to put the concept into practice in ways that ensured an appropriate balance between the needs of everyone involved in health care relationships. The 'Senses Framework' (Nolan, 1997; Nolan et al., 2001, 2002a,b, 2006) provides one way of achieving this.

The 'Senses Framework' was developed in parallel to, but without awareness of, the emergence of relationship-centred care described here. Its roots lie in the early work of Nolan, Grant, and Keady (1996, 1998) on the caring relationship and the influences exerted by Kahana and Young (1990) and Rolland (1988, 1990) mentioned earlier. Mulrooney (1997) provided further stimulus at the World Congress of Gerontology in Adelaide, Australia, where he promoted a vision of person and relationship-centred care that was not based on notions of autonomy and individuality, but rather was predicated on three core principles:

1. Respecting personhood
2. Valuing interdependence
3. Investing in caregiving as a choice

This model, while recognizing that each person is unique and has individual needs and intrinsic worth, sees people as being primarily interdependent, a value base that recognizes the reciprocity that is inherent in the best of relationships and promotes a balance between dependence and independence (Mulrooney, 1997). However, in situations where substantial care and support are required, personhood can only be respected and interdependence valued if the person providing the care does so willingly. This may not always be the case for family carers. Such considerations also apply to those in paid caring roles, whether professional or not. Indeed, this belief was central to Kitwood's (1997) vision of person-centred care, and he argued that if paid carers are not valued and accorded status then they will bring a feeling of being devalued into their work, which will inevitably be reflected in the care they provide for people with dementia.

An invitation to deliver a keynote address on the future role of nurses in the delivery of health and social care for older people (Nolan, 1997) led to the emergence of the 'Senses Framework'. The paper focused in particular on addressing the needs of frail older people who require ongoing support. It argued that the evolution of modern-day health care had put 'cure' centre stage and that caring had become an essentially

Person- and relationship-centred dementia care: Past, present, and future

devalued activity. As a consequence, those working in acute care have a clear sense of therapeutic direction and an explicit goal, cure, to which they aspire. Moreover, such a goal is highly valued and the 'excitement' and 'value' of working in an acute, hi-tech environment is constantly reinforced in the media and exalted by the public. In the absence of cure, the fledgling discipline of geriatric medicine substituted rehabilitation, based on achieving a certain degree of functional independence, as its therapeutic aim (Wilkin and Hughes, 1986). However, those working in longer-term care environments have always lacked a sense of therapeutic direction, hence the nihilism described by Kitwood (1997). The efforts of those working in long-term care have been consistently denigrated and accorded little or no value and status, as reflected in the academic literature, where it has been termed 'aimless residual care' (Evers, 1981), or at best 'good geriatric care' (Reed and Bond, 1991) where the aim is to keep older people safely 'warehoused'.

Nolan (1997) argued that, given the prevailing demography with those aged 85+ being the most rapidly increasing section of the population, health and social care had to create a positive environment for long-term care in order to ensure that the needs of frail older people were adequately met and that those providing care could experience a feeling of job satisfaction. He suggested that in a positive long-term care environment, older people should experience six 'Senses':

- *Security*: feeling safe physically, psychologically, and existentially;
- *Belonging*: maintaining important relationships and feeling part of a valued group or community;
- *Continuity*: creating links between the past, the present, and the future, and experiencing consistent care delivered by known people;
- *Purpose*: engaging in valued activities and having something to ensure the meaningful passage of time;
- *Achievement*: achieving valued goals and feeling that all efforts are valued; and
- *Significance*: to feel that each individual, who they are, and what they do in some way 'matters' to others considered important to that person.

However, he also argued that if staff were to create such an environment for older people then they, too, have to experience the 'Senses' for themselves. So, for example, staff need to feel secure in their terms of employment and that it is safe to raise any concerns they might have about standards of care; that they belong, not only to a staff team or group, but also to a wider community of practitioners—something that is hard to achieve in many long-term care environments where staff turnover is often very high, which compromises the Senses of belonging and continuity. The lack of therapeutic direction in long-term care has already been alluded to, and this seriously erodes a Sense of purpose and achievement for staff. The low status of work with frail older people (and

Person- and relationship-centred dementia care: Past, present, and future

indeed those whose needs fall outside the acute sector generally such as people with learning disabilities) and the lack of importance accorded it means that there is little to be gained by way of a sense of significance. Small wonder then that standards of care have been historically poor, as captured graphically in the titles of seminal works such as *The Last Refuge* (Townsend, 1962) and *Sans Everything* (Robb, 1967). Despite considerable improvements, scandals still arise with uncomfortable regularity.

The success of Kitwood's work and the enthusiasm with which it has been adopted is probably due in no small measure to the fact that it helped to create the Senses for staff working with people with dementia. After years of therapeutic nihilism, they suddenly had a sense of purpose (to realize person-centred care) and, with the advent of dementia care mapping, a way of demonstrating that they had achieved this. As the popularity of this approach spread, it helped to create a sense of belonging for an increasingly large group of people delivering person-centred care, and as the value accorded to this grew, so too did the sense of significance and importance attached to this area of practice.

While initially the Senses were largely conceptual, lacked a clear empirical basis, and had been developed with a long-term setting in mind, a major study in 1999 (Davies et al., 1999) demonstrated their value in an acute hospital context. Following the publication of the *Not Because They Are Old* report (Health Advisory Service 2000, 1998), which once more highlighted the lamentable standards of care received by older people in acute care settings, Davies and colleagues were commissioned by Help the Aged and the Orders of St John Care Trust to identify acute hospitals in which older people and their families had received good care, and to explore what it was that differentiated them from settings in which older people received poor care. Following a number of detailed case studies, Davies and colleagues (1999) concluded that it was the leadership of the ward sister (manager) that was the primary factor. In care environments in which older people and their families praised care, the sister created a 'positive culture', which had at its heart three essential features:

1. 'Valuing fundamental practice', so that essential elements of care such as help with personal hygiene, feeding and toileting were given a high priority. Sister herself often took part in such activities and provided a clear role model. Such work was seen as 'significant' and provided a strong sense of purpose and achievement.
2. 'Fostering a stable environment', where there was little staff turnover, thus creating a strong sense of belonging and continuity. At the same time, staff felt safe to question practice and innovate where this was seen as necessary.
3. 'Establishing clear and equitable therapeutic goals', so that staff knew what was expected of them. This involved negotiating the goals of care with the active involvement of older people and their families.

Person- and relationship-centred dementia care: Past, present, and future

This study demonstrated the value of the Senses in an acute setting and identified a wide range of factors that created the Senses not only for staff and older patients but also for family carers (Davies et al., 1999).

During this and later studies, an environment in which the Senses were met for all the major stakeholders, and not just one group, e.g. older people or staff, was termed an 'enriched environment' (Nolan et al., 2002a, 2006; Brown et al., 2008) and this is captured in Table 15.1.

Person- and relationship-centred dementia care: Past, present, and future

Table 15.1 The components of an enriched environment.

Stakeholder Senses	Older person	Staff	Family carers	Students
<i>Security</i>				
<i>Belonging</i>				
<i>Continuity</i>				
<i>Purpose</i>				
<i>Achievement</i>				
<i>Significance</i>				

Person- and relationship-centred dementia care: Past, present, and future

The matrix also includes students as studies showed (Nolan et al., 2002a, 2006; Brown et al., 2008) that if students experience an enriched learning environment during their clinical placements, then they are far more likely to choose to go and work with older people than if they experience an impoverished environment, where the Senses are not created. Importantly, the 'Senses' have been developed, refined, and shaped with the active involvement of staff, older people, family carers, and students who have taken part in several studies spanning a number of years (Davies et al., 1999; Nolan et al., 2001, 2002a, 2006; Faulkner et al., 2006; Brown et al., 2008).

Recently, Nicola Hatton (2014, 2016) has taken forward some of the ideas of relationship-centred care and has argued that wider social, environmental, and cultural factors are also very important. Here, Hatton (2016) is developing ideas around the person with dementia's relationships with non-human artefacts, for example through: i) familiar sounds and smells of the care home and how a sense of belonging, for example, can start to be engendered through this sensory exposure; and ii) the use and access to familiar material possession(s) to help give the person a sense of security. This addition, then, opens the door for relationship-centred care to be coupled with embodied selfhood and affect.

Now that we have considered the evolution of relationship-centred care and the Senses, the next section presents a case study that describes an application in a care home setting and where one of the chapter authors (JK) was involved.

Relationship-centred care and the Senses Framework: A case study of the Senses in Practice (SiPs)

This case study is taken from a project that involved two care homes in the North West of England between June 2009 and September 2010 (Keady et al., 2011), though here we concentrate on just one of the homes. The overall aim of the Senses in Practice (SiPs) pilot training programme was to develop a staff education programme reflecting the importance of relationships and providing staff with an opportunity to identify how they might enhance the care of people with dementia using the Senses Framework. Nolan and colleagues (2008) suggest that educational interventions need to be embedded into an organizational culture that provides opportunities for staff to engage in problem solving and promotes relationship-centred care.

The objectives of the SiPs project were to:

- Develop and deliver a training programme that encouraged staff to develop dementia care practice using the principles of relationship-centred care and the Senses Framework to build upon commitment and confidence;

Person- and relationship-centred dementia care: Past, present, and future

- Evaluate the impact of the training programme on the experiences of staff, residents, and families within the home;
- Evaluate how relationship-centred care contributes to the provision of individualized care.

The care home described here was a for-profit development in a residential suburb of the North West of England. The care home had five 'houses' that allowed specialist care and attention, including to residents with dementia, with a total capacity of 150 residents. Four houses were registered for nursing care and one house was registered for dementia nursing care. The care home had single occupancy rooms and offered several different facilities on-site, such as hairdressing. The care home was awarded a Care Quality Commission rating of 2 (good) in the February 2010 inspection. Ethical approval to conduct the study was granted on 2 June 2009 (IRAS reference number 09/H1302/43).

Prior to the training programme, family carers were invited to share some of their thoughts about the care home and care provision, some of which are reproduced below:

- Staff always make me feel very welcome, chat to me during the visit. My husband seems much happier than he was in the last home he was in;
- It would be nice if there were more trips out;
- Recently the carpet and soft furnishings have been renewed. This has made the visiting much more pleasant.

The SiPs training programme

The SiPs training programme comprised eight sessions lasting one hour. The sessions were facilitated predominantly in a designated training room. The sessions were jointly delivered by JK (Professor of Older People's Mental Health Nursing) and CS (Research Associate with a PhD background in dementia care) and followed a similar cycle, with each session focusing on a different Sense and structured as shown in Table 15.2.

Table 15.2 Sessions of the SiPs training programme.

	Title	Activity
1	Knowing why we care: understanding the values and skills we bring to caring.	Completion of attitudes and values questionnaire.
2	Creating a sense of continuity.	The use of life story work.

Person- and relationship-centred dementia care: Past, present, and future

3	Creating a sense of significance in everyday practice.	The use of memory chests.
4	Creating a sense of belonging in everyday practice.	Understanding what home means to people.
5	Creating a sense of purpose in everyday practice.	Understanding how we each define purpose in our everyday lives.
6	Creating a sense of achievement in everyday practice.	Understanding what makes people happy in their lives.
7	Creating a sense of security in everyday practice.	Feeling safe with those around you.
8	Putting it all together.	Discussion of record keeping to reflect how staff implement the Senses Framework for people with dementia.

The training programme comprised a series of interactive workshops where staff were encouraged to consider how important each of the Senses was for them as individuals in their own lives using activities and guided discussions. Staff were encouraged to draw on their personal and professional experiences and were supported in further discussions focusing on how their knowledge and understanding might improve the experience of routine care for people with dementia. Each staff group developed their own definitions of the Senses Framework to support their use in practice (see Table 15.3). The timing of the sessions was carefully negotiated to ensure maximum staff attendance and minimum disruption to the home. Nonetheless, attendance at the workshops fluctuated, although there was always a 'core group' of attendees.

Table 15.3 The Senses Framework and meanings: An overview developed by care home staff.

Sense	For Residents	For Families	For Staff
<i>Purpose</i>	Sense of identity; Individual care.	Recognizing the family's importance of caring for the resident.	Having a goal; Being needed; Being recognized by residents.

Person- and relationship-centred dementia care: Past, present, and future

<i>Achievement</i>	Accomplishment; Being content.	Involving families in the care of the resident.	Developing a life story book with one of the residents; Creating memory boxes with residents and their families.
<i>Security</i>	Familiarity with the environment; Familiar voices; Having keys (such as door keys); Memories; Routines; Stories of 'home' or the place the resident grew up; Directions to bedroom; Photographs and belongings in the bedroom.	Having a key worker to talk to; Knowing the resident is 'safe in the hands of staff'; Having the opportunity to be involved with the activities; Getting to know the staff and who they are; For staff understanding the resident's biography; Staff recognition that not all families want to visit and there are many different reasons for this; 'Christmas families'.	Feeling wanted; Being recognized by residents and their families; Team working (especially between day and night staff); Being flexible; Knowing people; Working on the same unit and developing relationships ('smiling faces'); The joy of caring.
<i>Significance</i>	Being treated as an individual.	Involving families in helping to develop life story books	Accomplishments being acknowledged.

Person- and relationship-centred dementia care: Past, present, and future

		and memory boxes.	
<i>Belonging</i>	Feeling of community; Familiar things, such as photographs and ornaments.	Being included in the running of the home; Being comfortable; Feeling integral to the care home.	'Home' and what 'makes a home'; Being part of the care home culture; Knowing staff and residents; Being comfortable.
<i>Continuity</i>	Routine; Things to do; Developing memory boxes and life story books; Continuity in terms of transition between home in the community and care home; Ensuring the well-being of residents.	Being involved in the resident's care; Being kept up-to-date.	Working on one unit; Learning about residents' life stories.

Reproduced with permission from Nolan, M. R., Brown, J., Davies, S., Nolan, J. and Keady, J. (2006). *The Senses Framework: Improving Care for Older People Through a Relationship-Centred Approach*. Getting Research into Practice (GRiP) Report No 2, University of Sheffield page 125

Through this approach, staff attending the training sessions developed a *Creating the Senses for ...* booklet which could be completed by residents, families, and staff. The purpose of the booklet was to offer insight into the resident's life, such as hobbies and holidays enjoyed. The booklet would be located in the resident's room, giving the resident a sense of ownership and empowerment. Moreover, during the sessions, the value of sensory boxes and memory boxes were discussed, and staff showed a keen interest in pursuing these ideas. Posters were displayed around the care home inviting staff, family members, and visitors to donate sensory items, particularly those with a reminiscence theme. As one of the care home staff shared on the final evaluation form: *'I look at the person [now], not the illness.'* It is a fitting testimony to the power of the Senses and life story work and their potential to transform lives and attitudes. It

Person- and relationship-centred dementia care: Past, present, and future

also provides an insight into how care home staff can develop an individualized activities role that is drawn from the biography of the person with dementia to complement their role in providing physical care.

The above case study was a pilot, but other more intensive interventions have demonstrated the potential for the Senses Framework to significantly improve outcomes for people with dementia, family carers, and staff in care home facilities. For example, a three-year study by Davies and colleagues (2007) actively engaged staff and families in enriching the environment in a care home for people with dementia and resulted in highly significant changes, including:

- The introduction of an activities programme
- Establishing a relatives' support group
- Designing and producing a welcome booklet for new residents and relatives
- Significant fundraising activities to support the work of the home
- The re-instatement of uniforms for staff (at the request of staff and families)
- A regular education programme for staff
- The creation of a 'skills profile' for qualified staff
- The introduction of PAT dog 'Missie'
- The entire re-design of the garden project with the input of local university students
- Significant building modifications.

Adapted from Davies, S., Atkinson, L., Aveyard, B., Martin, U., McCaffery, S. and Powell, A. (2007). Changing the culture within care homes for older people. In Nolan, M. R., Hanson, E., Grant, G. and Keady, J. (Eds.) *User Participation in Health and Social Care Research: Voices, Values and Evaluation*. Maidenhead: Open University Press, pp. 50–68. Copyright (c) 2007 McGraw-Hill.

Similar longer-term projects using the Senses Framework in the community have resulted in the introduction of innovative respite care schemes that have transformed the experiences of people with dementia, families, and staff (Ryan et al., 2008) and in providing a practice lens to view the meaning of interactions for younger people with dementia (Davies-Quarrell et al., 2010). However, these interventions do not represent 'quick fix' solutions and have involved considerable efforts that have fundamentally changed the culture of dementia care, much as was Kitwood's (1997) original goal. We conclude this chapter by looking to the future and suggesting two additional areas where we believe there is a need for culture change and where the Senses may have a role to play. These are the diagnostic process and addressing the needs of people with dementia and their families at a societal level.

Person- and relationship-centred dementia care: Past, present, and future

Wider implications of the Senses

Improving the experience of diagnosis

There is much current interest in the importance and value of an early diagnosis of dementia. For example, the benefits of early diagnosis may include relief from stress due to a better understanding of symptoms, risk reduction, and maximizing decision-making autonomy (Alzheimer's Disease International, 2011; 27). The same report (page 7) also suggested that receiving a diagnosis of dementia should be considered a human right and recommended that 'every country should have a national dementia strategy', with each strategy promoting early diagnosis and intervention through awareness raising, training of the health and social care workforce, and health system strengthening.

In the UK, the topic of early diagnosis is at centre stage of policy. Key commitment 1 of the first Prime Minister's Challenge on Dementia (Department of Health, 2012) was aligned to 'better diagnosis' and increasing diagnosis rates through regular (cognitive) checks for people aged over 65. Such a commitment is currently integrated into commissioning frameworks with financial incentives to reach improvement targets (Department of Health, 2012), set at 75% by 2017 across every area of England (Alzheimer's Society, 2015; 12).

While it could be argued that the current push towards early diagnosis and intervention is both laudable and necessary, the limited numbers of older (and younger) adults actually coming forward for a memory assessment to consider the existence of a dementia remain a cause for concern. For example, only 20–50% of people with dementia living in high-income countries have a diagnosis, with that percentage falling significantly in middle- or low-income countries (Alzheimer's Disease International, 2011; 4). These findings stand in contrast to the 'Value of Knowing' telephone survey (N=2,678) that examined public perceptions and awareness of Alzheimer's disease for adults aged 18 and over in five countries [US, Germany, France, Spain, and Poland: <http://www.alzheimer-europe.org/Research/Value-of-Knowing>; accessed 29 January 2018] where one of the main findings was that more than eight in ten adults—from 85% in Poland to 95% in Spain—said that if they were exhibiting confusion and memory loss, they would go to a doctor to determine if the cause of the symptoms was Alzheimer's disease.

These contrasting findings frame an important question, namely why, despite apparently positive public attitudes towards a diagnosis and increased policy and service attention in this area, does the under-reporting and underdetection of dementia exist? In response, a number of practical, sociological, and organizational explanations have been put forward, including: poor attitudes of general practitioners and primary care towards making a diagnosis (National Institute for Health and Clinical Excellence/Social Care Institute for Excellence, 2006; Manthorpe et al., 2013); stigma surrounding dementia and its diagnosis (MacRae,

Person- and relationship-centred dementia care: Past, present, and future

1999; Alzheimer's Disease International, 2012; Abley et al., 2013); an overall lack of professional knowledge about dementia (Ahmad et al., 2010); a threatening diagnostic process that probes for loss and not abilities (Keady and Gilliard, 2002; Samsi et al., 2014; Campbell et al., 2016); and limited public health information about dementia and its initial onset and presentation, especially as it impacts upon the neighbourhood and informal social networks (Keady et al., 2012; Ward et al., 2017).

All of the above suggests that, in terms of the Senses, there often currently exists an 'impoverished environment' with respect to people's first contact with the 'professional system' and their subsequent experience of the diagnostic process. So, a key question becomes: How can we create an enriched environment for people who suspect they have dementia and their families? We need to begin to explore how we can create a Sense of security when people first present with their fears about their 'memory' so that their concerns are not dismissed as 'just old age'. We also need to address the stigma associated with 'dementia' and, to that end, hopefully the work of people with dementia (e.g. the Three Nations Dementia Working Group, or the European Working Group of People with Dementia) can start to make a real difference. The priorities of the Three Nations Dementia Working Group (2017) are to:

- Bring the lived experience as experts with our personal knowledge of dementia that people value whether in a professional or non-professional capacity. As such our aim is to become the 'go to' group within the three nations (of England, Northern Ireland, and Wales) for anyone seeking input from people with dementia.
- Continue to contribute to society, to give value, advice, and information where required and requested.
- Help each other through mutual support, friendship, and understanding.
- Help all those affected by dementia. We understand your situation.
- Help those who are trying to help us (e.g. policy makers, service providers, academics, researchers, and businesses).

Against such a backdrop where citizenship and the social activism of people with dementia needs to be (rightfully) accommodated, we need to make the diagnostic procedure less potentially alienating and fragmented so that Senses of belonging and continuity are established from the outset.

Enriching the neighbourhood environment

In our view, there is also much that could be done to 'enrich' the community and neighbourhood environment in which people with dementia and their families live (Keady et al., 2012, 2014; Ward et al., 2017). Current strategies have started to take account of the everyday lives of people with dementia that take place in public places and spaces, such as in streets, shops, and civic amenities, e.g. the local leisure centre,

Person- and relationship-centred dementia care: Past, present, and future

cinema, public library, and so on (Alzheimer's Society, 2013). We wish to stress the responsibility that society has (not just professional services or carers) to enrich the life world of people with dementia.

Over the last five years, the rise of dementia-friendly communities has grown into a world-wide movement, with Japan as trailblazer, with many of its dementia-friendly city initiatives and public education campaigns being held up as international models of good practice (Alzheimer's Disease International, 2015). While the notion of what may constitute a dementia-friendly community is open to interpretation (Lin, 2017), Crampton and colleagues (2012) have identified four key dimensions: people, places, networks, and resources, with people living with dementia positioned at the centre of each dimension.

Arguably, it is at this personal-public space interface that relationship-centred care, as expressed through the Senses Framework, can be further developed to include a new dimension for people with dementia and their families—one that we have named 'the Neighbourhood Space'. In charting new directions that would improve the quality of lives for people with dementia and their families, we need to consider how 'the Neighbourhood Space' can be enriched so that people with dementia feel safe to participate more fully and to 'maintain their involvement' (Keady, 1997, 1999) with their community. With subtle additions to the original 'reach' of the Senses Framework, 'the Neighbourhood Space' now adds a further dimension that includes the relationships experienced by people with dementia and their families when living their lives 'outside the front door'. The Neighbourhood Space complements existing relationships with the family carer and care staff. It also sets a challenge for local civic amenities and transport providers, for example, to take into account the cognitive disabilities of dementia, and how these can affect judgment, decision-making, and recall, so that at the very least people with dementia experience a Sense of security in their environment.

However, to truly enrich 'the Neighbourhood Space', we need to address wider questions, such as how the Senses of belonging and continuity for people with dementia and their families be sustained; how we can ensure that they have access to meaningful activities that provide a Sense of purpose and achievement; and perhaps most importantly of all, how we can ensure that people with dementia and their families have a Sense of significance and genuinely feel that they 'matter' to the society in which they live. There is, of course, a significant part that professional and paid carers can play in addressing such questions, but the role of society as a whole is even more important. Extending the notion of a relationship-centred approach to care beyond the 'therapeutic quadrangle' will enable debate to occur at a fundamental level. This debate needs to address the values that society believes should underpin support and help for those in need. And it is a future challenge for us all.

Person- and relationship-centred dementia care: Past, present, and future

Acknowledgements

Dr Caroline Swarbrick and Dr Christine Brown Wilson [at the time], Division of Nursing, Midwifery and Social Work, The University of Manchester for their essential work and roles on the SiPs pilot practice development project and for consenting to this case study being shared in the chapter. Special thanks are also extended to Dr Clive Bowman and BUPA Giving for their funding of the SiPs project, and to all the care home staff who participated in the sessions. Finally, our thanks are also extended to Linda Welch at the Division of Nursing, Midwifery and Social Work, The University of Manchester for her help in preparing the update of this chapter in January 2018.

Psychological treatments

Chapter: Psychological treatments

Author(s): Philip Wilkinson and Ken Laidlaw

DOI: 10.1093/med/9780198807292.003.0016

Introduction

Thirty years ago, a review of psychological treatments in older people concluded ‘therapists of all stances have been slow to respond to the needs of the aged ... exploratory work is beginning, however ...’ (Cooper and Murphy, 1986). The authors noted, in the literature of the time, psychoanalytical approaches predominated while work in cognitive therapy was beginning. Since then, there have been many developments in response to the specific needs of an increasing older population, including tailoring of interventions to embrace cognitive and physical changes, delivery of therapies in age-appropriate settings, and therapies with caregivers of people with dementia. Working psychologically with older people offers specific therapeutic opportunities. For instance, review of life experiences can be a rich therapeutic resource and can help in understanding the older patient’s current difficulties (Thompson, 2011). Providing therapies that include opportunities for social interaction can confer benefits (Pitkala et al., 2011). Engaging the family

Psychological treatments

members of an older person can help to elucidate the beliefs and behaviours of the family that might be influencing the illness and adherence to a treatment plan (Stahl et al., 2016). There is now an optimism for the outcome of psychological therapies with older people and a recognition that the new cohort of ageing baby boomers will ask for more access to psychological therapies.

Psychological treatment studies with older people address a range of outcomes. As well as clinical endpoints such as symptom severity or remission of depression, other relevant outcomes might include impact on activities of daily living and quality of life, caregiver wellbeing, rates of care home admission, rates of progression from sub-syndromal to case-level illness, or prescribing rates of potentially harmful antipsychotic medication in dementia.

Older patients and their clinicians, in considering psychological treatment, need to be aware of their wide range of potential benefits and applications; these are summarised in Box 16.1. The aims and methods of different therapies overlap. For example, in both cognitive behaviour therapy (CBT) and interpersonal therapy (IPT), an important step in treating a depressed dementia caregiver might be to establish a new social network and, although the goal is the same, the two therapies will employ different techniques to reach it. This chapter provides an overview of the range of efficacious psychological treatments for older people with consideration of indication, access, and adaptation. CBT and IPT are reviewed in depth in Chapter 17 and Chapter 18.

Box 16.1 Indications for psychological treatments with older adults

- Patient preference, as an alternative treatment to medication, e.g. in the treatment of an anxiety disorder;
- To augment the effect of psychotropic medication, e.g. in the treatment of a depressive disorder;
- Prevention of progression from subsyndromal depression to case-level depression;
- Prevention of recurrence of depression;
- As part of a collaborative care intervention in the treatment of depressive illness;
- To foster adherence to medication, e.g. in the treatment of bipolar disorder;
- To avoid the use of potentially harmful medication, e.g. in managing behavioural symptoms of dementia;
- To help distressed caregivers, e.g. treating a dementia caregiver experiencing depressive and anxiety symptoms.

Psychological treatments

Box 16.2 lists some of the therapies currently used with older people. Treatments can be divided into those devised specifically for older adults (usually to help patients with dementia) and those also used with younger adults (such as treatments for depression). Therapies in the first category include reminiscence therapy, validation therapy, and reality orientation. These were some of the first treatment approaches to be formalized and evaluated, starting in the 1960s. Reminiscence therapy uses group discussions, photographs, recordings, and objects to trigger personal memories and promote wellbeing. Many of the early trials used in their evaluation have significant shortcomings by today's methodological standards. A more recent large multicentre study of reminiscence groups for people with dementia and their family caregivers did not provide support for the efficacy or cost-effectiveness of reminiscence groups (Woods, Orrell, et al., 2016).

Box 16.2 Some of the psychological treatments used with older adults

- Cognitive behaviour therapy
- Problem-solving therapy
- Interpersonal therapy
- Systemic therapy
- Psychoanalytic and psychodynamic psychotherapy
- Reminiscence therapy
- Cognitive stimulation therapy
- Cognitive training
- Cognitive rehabilitation

There is now an increasing distinction between interventions that are of high intensity and low intensity. High-intensity interventions include CBT or IPT delivered by a therapist face to face (National Institute of Health and Care Excellence, 2017). In these, the therapist has flexibility in treatment delivery according to a formulation of each individual's problems. In contrast, low-intensity therapies are usually briefer, based on generic protocols for specific disorders, and typically involve guided written or audio-recorded self-help materials or Internet-delivered strategies supported by a therapist. The recent expansion of low-intensity interventions reflects a move to increase the availability of psychological treatments while limiting the costs of training therapists. In the UK, the Improving Access to Psychological Therapies (IAPT) programme was established ten years ago to provide high- and low-intensity interventions for depression and anxiety (Department of Health, 2013; www.england.nhs.uk/mental-health/adults/iapt/). Interventions may also be incorporated into stepped care programmes, whereby more intensive

Psychological treatments

interventions are reserved for people not responding to low-intensity steps (van't Veer-Tzelaar et al., 2009). When able to access treatment via IAPT, older people tend to make good recoveries with low levels of attrition from treatment (Chaplin et al., 2015).

Making psychological treatments available to older people

Pettit and colleagues (2017) found referral rates of older adults to an IAPT service to be lower than those of younger adults. The proportion of those attending first treatment and showing clinical improvement increased with age. Several barriers to referral were suggested, including older patients' own perceptions of psychological treatments and communication problems between patients and doctors. Box 16.3 shows suggested methods for overcoming these barriers. Means of improving patients' access to treatment also include cognitive bibliotherapy (DiNapoli and Scogin, 2014) and Internet-based systems which appear to be acceptable to patients (Choi et al., 2014). However, the benefits of Internet delivery with or without support by a therapist are unclear (Olthuis, 2016). Delivery of therapy by telephone may overcome obstacles to access and stigma, although it is preferable to start with face-to-face sessions to establish a therapeutic rapport (Blanco et al., 2012). Therapy by telephone can pose additional challenges, e.g. being unable to observe non-verbal communications, and a greater susceptibility to distraction. Older patients favour an active rather than reflective participation in psychological treatment, an acknowledgment of spirituality, and discussion of their shame in seeking help (Dakin and Arean, 2012).

Box 16.3 Steps to increase the uptake of psychological treatment services by older people

- Increase the range of referral routes, such as via social services
- Offer a choice of venue
- Use age-appropriate advertising of services, such as posters in community centres
- Ensure that therapists understand lifespan development and needs of older people
- Provide interventions that give regard to long-term medical conditions

Department of Health, 2013. © Crown Copyright 2013

A significant development in recent years is the use of collaborative care interventions with older adults. These multicomponent interventions include, for example, programmes to treat major depression and dysthymia (Hunkeler et al., 2006) or to prevent progression from

Psychological treatments

subsyndromal to case-level depression (Gilbody et al., 2017). A key feature of a collaborative care intervention is the involvement of a case manager who delivers an intervention, e.g. problem-solving therapy or behavioural activation, while monitoring the patient's symptoms and providing a bridge between primary and secondary care services.

Taking account of sensory and cognitive changes

Deficits in verbal reasoning, speed of responses, and sensory function may result in difficulty understanding the complex verbal content of some psychological treatments. Therefore, evaluation for psychological treatment should include at least a brief assessment to look for possible deficits (Gallagher-Thompson and Thompson, 2010). Frequently asking patients to summarize their understanding of therapy sessions also helps the therapist to check a patient's understanding of therapy. Use of cued recall and recognition memory ('say it, show it, do it') also help to compensate for any deficits in spontaneous recall. Sensory deficits can often be circumvented by using technical aids or by audio recording therapy manuals for visually impaired patients. It is possible that psychotherapeutic strategies directly targeting deficits in planning and organizational skills may help to enhance response to antidepressant treatment (Pimontel et al., 2016). Adaptations of CBT and IPT are discussed in Chapter 17 and Chapter 18.

Psychological interventions in dementia

Psychotropic medications are known to be of limited benefit in treating depression and anxiety in dementia (Orgeta et al., 2017), so there is a need to develop and evaluate psychological approaches. The evidence for psychological interventions in dementia care has generally been derived from short-term studies, leaving a need for larger trials whose findings are applicable to real-world clinical settings and populations, including caregivers (Department of Health, 2011). There is also a lack of evidence of benefit on important outcomes such as quality of life and activities of daily living and a paucity of data on long-term efficacy and cost-effectiveness of psychological treatments in dementia (Orgeta et al., 2015). Cognitive behavioural and interpersonal therapy interventions for depression and anxiety in people with dementia and for caregivers are reviewed in Chapter 17 and Chapter 18 and interventions for people with dementia living in care homes are reviewed in Chapter 19.

Box 16.4 summarizes psychological treatment approaches to improve cognitive symptoms of dementia. Group cognitive stimulation therapy (CST) appears to boost cognitive function in people with mild to moderate dementia, although the duration of any benefits is unclear (Woods, Aguirre, et al., 2012). A model of CST adapted to improve access by enabling delivery by a caregiver or friend has been evaluated in a large study in the UK National Health Service (Orrell et al., 2017): no benefit

Psychological treatments

was demonstrated in terms of cognition, quality of life, or caregiver wellbeing.

Box 16.4 Psychological treatment approaches to enhancing cognitive function

- *Cognitive stimulation*: Engagement in a range of group activities and discussions to enhance cognitive and social functioning.
- *Cognitive training*: Guided practice with individuals or groups on tasks to enhance particular cognitive functions using pencil and paper or computerized exercises.
- *Cognitive rehabilitation*: Individual therapy to address personally relevant goals with an emphasis on improving performance in everyday life, rather than on cognitive tests.

Source: data from Clare L., Woods RT. Cognitive training and cognitive rehabilitation for people with early-stage Alzheimer's disease: a review. *Neuropsychological Rehabilitation*, 14: 385–401. 2004, Taylor & Francis.

Systemic therapy approaches can lend useful perspectives in working with families coping with dementia. In systemic approaches, the family's beliefs and behaviour are understood as connected in a circular, rather than a linear, relationship (Anderson and Ekdawi, 2010). For instance, when a caregiver is known to be critical of a person with dementia who has become depressed, the criticism is not seen as the direct cause of the depression but as part of a dynamic interaction between both people's behaviours and emotions. This is illustrated in Fig. 16.1 and Fig. 16.2 in the case of Tom, a man with dementia, his wife Bertha, and their daughter. This perspective can help to facilitate communication when different views are held within a family; furthermore, it is useful when clinical staff have raised concerns about difficulties between family members. Principles of systemic therapy can be employed in routine meetings with patients and families by giving consideration to seating arrangements to facilitate connections, framing of questions to help generate goals, and by talking separately to different members in the family group in order to encourage reflection (Anderson and Johnson, 2010).

Introduction

Cognitive behavioural therapy (CBT) for older people is a mainstream treatment option for common mental health problems, e.g. depression and the anxiety disorders. CBT is particularly applicable as an intervention with older people as it is a problem-focused, skill-enhancing, individually empowering, present-oriented, straightforward-to-use method.

Over our professional careers, we have seen some important myths and misconceptions disproven about CBT with older people. The former consensus was that older people would not be amenable to modifying their thinking (cognitive restructuring) sufficiently for treatment to be effective; this clearly is not the case (Gould et al. 2012a,b; Wilson et al., 2008). Rather than being a natural outcome of the challenges associated with ageing, depression appears to be less common in older people and especially so when compared to working age adults, and Blanchflower

Cognitive behavioural therapy

and Oswald (2008) indicated that ‘Happiness is approximately U-shaped throughout the life-course; mental distress tends to reach a maximum in middle age’. Additionally, practitioners thought that older people would not want ‘talking cures’; on the contrary. For example, in primary care settings in particular, older people view psychological therapy as effective and as acceptable as medication but with fewer unwanted side-effects and, if given a choice, prefer to receive psychotherapeutic treatments rather than psychotropic medications (Gum et al., 2006; MacKenzie et al., 2008). As cohorts of older people change, we expect to see the use of CBT increase.

Another misconception was that older people are ‘too set in their ways’ to change. Data from longitudinal studies from gerontology (the science of ageing) testifies that emotional change occurs across our entire lifespan, and as one ages emotional regulation improves along with the experience of better emotional stability (Carstensen et al., 2011). One could argue that older people make better candidates for CBT because of having both positive and negative experiences across the lifespan; as a consequence, they may be more understanding of their own, and others’, frailties and of their own personal resources. Indeed, recent data from the National Health Service in England—where older people can access Improving Access to Psychological Therapies (IAPT) services—suggest older people achieve good treatment outcomes in comparison to working age adults (Chaplin et al., 2015). Based on national clinical data, on average, older people are recorded as having recovery rates of 64.3% compared to 50.1% for working age adults after a course of treatment (NHS Digital, 2017).

Cognitive behaviour therapy (CBT)

CBT was originally developed by A.T. Beck in the 1970s and subsequently applied successfully with older people by Thompson and colleagues in the 1980s (Gallagher-Thompson and Thompson, 2010). CBT has an elegantly simple model: the way one thinks about a problem has an impact upon one’s feelings and behaviours. CBT considers physical and psychological states to be two sides of the same coin and thus each affects the other (Laidlaw, 2015). When one is physically low one often feels psychologically low: think of a time when you have a very bad head cold, and you may understand. This simple model is very commonly known as the four components model of CBT (Fig. 17.1). In this example, Mr Adams, who has Parkinson’s disease, thinks people are looking at him and when he attempts to put air in his car tyres at the local garage this sets off a negative reaction. As can be observed, a negative vicious cycle ensues, with his negative thoughts generating negative effects and a subsequent deleterious impact on behaviour. At the same time, physical changes, e.g. increased heart rate and other negative sensations, convince him that he is inadequate to the task. CBT therapists use the model to identify cognitions and behaviours to focus upon in treatment.

Cognitive behavioural therapy

Fig. 17.1
Four components model of CBT.

Fig. 17.1 helps the patient understand the reciprocal nature of connections between thoughts, feelings, behaviour, and the physical state. Therapists alert their patients to the fact they can change the way they think about things and the way they behave. If thoughts and behaviours are connected to feelings and to physical consequences, then changing one element in this cycle can lead to change in everything. This model is used to socialize patients into the particular approach to symptom change adopted within CBT.

The model reminds us of another integral part of the CBT model, which states that it is not the *situation* that is problematic, per se, but how one *views* the situation that causes problems. This idea is not a new one—the stoic Epictetus said that ‘Men are disturbed not by things, but by the views which they take of them’. So, for Mr Adams, it is his thoughts that cause the problem, rather than the act of checking his tyres.

The central concept of the cognitive behavioural model is that emotional states, both positive and negative, are determined by the way in which the person processes information about the self and the world around. Negative automatic thoughts fuel unpleasant emotional states and particular patterns of behaviour which, in turn, maintain distorted thinking patterns (Beck et al., 1979). Unhelpful negative thinking patterns may be triggered by events in the outside world, but underlying these are belief systems, or assumptions, that are often quite specific to the individual. Older people may hold personal beliefs that were helpful to them in their younger years, but that give rise to problems in the face of negative life events or impoverished social circumstances in later life (James, 2010). For instance, an older woman who holds the belief ‘my place is in the family’ may lead a contented life for many years, only to become depressed when her adult children and grandchildren move away from her area, leaving her on her own.

In CBT, information about the patient’s thought patterns and underlying beliefs are used to derive a case formulation. A formulation can be thought of as a jigsaw puzzle that brings together pieces of information in

Cognitive behavioural therapy

order to see the full picture. Formulations describe how an individual experiences the world and responds habitually to challenges and difficulties. They incorporate the information about a patient that is important for understanding how the person is affected by their current difficulties and what may be important idiosyncratic appraisals the individual is prone to making. Formulation in CBT recognizes that there are overt elements (thoughts, feelings, behaviour) and covert elements (core beliefs and conditional beliefs, also known as maladaptive belief structures, or schemata). Developing a formulation with a patient is helpful at the early stages of therapy in order to predict difficulties and identify potential obstacles to a good outcome. Fig. 17.2 shows a depression formulation schematic based on the Beck model of CBT, which is the most commonly used CBT format.

Fig. 17.2

Beck model of CBT and formulation diagram for depression.

A formulation in CBT helps the therapist and patient to reach a shared understanding of why and how an episode of depression or anxiety has come about, devise therapeutic interventions, and keep the therapy on track. This formulation-driven approach to treatment is combined with an empirically based treatment protocol specific to the disorder in question. Formulations can take many forms, according to the needs of the patient and the aims of the intervention (James, 2010). CBT is usually delivered to the patient as an individual; when it is used as a group treatment, there is a greater emphasis on the disorder-specific formulation than on individual formulations.

When working with older people there may be a need to take account of age-related factors. Laidlaw and colleagues have produced a comprehensive conceptualization framework (CCF; see Laidlaw et al., 2004) to help therapists apply CBT with older people by providing a way of framing or contextualizing problems within the standard CBT model. The main elements of the CCF (Fig. 17.3) are cohort beliefs, transition in role-investments, intergenerational linkages, the sociocultural context,

Cognitive behavioural therapy

and health status. Each element serves to broaden the understanding that a therapist will draw on when working with older people. The therapist may find that some elements are more important than others when contextualizing the nature of the client's difficulties.

Fig. 17.3
Comprehensive conceptualization framework for CBT with older people.

The CCF emphasizes the importance of considering cohort values when working with older people. This is the idea that beliefs held by older people may be influenced by society and the generation into which they were born. In many cases, a patient will be four to five decades older than their therapist, and as such there will be differences in values, cultures, and understandings. Typically, these beliefs begin in childhood and are reinforced over the years. For example, there could be an important interaction between generational beliefs held by a cohort born during the 1930s in the UK, e.g. 'stand on your own two feet' (meaning it is wrong to ask for help), and cohort familial beliefs transmitted as family rules, e.g. 'never wash your dirty linen in public' (meaning remain circumspect about discussing emotional difficulties), or 'older people must not be a burden on their families', as well as ideas about illness such as 'depression is shameful'. These beliefs may become apparent in the early sessions of CBT if the patient seems reluctant to engage in treatment.

CBT involves an active exchange of ideas between patient and therapist, with the therapist able to draw upon a range of cognitive and behavioural techniques to help the patient to identify maladaptive thoughts and beliefs in order to modify unhelpful behavioural and emotional responses to situations. Negative thoughts may be tackled directly through diary monitoring or through the use of behavioural experiments. These are planned activities undertaken by patients in order to disconfirm existing unhelpful thoughts and provide evidence for new, more adaptive thoughts. Many of these exercises, or *homework*, are carried out between therapy sessions by the patient and backed up with written notes and records.

The competent delivery of CBT requires the therapist to work collaboratively with the patient. Treatment is supported by therapist

Cognitive behavioural therapy

supervision and use of therapist competence measures (Roth and Pilling, 2007). Measurement scales are used to assess the severity of the patient's symptoms as well as changes specific to CBT, such as the patient's thinking style and core beliefs. In the last decade a number of anxiety measures specifically for use with older people have been developed (Yochim et al., 2011). The Royal College of Psychiatrists' Faculty of Old Age Psychiatry (RCPsych, 2012) produced a useful assessment guideline for individual patient outcome measurement.

CBT in the treatment of depression with older people

A large body of evidence now supports the efficacy of CBT as a treatment for depression with adults of working age (NICE, 2018). Individual CBT is as efficacious as antidepressants in reducing symptoms of depression in people with mild to moderate depression and produces more enduring benefit than antidepressant treatment alone. CBT also appears to be better tolerated than antidepressants. Adding CBT to antidepressant treatment can also improve outcome in more severe depression and possibly in chronic depression and is well tolerated by older people (Hanson and Scogin, 2008).

There are a number of published clinical trials of CBT for late life depression. Most of these, however, have methodological shortcomings, e.g. small sample sizes, reliance on relatively young media-recruited participants, absence of suitable control groups, absence of robust intention-to-treat designs, and unspecified treatment protocols (Gould et al., 2012b). Comparison groups in these trials include other psychotherapies in individual and group format, placebo, waiting list, and antidepressant medication. Evidence reviews for the updated NICE Depression Guideline (2018) found data from five randomized controlled trials (RCTs) showing a positive effect of CBT in treating depression in people aged 60 and over compared with waiting list or treatment as usual, and data from two studies providing evidence of benefit in inducing remission. The benefits in older adults appeared stronger than in adults under 60, but these differences did not achieve statistical significance. Statistically significant data indicated that older people are less likely to drop out of treatment with CBT than younger adults. The authors of one of the studies included in the NICE review (Serfaty et al., 2009) conclude their results discredit the myth that depressed older people are simply lonely and only lack a listening ear to recover, as those in their talking control group did less well than those in the CBT treatment group. Group CBT has also been evaluated in the prevention of depression recurrence (Wilkinson et al., 2009), but currently there is insufficient evidence from which to draw any clear conclusion on its efficacy with older people (NICE, 2018). There remains a need for large, high-quality RCTs of CBT to assess the effectiveness and cost-effectiveness of CBT, including in combination with antidepressant medication, in people aged 75 and over.

Cognitive behavioural therapy

Content of CBT in the treatment of depression

CBT is a uniquely constructed format of psychological therapy with each CBT session sharing identical structural elements. The format of a typical CBT session includes agenda setting (identifying the focus of the session), a bridge between sessions (ensuring continuity of focus), symptom monitoring, review of previous homework tasks completed outside of the session, a focus on current problems, and agreement to work collaboratively. Behavioural strategies are used early on in treatment with the aim of making some immediate positive impact on mood and helping the patient to engage with therapy. Activity monitoring using a simple diary can show patients how inactivity worsens low mood and the effect of negative thinking on underestimating achievement and enjoyment. A typical course of individual CBT for depression lasts up to 16 sessions and involves cognitive and behavioural elements. Treatment is usually divided into early, middle, and late stages. The aims of the early stage of CBT treatment are to both establish a sound therapeutic alliance as well as a shared understanding of problems so these may be translated into goals for treatment. At the end of this stage it is usual to have shared a formulation with the patient. In the middle stage of CBT, there is an emphasis upon cognitive and behavioural change. During this stage of treatment there is a great focus on identifying and challenging maladaptive negative thoughts (termed cognitive restructuring). The primary aim of CBT is symptom reduction and this stage equips the patients with the skills to bring about such change.

Cognitive restructuring is usually achieved through the use of specific thought diaries completed by the patient as a homework task. Fig. 17.4 shows a clinical example. Mr. Gordon is recently retired and decides he wants to enrol in a short course. He is worried that at his age this would be beyond his capabilities. The therapist helps Mr. Gordon find ways to 'answer' negative thoughts using the diary with the assumption this skill will generalize into everyday use. In challenging negative thoughts (cognitions), patients are taught certain skills to use, e.g. looking for evidence for and against their thoughts. Additionally, the patient can ask himself what is an alternative way to think about this situation. The basis of cognitive restructuring is that there is always more than one way to think about a situation or an experience.

Cognitive behavioural therapy

1. What actual event or thoughts, or decisions or reactions led to the unpleasant emotion?	1. What thought(s) and/or image(s) went through your mind?	1. What emotion(s) (distress/anger/etc) did you feel at the time?	1. Use questions at bottom to compare a response to the automatic thought(s).	1. How much do you now believe each automatic thought?
2. What (if any) decreasing physical sensations did you have?	2. How much did you believe each one at the time?	2. How intense (0-100%) was the emotion?	2. How much do you believe each response?	2. What emotion(s) do you feel now? How intense (0-100%) is the emotion?
3. What (if any) increasing physical sensations did you have?	3. What (if any) increasing physical sensations did you have?	3. What (if any) increasing physical sensations did you have?	3. What (if any) increasing physical sensations did you have?	3. What will you do for the first time?
Talking on the telephone about starting an OCU (openings course)	When I'm not capable of doing it	Anxiety Frustration 90%	I've done a lot of courses over my lifetime and managed most of them. I have successfully completed 90% of all courses in my life. By focusing on how well I do I am focusing on a positive aspect of what I am aiming for. I won't know if I don't try	Worried but calm Anxiety 50% I will start the course

Fig. 17.4

Dysfunctional thought record in CBT: example of Mr Gordon.

The final stage of therapy encompasses two main tasks to accomplish; (1) the agreement of an appropriate termination point for therapy, and (2) the elaboration of a relapse prevention plan. In this stage the therapist is empowering the patient to become their own therapist outside of treatment.

Behavioural activation (BA)

Behavioural activation (BA) can be used as a component of CBT or as a stand-alone intervention in depression. It aims to overcome the lack of response-contingent positive reinforcement in depressed patients' lives. Negative life events are seen as decreasing the likelihood of adaptive behaviours for vulnerable individuals, which leads to a downward spiral of low mood and a decrease in motivation (Martell et al., 2010). The key strategy in BA is that frequency and occurrence of pleasant events are increased. Graded exposure and graded hierarchies are necessary tools to help a client get started on activities and problem solving is also necessary in order to overcome practical obstacles that may prevent the client from engaging in tasks. Depressed individuals are more likely to be sensitive to negative stimuli, and BA aims to increase the likelihood that beneficial patterns of behaviour will be positively reinforced. Small studies of BA with older people suggest benefit in reducing depressive symptoms, but further better-quality trials are needed (Orgeta et al., 2017).

Problem-solving therapy (PST)

Problem-solving therapy (PST) is a brief, active, goal-oriented intervention related to CBT. It can be used as a stand-alone treatment or its methods can be incorporated into a course of CBT. It offers a practical approach to overcoming the inactivity and impaired problem solving and decision-making that occur in depression. Patients are supported in generating and testing out a range of possible solutions to the difficulties they are encountering. For older people experiencing long-term illness, these solutions will take the form of practical adaptations to foster adaptation to disability. PST appears to reduce depression severity in

Cognitive behavioural therapy

older people, but more studies are needed to assess its effects on mood and disability (Kirkham et al., 2016).

CBT for late life anxiety disorders

The UK National Institute for Health and Clinical Excellence (NICE) concluded that CBT is an efficacious treatment for generalized anxiety disorder and panic disorder in younger adults (NICE, 2012). Research into treatments for anxiety disorders in older people, however, lags behind that in younger adults, and NICE, while recommending CBT to treat anxiety disorders in adults of all ages, makes no recommendations specific to older people. Most trials with older people have been published in the US and there are methodological issues as many studies enrol people in their 60s and 70s, rather than older people who may be routinely seen in clinical practice (Gould et al., 2012a). Stanley and colleagues (2009), in an RCT treatment for generalized anxiety disorder (GAD), has answered many of these criticisms with a study conducted in primary care settings showing good treatment outcome. Wuthrich and Rapee (2013) and Wuthrich and colleagues (2016) demonstrated that CBT is efficacious for comorbid anxiety disorder and depression—research especially welcome as it provides important outcome data for CBT with older people that is closer to the experience of treatment in routine clinical settings. Finally, Kishita and Laidlaw (2017) published the first meta-analysis comparing CBT outcome for GAD between older people and working age adults. This study confirms that CBT with older people is as efficacious for GAD as with adults of working age.

Content of CBT in the treatment of anxiety

While there is overlap between anxiety and depression in terms of symptoms and cognitions (negative predictions and a negative bias in appraising current experiences), in anxiety the negative appraisals tend to be more selective and specific to certain situations (Beck et al., 1985; Worlitzky-Taylor et al., 2010). The experience of anxiety may also tend to increase the probability of the feared event occurring. For example, a socially anxious patient may hesitate in social situations, thereby undermining social performance. There are a number of disorder-specific models of anxiety disorders. For instance, according to the cognitive model of panic disorder, sufferers misinterpret physical sensations of anxiety as signs of imminent physical catastrophe (Clark, 1986). In health anxiety, patients are afraid of having an undiagnosed serious illness; they monitor and overinterpret physical symptoms and engage in safety-seeking behaviours that exacerbate their anxiety (Silver et al., 2004). Patients with GAD experience a number of fears about their everyday circumstances and engage in repetitive worry in an attempt to solve problems. CBT for GAD focuses less on the content of worrisome thoughts and more on changing the process of managing worries.

Cognitive behavioural therapy

CBT in the treatment of patients with physical illness

In a classic text, Rybarczyk and colleagues (1992) outline five elements that therapists need to take into account when working with physical illnesses in depression and anxiety disorders: (1) practical barriers to participation in therapy; (2) accepting depression as a separate but reversible problem distinct from their ongoing physical problems; (3) identifying and limiting excess disability; (4) recognizing and limiting losses of roles and autonomy; and (5) challenging perception of oneself as a burden to others. CBT can be a good fit for older people living with long-term physical conditions as it encourages self-efficacy in the management of their condition and often provides a problem-solving approach to the challenges of living with a long-term condition. CBT has been shown to be efficacious for depression in a number of physical conditions. For example, Dobkin and colleagues (2011) evaluated CBT for depression in Parkinson's disease. The CBT group reported significantly greater reductions in Hamilton depression (HAM-D) scores, and significantly more treatment responders at the end of treatment (56% versus 8%) in comparison to the group who received clinical monitoring only. Evidence for the efficacy of CBT for post-stroke depression is currently limited to two small trials (Kneebone and Jeffries, 2013; Thomas et al., 2013) and more research is necessary. A recent review of the efficacy of CBT for chronic obstructive pulmonary disease (COPD; see Baraniak and Sheffield, 2011) reports mixed findings on the outcome for CBT for depression but small effects of CBT for anxiety in COPD. A meta-analysis of RCTs of CBT and problem-solving therapy for depression in people with a range of physical illnesses (Beltman et al., 2010) showed benefits of CBT with similar effect sizes across different physical conditions.

CBT with dementia caregivers

Identifying and managing depression in caregivers is important as it is associated with increased breakdown of care and unhelpful caregiver behaviours (Cooper et al., 2010). NICE (2006) evaluated data from two systematic reviews and 25 trials and concluded that there is evidence of effectiveness of CBT on symptoms of depression and anxiety in caregivers who have clinically significant symptoms. The review also concluded that therapy for the carer can improve the mental state of the person being cared for and delay the move to institutional care. Reframing of negative automatic thoughts appears to be an active ingredient of therapy, at least in reducing caregiver depression and anxiety (Vernooij-Dassen et al., 2011). There are also descriptions of mindfulness-based cognitive therapy (MBCT) used with dementia caregivers (Franco et al., 2010; Oken et al., 2010) and with the person with dementia along with their caregiver (Kemp et al., 2016)

Overall, the evidence for dementia caregiving suggests active interventions are more effective than passive interventions. CBT is most beneficial when targeting specific symptoms of depression and anxiety.

Cognitive behavioural therapy

While psychoeducation improves subjective wellbeing, it is effective in reducing distress only if it is active. Two comprehensive reports have confirmed the efficacy of CBT for caregivers. Funded by the US Veteran's administration, Goy and colleagues (2010) published a systematic review of the evidence base of interventions aimed at non-professional carers (informal caregivers). In the UK, Elvish and colleagues (2012) examined the evidence for psychosocial interventions with caregivers and provided sound recommendations when working with caregivers.

CBT for people with dementia

Evidence for the efficacy of CBT in anxiety and depression in dementia is intriguing and comes from a range of small clinical trials and case studies that suggest that, at least in the mild to moderate stages of dementia, CBT may be efficacious in reducing depression and anxiety (see Orgeta et al., 2017 for review). In the UK, a small trial of CBT reported very promising results (Spector et al., 2015). In the US, a recent development of Problem Adaptation Therapy (PATH) by Kiosses and colleagues (2011) has shown promising results around a 12-session home-delivered intervention based on PST that recruits caregivers as co-therapists. Kiosses and colleagues (2015) carried out a reasonably large RCT of PATH and reported potentially exciting results for a new CBT approach, although the study needs replication and extension as the data only report outcome at 12 weeks' end of treatment and no follow-up. Currently, we are at an exciting stage of development in CBT; there is potential to extend this form of treatment to people facing the often-difficult transition after diagnosis with a dementia.

Interpersonal psychotherapy

Chapter: Interpersonal psychotherapy

Author(s): Philip Wilkinson and Ken Laidlaw

DOI: 10.1093/med/9780198807292.003.0018

Introduction

Interpersonal psychotherapy (IPT) is based on the straightforward observation that depression has a negative impact on relationships (Weissman et al., 2000). Fundamental to IPT is the assumption that interpersonally relevant life events increase an individual's vulnerability to developing depression, and depression itself may worsen or, at the very least, maintain interpersonal problems (Hinrichsen and Iselin, 2014). The model does not ignore the biological underpinnings of depression or the role of physical treatments, but it places the emphasis of intervention within the interpersonal domain. IPT is informed by attachment, communication, and social theories (Weissman et al., 2000). Early experiences and unmet attachment needs are seen as important in the aetiology of depression. Interpersonal problems are classified into four categories: complicated bereavements, role transitions, interpersonal disputes, and interpersonal deficits. A role transition may be the loss of a role, e.g. retirement from work, or the acquisition of a new role, e.g.

Interpersonal psychotherapy

becoming a carer for a spouse with dementia. A role dispute is a conflict in a relationship that may occur, for instance, when an older person dealing with ill health resists accepting the practical and emotional support offered by an adult son or daughter.

IPT aims to reduce symptoms of depression by helping patients to better manage interpersonal problems and by improving social functioning. Symptoms are linked to interpersonal events and interactions in order to discover ways to improve communication and repair or build social supports (Ravitz et al., 2013). Understanding the patient's culture is important, and we must grasp how they believe their depression has been caused and how they would usually approach this type of problem. IPT interventions consist of behavioural change methods, enhanced communication analyses, and encouraging expression of emotions, among other techniques. The therapeutic relationship is considered important in IPT (Hinrichsen and Iselin, 2014).

Applications of IPT

Early practitioners of IPT were quick to see the relevance of the model to late-life depression (Sholomskas et al., 1983). It has since been used in post-stroke depression (Finkenzeller et al., 2009) and there is proof of concept of IPT as an intervention for depressed older people with suicidal ideation (Heisel et al., 2015). IPT has also been developed for Internet delivery (Donker et al., 2013).

Treating depression without cognitive impairment

IPT follows a set structure, the plan and time frame being made explicit from the start. Lemma and colleagues (2007) outline the competences necessary for effective IPT (see <http://www.ucl.ac.uk/clinical-psychology/competency-maps/ipt-map.html>). Initial sessions focus on the patient's styles of communication and attachment (secure, avoidant, or anxious) and include a detailed survey of relationships. These not only include family and social relationships but also those with other key people, e.g. professionals. Education on the nature of depression is given with an emphasis on depression as an illness and, in the initial stages of therapy, patients are encouraged to accept the 'sick role' and the limitations their depression places upon them. Identifying with the 'sick role' helps a patient lessen self-blame. Nevertheless, during this phase of treatment, the therapist encourages the patient to address their current problems. Sessions three to 12 use specific techniques to work on the identified foci and sessions 13 and 14 are for review and planning for the future (Stuart and Robertson, 2012). The most common IPT problem with older people is role transition, as late life is commonly a time of both role loss *and* acquisition (Hinrichsen and Clougherty, 2006). Within the theoretical model of IPT, various therapeutic techniques can be employed to tackle the identified problems. These include facilitation of expression of mood, problem solving, and cognitive strategies aimed at the patient's attitudes to roles and relationships. Sometimes directive and practical

Interpersonal psychotherapy

interventions may also be useful, such as help with transport or finances. Fig. 18.1 shows how problem-solving methods may be used in IPT.

Fig. 18.1
An overview of problem solving in IPT.

Few adaptations are necessary when using IPT with older people without cognitive impairment. Hearing acuity and educational status should be taken into account and sessions may need to be shortened for medically ill patients. It may also help to involve the spouse or any other significant person in evaluating interpersonal problems, and telephone top-up sessions may be beneficial (Miller, 2008).

IPT can also be provided in group format. Before group sessions begin, the patient receives two individual sessions for assessment and preparation for the group. In group format, psychoeducational aspects of treatment are strengthened and participants can join one another in applying therapeutic techniques, e.g. decision analysis (Scocco et al., 2002), while the forum can provide practical and empathic interactions between group members (Robertson, 2004).

Dealing with grief and loss

Grief and loss are the reactions that may give rise to depression in response to the death of a significant person or people. The therapist's role is to facilitate the grieving process by clarifying the nature of the relationship with the deceased and by helping the patient look for alternative supports and interests. Complicated grief reactions might be

Interpersonal psychotherapy

precipitated by the loss of apparently unimportant figures because of unexpressed grief relating to losses much earlier in life (Frank et al., 1993). IPT aims to help the grieving patient relinquish the attachment to the lost figure, to communicate the loss to others, and to develop new attachments (Stuart and Robertson, 2012). A grief reaction may be for a spouse who has become disabled or has dementia. In this situation, IPT helps the patient maximize the remaining positive aspects of the relationship, grieve for what has been lost, and to give support in making the most of the social network. When working with a patient facing his or her own death, an anticipatory grief approach might be taken to help engagement with the social network and by putting affairs in order.

Dealing with role disputes

Role disputes are interpersonal struggles typically with the partner or other family member and may become apparent when older people suffer disabling physical illnesses. Role disputes both contribute to depression and are made worse by the social withdrawal associated with depression. The therapist's role is to help the patient to understand his or her role in the dispute, link it with the depression, and then to take a problem-solving approach to change aspects of the relationship. It may be that the problem can be overcome if communications are improved, or in some cases it may be that the relationship cannot be repaired. With older adults, it is often preferable to try to bolster a relationship rather than risk a significant loss. For some couples, the potential for role disputes declines as they grow more comfortable together in late life; in others, there is increased interpersonal tension due to illness burden and increased proximity, or caregiving for a dementia spouse. Sometimes role disputes involve ill or financially dependent children or grandchildren (Stuart and Robertson, 2012).

Dealing with role transition

Role transition means a shift in an interpersonal role such as retirement or increased dependency on an adult son or daughter after the onset of chronic illness. The therapist helps the patient to understand the link between the role transition and depression and to look for positive as well as negative aspects of the transition to help the patient develop a greater sense of mastery in the new role. During IPT with older adults, an initial focus of role transition often resolves, only to reveal more long-standing role disputes, often with the spouse (Miller and Reynolds, 2002).

Dealing with interpersonal deficits

Interpersonal deficits (or interpersonal sensitivity) is the least validated of the four problem areas in IPT and is usually avoided as the therapeutic focus if possible. It implies a long-term difficulty in forming interpersonal relationships and may be accompanied by an impoverished interpersonal network. This will include patients with personality disorder but could also embrace those with chronic low-grade mood disorder. As with other problem areas in IPT, treatment does not focus on the early origins of the

Interpersonal psychotherapy

deficits, but rather on ways of reducing social isolation, which may include identifying and reversing unhelpful patterns of relating, or improving assertiveness skills.

Maintenance treatment of depression

After completion of a 16-session course of IPT, further sessions spaced over weeks or months can be provided to try to prevent recurrence of depression. The therapist and patient aim to identify factors likely to be involved in the recurrence of depression, including social deficits and long-standing patterns of interpersonal behaviour (Frank et al., 1993). Therapy is likely to involve a greater number of foci than acute phase treatment and to include a plan for identifying the early warning signs of future episodes of depression. When patients have been depressed for long periods, they may also need help in adapting to being a well person again, which in itself constitutes a role transition.

Treating anxiety

When anxiety is present alongside depression, some authors suggest certain modifications to IPT, such as providing an explanation of anxiety and its impact on relationships and the incorporation of cognitive behavioural strategies (Cyranowski et al., 2005). In the last few years, IPT has also been used in the management of primary anxiety disorders, including post-traumatic stress disorder and social phobia. Intuitively, IPT should help people to overcome some of the social effects of anxiety, such as avoidance and interpersonal sensitivity, and help older adults when anxiety disorders are triggered by retirement or traumatic events (Robertson et al., 2004).

Treating depression with cognitive impairment

When depression is associated with permanent cognitive impairment, the aim of IPT is to help the patient achieve a new steady state of function commensurate with current cognitive ability. The patient is reminded of the abilities that remain intact that could be further developed or enhanced and, when necessary, helped to accept increased dependency on others (Miller, 2008). The therapist may adopt a more active role to steer the patient towards achievable goals. Caregivers, when involved, may benefit from education on the nature of the cognitive impairment and help in understanding their own responses. For instance, they may have been misreading signs of depleted executive function as laziness or contrariness.

Evidence-based guidance on IPT in treating depression and studies of IPT with older people

IPT has been evaluated in a range of psychiatric disorders and most rigorously in depression (Cuijpers et al., 2011; Cuijpers et al., 2016). IPT appears to be more effective in treating depression when used in combination with medication, and is also used in subthreshold depression

Interpersonal psychotherapy

to prevent progression to major depression, and as a maintenance treatment. The UK National Institute for Health and Clinical Excellence (NICE) draft Depression Guideline recommends IPT for the treatment of less severe depression when a focus on interpersonal difficulties is appropriate and cognitive behaviour therapy, behavioural activation, and antidepressant medication have been ineffective or declined (NICE, 2018).

Two of the most influential trials of IPT with older people have been conducted when participants entered the maintenance phase of treatment for depression. These trials examined the effect of IPT with or without antidepressant treatment in participants who had recovered from an episode of depression while receiving a combination of IPT and antidepressant. In the first (Reynolds et al., 1999), participants were relatively young outpatients (60 years or over) who had suffered at least two episodes of depression. In maintenance treatment they received nortriptyline alone, drug placebo alone, IPT alone, or a combination of both treatments. Follow-up was at monthly intervals for three years. The combination of IPT and antidepressant produced the lowest recurrence rate on the Hamilton Rating Scale for Depression and was superior to both drug placebo and IPT alone

In the second study (Reynolds et al., 2006), participants were aged 70 years or over and had more medical illness than in the first study. Some also had cognitive impairment and may have been developing dementia. Half of the participants were in their first episode of depression. They were randomly assigned to paroxetine alone, placebo alone, monthly IPT alone, or a combination of paroxetine and IPT and followed for two years. Randomization was stratified according to number of episodes of depression, use of augmented pharmacotherapy in the acute phase, and degree of cognitive impairment. Combined treatment did not produce lower recurrence rates than antidepressant alone and IPT was no more efficacious than drug placebo. The authors suggest that the cases of depression in this study were more resistant to treatment due to cognitive impairment. Cuijpers and colleagues (2011) concluded that there 'is no doubt that IPT efficaciously treats depression, both as an independent treatment and in combination with pharmacotherapy. IPT deserves its place in treatment guidelines as one of the most empirically validated treatments for depression.'

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Author(s): Ian A. James and Alan Howarth

DOI: 10.1093/med/9780198807292.003.0019

Introduction

This chapter provides an overview of the non-drug treatments offered to care home residents, paying particular attention to the literature on those residents with cognitive impairment. Depending on age and home type, it is estimated between 52–80% of residents will have some form of dementia (Alzheimer's Society, 2013). It is the unique housing of so many people with complex needs together within communal units that provides the necessity for special attention.

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Context

Care homes in the UK can trace their origins to the sixteenth-century provisions of religious orders, the seventeenth-century Poor Laws and workhouses, and the eighteenth-century infirmaries. By the twentieth century, care of the elderly was regarded as a concern of the State. With the establishment of the NHS and the rise of geriatric medicine in the UK, rapid improvement occurred in services offered to the aged (British Geriatric Society, 2016). Even at this time, however, there were worries that the high numbers of chronically sick older people could seriously hinder the establishment of the embryonic NHS. This latter concern is still prevalent, and was a major reason from the 1980s for the NHS to gradually withdraw its role in the long-term care of the elderly. Today, continuing care provision is chiefly the role of both the private and charitable sectors. According to the Commission for Quality of Care (Oscar Research, 2017) there are over 22,000 care homes in the UK (Scotland 1618; Wales; 1161, Northern Ireland 580), with an average occupancy of 88%. The overarching ethos in care homes is that they are places where people with complex health needs live; it is their home, and quality of life (QoL) matters. Approximately 416,000 people live in care homes (Laing, 2014). This is 4% of the population aged 65 years and over, rising to 16% of those aged 85 or more.

It is important to highlight before proceeding further that in the UK the term 'care home' is a catch-all term used for nursing homes (care homes with nursing care) and residential homes (care homes without nursing care). Care homes with nursing care provide help and assistance with personal care, which is also provided by those without nursing care (residential care homes), but they also have registered nurses and care assistants who provide 24-hour nursing care. In addition to providing general nursing care, many homes offer rehabilitation services, such as physical, speech, and pain therapies, dementia care, and palliative care. The latter homes are for people who are very frail or have complex health care requirements.

This shift in service delivery to the private sector has had major consequences in terms of funding, governance, quality of care, staffing, service provision, and coordination, with respect to 24-hour care provision. Surveys also suggest that the characteristics of people entering private care have been affected by policy changes, with residents entering care being older, more chronically ill, and more cognitively impaired (Peace, 2003). While such profiles have major implications in terms of the treatments required by residents, the trends are not necessarily seen negatively. Indeed, a number of the UK's Dementia Strategies have called for the proportion of people with dementia living in care homes to decrease, seeking to support more people in their own homes for longer (Care Quality Commission, 2017; Alzheimer's Society, 2014). The profiles of the staff caring for this highly impaired, vulnerable group of patients have also changed due to the private sector's involvement, with work forces tending to be more itinerant, less well

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

educated, poorly paid, and foreign-born compared to the few remaining equivalent NHS or local authority homes (Peace, 2003). The latter feature is relevant in terms of the effective delivery of non-pharmacological treatments due to the fact that it is the staff who are invariably delivering such treatments, whether formally or informally, via their communication skills (James and Jackman, 2017; Eggenberger et al., 2013).

An understanding of the different needs of residents in care homes, and how interventions may be best tailored to meet them, is essential. Fig. 19.1 maps out a range of needs in a 3-D model and attempts to capture the diversity along three different continua; an axis of good to poor physical health, an axis of good to poor cognitive health, and one for good to poor mental health. While this model does not entirely account for the variations in symptoms of all residents, it highlights the complex nature of people residing in care homes.

Fig. 19.1
Three-axes representation of health

Using this model, it becomes apparent that care homes could be caring for residents who are in good physical and mental health and cognitively intact and residents who are significantly impaired in each of these domains (along with all the people in between). As expected, the needs of people at different points along these continua will differ greatly, as will the mechanisms of providing treatment and support. Indeed, those who are not suffering from a recognized 'condition' (e.g. diabetes, delirium, depression) will not require specific clinical treatments, but active steps will be required to ensure they do not develop the conditions. This is an important point as it suggests that clinical input should be both preventative as well as reactive.

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Table 19.1 highlights common health conditions experienced by older people in care, and some are preventable with the use of appropriate screening procedures, policies, dietary care, and staff training. The items in this table are also triggers to agitation and other problematic behaviours displayed by residents (James and Jackman, 2017). As such, the table reminds us that the axes in Fig. 19.1 are not independent of one another, and a change on one axis may produce changes on the others. For example, take Morris, who was referred to clinical services because of his depression, constant shouting, poor mobility, and cognitive impairment. Following successful treatment of the arthritis in his knees, he became more independent, his mood improved significantly, and he stopped shouting. In Morris's case, the two latter features were both 'reversible' conditions, whereas his dementia was not significantly impacted by the changes. In this case, his cognitive impairment was seen as an 'irreversible' feature.

Table 19.1 Common health conditions observed in residents in care homes.	
Muscles	• Severe cramps • Spasms • Poor coordination • Balance and posture
Skeletal problems	• Arthritis • Osteoporosis • Spinal injuries
Skin integrity	• Rashes • Bruising • Redness • Swelling • Unusual colour
Swallowing/eating	• History of choking or aspiration • Pocketing of food in cheeks • Excessive chewing
Oral and dental	• Gum disease • Dental decay

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

	• Ill-fitting denture(s) • Bad breath
Mobility	• Recent falls • Use of mobility aids • Abnormal gait • Ill-fitting shoes
Endocrine (metabolic) disorders	• Hypoglycaemia associated with diabetes • Hyperparathyroidism • Thyroid problems (hypothyroidism & thyrotoxicosis) • Liver cirrhosis • Kidney failure • Rapid changes in sodium levels
Bladder and bowel	• Incontinence • Constipation • Diarrhoea • Frequency • Colour • Odour • Infection
Drug intoxication and side-effects	• Effects of prescribed and non-prescribed drugs
Wound	• Skin tears • Ulcers • Wound discharge • Odour
Pain/discomfort	• Fidgeting, restlessness • Guarding a joint/limb • Grimacing

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

	• Calling out • Groaning
Sleep	• Insomnia • Daytime napping • Sundowning • Nightmares • Sleep apnoea
Sensory	• Alterations in vision, hearing, touch • Taste and smell deficits
Blood pressure	• Hypertension • Hypotension
Nutrition/hydration	• Inadequate oral intake • Weight gain/loss • Inability to eat/drink independently • Folate deficiency • Vitamin B12 deficiency

In many respects, the work of a therapist is to determine what aspects of a resident's presentation are reversible, and then use the correct techniques and skills to reverse them. In contrast, the irreversible conditions often require effective management strategies (e.g. symptom management via drugs, surgery, staff support, specialist equipment, etc.). It is important to note, however, that even when a condition is unlikely to be reversed, the person can benefit from identification and treatment of its psychosocial consequences (see the disability model of dementia, Ballard et al., 2001). Consider Joan, who had experienced a stroke five years ago and which left her with severe right-sided weakness. Unfortunately, the resulting mobility problems prevented her leaving the home to go to the day centre, go out with her family, walk in the home's garden, etc. These were all activities that previously gave her a sense of

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

wellbeing. Although the stroke damage is irreversible, the problematic consequences of her poor mobility can be dealt with, and via the correct management she could be able to attend the day centre (training in use of walking frame, assisted-transport to the day centre) and gain access to the garden (installation of a ramp).

In many situations, features on the Mental Health axis of Fig. **19.1** are the easiest to reverse and enhance (i.e. improvements in wellbeing and mood) but they also arguably lead to the greatest distress. For example, depressive symptoms have been found to be associated with disruptive vocalization, one of the forms of agitation often described as difficult to ameliorate in care homes (Dwyer and Byrne, 2000). Underlying depression has an impact on many neuropsychiatric symptoms. It could also be argued that good mental health is the most important status to achieve because if contentment can be obtained, even if an individual has dementia and a serious heart condition, a high QoL is possible. The remainder of this chapter focuses on the methods used to improve people's mental health status. However, it is relevant to state that a key component of non-pharmacological treatments is the use of both adequate screening and treatments for physical conditions (Table 19.1), particularly pain and delirium, which are frequently related to distress, problematic behaviours, and poor mental health.

Mental health conditions

While acknowledging that mental health concerns cover a wide range of diagnostic conditions, for the purpose of this chapter we deal mainly with issues relating to people experiencing cognitive impairment, and in particular those displaying low mood and/or Behavioural and Psychological Symptoms of Dementia (BPSD). These conditions are both seen as markers of stress and distress in dementia (Alzheimer Scotland, 2015). This chapter refers to BPSD as Behaviours that Challenge (BtC), the term used in previous UK national guidance (NICE-SCIE, 2007). We note that the current guidance (NICE, 2018) uses the term non-cognitive symptoms, which is too imprecise for the purpose of this chapter.

Recent randomized controlled trials (RCTs; see Moniz-Cook et al., 2017; James et al., 2017) conducted a survey of mental health conditions with 2185 residents across 63 care homes in the North of England, using the Challenging Behaviour Scale (Moniz-Cook et al., 2001; see Table 19.2). Measured on the Challenging Behaviour Scale, the prevalence of BtC was found to be high, with 87.5% of the 2185 residents exhibiting one or more BtC (Moniz-Cook et al., 2017) (Table 19.2). Only one in eight residents did not display any BtC (N = 274), while 40% displayed ten or more. The high prevalence is in keeping with the majority of studies in care homes with previous rates of 82% (Ballard et al., 2001), 80.5% (Selbaeck et al., 2007) and 91.7% (Bergh et al., 2011); although lower rates of 20% have also been recorded when using more conservative methodologies (Bowman et al., 2004).

Source: data from Moniz-Cook E, Woods R, Gardiner E, Silver M, Agar S. (2001). The Challenging Behaviour Scale (CBS): Development of a scale for staff caring for older people in residential and nursing homes. *British Journal of Clinical Psychology*. 40:309-22.

The most frequent behaviours were 'acts of omission' relating to the theme of low affect and 'apathy'. This was consistent with the pan-European study of Aalten and colleagues (2007) which found that apathy was the most common challenge for staff, occurring in 56% of their sample (n = 2808). BtC occurred concurrently, which was also consistent with previous studies (Lyketos, 2007; Volicer, 2007). Such a finding argues against the common clinical practice of treating a particular BtC independently of the rest of the person's presentation (e.g. using risperidone to treat agitation, see Holmes, 2009). Rather, it is more consistent with the notion of the behaviours being manifestations of general distress, calling upon us to undertake more comprehensive assessments of behaviour and identify underlying unifying causes of the full range of the resident's problematic presentations.

Non-pharmacological treatments

International and national reports (Brasure et al., 2016; German Dementia Alliance, 2014; Alzheimer Scotland, 2015) and guidelines (Brechin et al., 2013; NICE, 2018) have highlighted the need for effective non-pharmacological treatments for BtC. Greater use of psychosocial interventions is also consistent with the recent push for giving all people, whatever their status or disability, better access to psychological therapies (NHS England, 2018). However, despite there being a clear need for the use of non-pharmacological treatments, there is little agreement about which ones to use. Cohen-Mansfield's (2001) systematic review of psychological treatments for BtC classified eight types of intervention: sensory, social contact (real or simulated), behaviour therapy, staff training, structured activities, environmental interventions, medical/nursing care interventions, and combination therapies. The study identified 83 non-pharmacological intervention studies via search, although many of these were of a poor standard. Since then, there have been a number of other systematic reviews (Livingston et al., 2005; Ayalon et al., 2006; O'Neil et al., 2011). A meta-review by Vernooij-Dassen

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

and colleagues (2010) included 28 reviews related to long-term psychosocial interventions. There were positive effects with behavioural management techniques in relation to mood, behaviour, and physical activities of persons with dementia (PWD). Brasure and colleagues (2016) conducted an extremely comprehensive review that showed only cautious support for non-pharmacological approaches, although it restricted its focus to the treatment of agitation and aggression. More positive findings have been reported in the UK from the WHELD programme (Improving Wellbeing and Health for People with Dementia, see Ballard et al., 2016). This was a five-year programme that undertook three systematic reviews: the first review identified evidence-based training materials; the second examined the evidence for psychosocial treatments for BtC; and the third examined the factors influencing staff use of psychological and social interventions in practice. The findings from the three reviews led the WHELD team to develop care packages that incorporated best-practice interventions. In the subsequent trial, the WHELD treatment package was comprised of: training staff on person-centred care; promoting social activities and interactions; and providing care home staff and general practitioners with updated knowledge regarding the optimal use of psychotropic medications. Using this set of three interventions, the researchers engaged in an RCT with over a thousand residents in 69 care homes. The result was a range of positive findings in relation to resident wellbeing, some of which are yet to be published (Ballard et al., 2016).

Conducting reviews of treatments in this area is rather complex. Firstly, the target 'participants' are far from homogenous; many are physically frail, have dementia and/or anxiety and depression, and are engaging in poorly defined behaviours. Studies address a range of different symptoms of mood or behaviour and outcome measures range widely, which can make the findings difficult to compare. Specific problems relating to conducting research in the area also include difficulties administering a conceptually discrete intervention package.

There is often overlap between the various forms of therapy, and many will include a mixture of environmental, orientation, and staff-training features. Hence, it is difficult to determine which aspect of the package is the change element; such confounds also mean it is problematic comparing the forms of therapy with each other. It is often unfeasible to run double-blind studies due to the rather overt nature of the interventions and difficulty in devising placebo conditions. Despite this, there are several good-quality RCTs and other experimental trials (Table 19.3).

Table 19.3 Non-pharmacological approaches and their evidence base.

Therapies	Systematic Reviews and Empirical Status	Key Articles

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

I—Preventative approaches: These are generally designed to promote a positive therapeutic milieu and positive wellbeing. It is suggested that improving people's general levels of contentment serves to improve mood, and reduces anxiety and the incidences of BtC.		
Reality orientation: Uses rehearsal and physical prompts to improve cognitive functioning related to personal orientation.	Spector and colleagues (2002) identified six RCTs. The reviewers concluded there was evidence of improvements in terms of cognitive and behavioural features. RO is now assessed under Cognitive Stimulation Therapy.	Scanland and Emershaw (1993); Woods et al. (2012)
Cognitive stimulation therapy: Uses structured activities to stimulate mental and physical abilities. Usually undertaken in a structured, group format and derived from RO.	Woods and colleagues (2005, updated 2012) suggested that CST had a beneficial effect on memory, cognition, and QoL. Good evidence base for group format, less so for one-to-one packages. Found to be a cost-effective alternative to antipsychotics in reducing distress (NHS III, 2011)	Spector et al. (2006); Woods et al. (2012); Orrell et al. (2014)
Reminiscence therapy: Involves discussion of past experiences individually or in a group format. Photographs, familiar objects, or sensory items used to prompt recall and discussion.	Woods and colleagues (2005b, updated 2009) identified five RCTs, four containing extractable data. The reviewers reported significant results in terms of cognitions, mood, care giver strain, and functional	Bohlmeijer et al. (2003); Brooker and Duce (2000); Lin, Dai, and Hwang (2003)

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

	abilities. However, the quality of the studies was perceived to be poor.	
Validation therapy: Based on the general principle of acceptance of the reality of the person and validation of his/her experience.	Neal and Barton Wright (2003, updated 2009) identified three studies, two showing positive effects. However, the reviewers concluded there was insufficient evidence to view the approach as effective.	Schrijnemaekers et al (2002); Feil (1993; 1995)
Psychomotor and exercise therapy: Exercises (e.g. walking and ball games) are used to target depression and behavioural difficulties. The psychomotor interventions are often targeted at enhancing cognitive abilities in addition to physical wellbeing.	Montgomery and Denis (2002) examined the impact of exercise on sleep problems identified one trial that demonstrated significant effects on a range of sleep variables. Teri and colleagues have undertaken extensive work in this area under the generic title of the Seattle Protocols, and shown evidence of effectiveness for tailored and 'fun' activities.	Eggermont and Scherder (2006); Teri et al. (2008)
Multisensory stimulation: Stimuli such as light, sound, and tactile sensations, often in specially designed rooms, used to increase the opportunity for communication and	Chung and Lai (2002, updated 2009) identified a small number of RCTs. A more recent study has shown promising results (Maseda et al., 2014), but was poorly reported. As	Baker et al. (2001); van Weert et al. (2005a,b); Maseda et al. (2014)

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

improved quality of experience.	such, to date there is insufficient evidence to view the approach as effective.	
Aromatherapy: Use of essential oils to provide sensory experiences and interactions with staff. The oils can be administered via massage techniques or in patients' baths.	Holt and colleagues (2009) identified two RCTs, but only Ballard et al. (2002) trial reviewed, and found to favour use of essential oils over control oil. More recent trials have mainly failed to find significant effects (AHRQ, 2016).	Ballard et al. (2002); Fujii et al. (2008); Yang et al (2015)
Bright light therapy: Use of full spectrum light to enhance wellbeing, increase activity, and promote day/night sleeping cycles.	Four good quality trials in area. Reviewed by AHRQ (2016), who concluded that only one trial has shown moderate effects (Burns et al., 2009), and this study has methodological flaws. Forbes and colleagues (2014) state there is insufficient evidence at this point in time to recommend its use.	Burns et al. (2009); Forbes et al. (2014)
Music therapy: Includes playing and/or listening to music as a way of generally enhancing wellbeing. Can be used in movement therapies.	Vink and Birks (2009) identified five studies. However, the quality of the studies was poor. As such, the reviewers concluded there was insufficient evidence to view the approach as effective.	Sherratt (2004); Remington et al. (2002)

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Environmental manipulation: use of environmental cues, signage, and appropriate building layout in order to facilitate communication, exercise, and pleasure and to reduce disorientation.	The adaption of environments to meet the needs of PWD has been explored extensively by researchers at the Dementia Services Development Centre (DSDC) at Stirling University. They have produced a number of successful interventions. Handley and colleagues (2015) have undertaken a review of helpful strategies used in hospital settings to improve outcomes for people living with dementia and their family/carers.	Zuidema et al (2010); Day et al. (2000) DSDC (2014)
II—Intervention strategies (formulation-led approaches): These are reactive strategies, responding to difficulties that have already been diagnosed (depression, anxiety) or observed (agitation, shouting, wandering) and the procedures are specifically targeted to intervene with the problem or its causes. These approaches routinely involve the development of a formulation to help understand the triggering and maintaining features of the problem.		
Behavioural management techniques/ Functional analysis (FA): Based on learning theory and utilizing the antecedents and consequences of behaviour to devise and execute interventions. The approach has a long therapeutic tradition and can be applied to all people, no matter	A systematic review by Spira and Edelstein (2006) reported 23 studies. These tended to be of poor to moderate quality, and many were single case design. Moniz-Cook and colleagues (2012) identified eighteen studies with weak but favourable evidence.	Teri et al (2005); Moniz-Cook et al. (2012)

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

the level of cognitive impairment.		
Psychotherapies: Adaptions for 1:1 therapy with people with dementia are recent developments, and limited to people with mild dementia. However, use of the underlying principles of CBT, IPT, and psychodynamic approaches are widespread, particularly in programmes aimed at promoting improved carer interactions.	Teri et al. (1997) demonstrated the positive impact of CBT on mood and problem-solving abilities in people with dementia. Teri and Gallagher-Thompson's (1991) RCT revealed significant reduction in depression for both people with dementia and their carers. Scholey and Woods (2003) undertook CBT with seven people with dementia and depression, and identified key themes in such work.	Teri et al., (1991); Miller (2009); James (2010)

The first group of approaches are *preventative strategies* and are generally designed to promote a positive therapeutic milieu and positive wellbeing. It is suggested that improving people's general levels of contentment serves to improve mood, and reduces anxiety and the incidences of BtC. In our discussion of these, we have distinguished between more established and 'alternative' preventative strategies.

The second form of approach is *formulation-led intervention*, which is used when a specific issue requires treatment, for example, a BtC, or disorder (e.g. depression, anxiety). In the case of formulation-led interventions, the procedures are specifically targeted to intervene with the problem or its causes. The formulation-led interventions involve the development of a formulation (i.e. conceptual map) to help understand the triggering and maintaining features of the problem. It is noteworthy that the formulations are not the actual mechanisms of change; they are methods used to obtain information about biopsychosocial features, helping clinicians to target their therapeutic approaches. They lead to care plans, which give precise instruction about what needs to be done. The formulation allows for correct choice of treatments and precise and orchestrated delivery manner to meet the PWD's needs.

Use of preventative approaches

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Preventative approaches are designed to create an atmosphere and environment aimed at promoting the wellbeing of PWD. Many of the approaches in this category could be termed person-centred in that they are designed to (i) support the strengths of PWD; (ii) focus on their difficulties; and (iii) foster psychological health and validate their daily experiences (Brooker, 2007). This section discusses the approaches in descending order of their evidence base, moving from the more established and empirically tested therapies to those methods for which the evidence is weaker.

Established preventative therapies

Reality orientation (RO)

RO attempts to orientate residents to the present via the use of cues (clocks, calendars, newspapers) and/or discussion. The rationale underpinning this strategy suggests that, owing to memory and orientation problems, PWD are often confused, which may lead to social disengagement. However, if PWDs are provided with cues that enable them to engage in what is happening in the 'here and now', they are able to participate in conversations in a more confident and fulfilling way. The provision of environmental cues (signs, picture boards) also has the advantage of assisting residents with dementia to find their way around their setting.

RO used to be one of the most widely used strategies, but in recent years it has become less popular as concerns have been raised about the inflexible way in which it has been practised in some services. There is debate regarding the efficacy of the approach (Verkaik et al., 2005), which centres around claims that RO can remind the participants of their deterioration (Goudie and Stokes, 1989) and that it can lead to repeated confrontations with the PWD (Brooker et al., 2001).

Cognitive stimulation therapy (CST)

CST developed from RO and involves activating residents' remaining cognitive functioning through the use of stimulating activities (e.g. use of physical games, word and number games, everyday objects; see Spector et al., 2006). In its purest form CST is a manualized approach that is run in groups and led by a trained facilitator. Each session follows a general theme, with choices of activities in order to cater to the interests of the group. There are warm-up activities, a RO board (containing information about the group), and often a 'theme song'.

Livingston and colleagues' (2005) systematic review of six studies of varying quality (e.g. Spector et al., 2006; Romero and Wenz, 2001) concluded that this approach showed promise across a range of situations. This view was confirmed in an expert review (Woods, Aguire, Spector, and Orrell, 2012), which concluded that there is consistent support for CST, over and above the effects of medication in relation to improvements in QoL. It also demonstrates cost effectiveness due to the

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

fact that it can often be performed in a group setting (Knapp et al., 2006). There is ongoing work examining the longer-term effects of CST, referred to as *maintenance CST*. For example, in a trial consisting of 26 weekly sessions of extended CST there were significant continued benefits found in terms of some variables (although not all), such as QoL (Orrell et al., 2014).

Reminiscence therapy (RMT)

RMT involves residents reliving past experiences, especially those that might be positive and personally significant (e.g. family holidays, weddings). It can be delivered as a group therapy or with individuals (Kaiser and Eley, 2016) and may utilize photographs, art, music, etc., to provide stimulation. RMT is seen as a way of increasing levels of wellbeing, providing pleasure, and boosting cognitive stimulation.

When working with PWD in care facilities, care staff and families are often encouraged to jointly construct historical reviews of the residents' lives (i.e. life stories). Life story work is helpful in promoting attachments between staff and residents, particularly in cases where residents have poor communication skills. Evidence supporting this comes from work undertaken by Subramaniam and colleagues (2014), whose qualitative findings showed that care home staff reported having a greater knowledge and more positive attitudes towards dementia after the use of life story books.

However, while there is growing evidence that RMT is an effective treatment for older PWD (Testad et al., 2014; Cotelli, 2012; Subramaniam and Woods, 2012), studies continue to show mixed results for its effectiveness within care home settings (e.g. Gudex et al., 2010, Hsieh et al., 2010). As a result, careful consideration is needed about the aims for its use.

Validation therapy (VT)

VT was developed to address the perceived lack of flexibility of the RO approach with PWD. Its originator Naomi Feil (Feil, 1993; 1999) suggested that some of the features associated with dementia, such as repetition and retreating into the past, were active strategies to avoid stress, boredom, and loneliness, and were most often used by people with moderate or advanced dementia. She argues that the PWD can retreat into an inner reality based on feelings, rather than intellect, as they find their present reality too painful. VT therapists thus attempt to communicate with the PWD through empathizing with the feelings and hidden meanings behind their confused speech and behaviour. It is the emotional content of what is being said that is important, rather than the person's orientation to the present.

It is, however, suggested that therapists can become too focused on confused communication and fail to identify simple explanations such as pain or hunger. Neal and Barton Wright (2003) evaluated VT's

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

effectiveness across a number of controlled trials employing cognitive and behavioural measures (e.g. Finnema et al., 1998, 2000). They concluded that, despite some positive indicators in terms of depression (Toseland et al., 1997), its efficacy remains equivocal. Subsequent small controlled studies (Deponte and Missan, 2007; Tondi et al., 2007) have found a reduction in behavioural disturbance and so this approach may be helpful in addressing these signs of distress.

Environmental modification

Environmental modification is based on the premise that, by developing a psychosocial understanding of behaviour and its meaning for the person, the environment can be changed to meet his/her needs. Evidence suggests that modifying environments can be effective in improving wellbeing and reducing unwanted behaviours for people with mild or severe dementia (Bowie and Mountain, 1997). The use of colour and structure in an environment can help with orientation (Gibson et al., 2004). Designing an environment with a more home-like atmosphere with good lighting and some environmental stimulation can reduce unwanted and agitated behaviours (Day et al., 2000). Access to safe gardens and outdoor spaces is also beneficial and opens up the possibility to develop horticultural type therapies with residents.

In recent years there has been a growing tendency in some care facilities to recreate artificial environments (e.g. pubs, bars, cafes, market places) with the notion that this may reduce levels of agitation and increase levels of interaction between residents. Critics have warned, however, that these artificial environments should always sell/offer items for sale consistent with their proposed purpose (Mental Health Foundation (MHF), 2016). The MHF report on deception in dementia care, considers that 'pubs that do not provide drinks are likely to further confuse and agitate PWD'. A comprehensive evidence-base has yet to be established in this area, although a number of controlled studies (Livingston et al., 2005) and a larger number of non-controlled studies have shown environment and design to be important (Hulme et al., 2010; Zuidema et al., 2010).

Psychomotor therapy

Psychomotor therapy, sometimes referred to as activity therapy, is a varied group of action-based activities, such as sport or drama. Cohen-Mansfield and colleagues (2010) demonstrated the positive impact of a range of such activities for residents in care. The findings revealed that the most enjoyable tasks were those that involved engaging with living things (people, real baby, animals), followed by tasks involving some form of social simulation (use of dolls, simulation presence videos). However, when length of engagement was assessed (i.e. length of time spent on task), the residents spent longer on tasks that mimicked work-like activities (stamping envelopes, sorting jewellery, folding towels). These results are likely to have important consequences in terms of the sorts of

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

activities carers can use to help occupy PWD in order to enhance well-being, increase self-worth, and relieve boredom.

Studies of specific action-based activities have provided mixed results. Studies of drama and movement groups have showed positive outcomes in terms of increased communication (Hokkanen et al., 2003) and moderate benefits in terms of relaxation and orientation (Wilkinson et al. 1998). The therapeutic use of touch occurring with activity programmes has also been found to reduce disruptive vocalizations (Woods et al., 2005). A good quality-controlled trial by Montgomery and Dennis (2002) showed a positive impact on a range of sleep variables.

Despite these findings, two better quality-controlled trials conducted in the area failed to find significant differences in terms of depression and apathy when compared to treatment as usual (Hopman-Rock et al., 1999; Dröes, 1991). Of further concern was the attempted systematic review by Karkou and Meekums (2017) on dance movement therapy, and their conclusion that none of the available studies were sufficiently robust to meet their inclusion criteria.

Exercise

The benefits of moderate exercise in relation to chronic degenerative disease is well established (Heyn et al., 2004). Vogel and colleagues (2009) has reviewed aerobic exercise health benefits, which include a reduction in cardiovascular morbidity and mortality, optimization in blood pressure and lipid profile, improved executive function, cardiorespiratory fitness, and insulin sensitivity (Colcombe and Kramer, 2003). Other benefits, such as a slower rate of decline of activities of daily living, have been shown to result from a simple exercise programme, one hour twice a week (Rolland et al., 2007). Exercise has also been shown to increase older people's mood and confidence (Young and Dinan, 1994; Singh et al., 2005; Guzman et al., 2016), but not necessarily reduce BtC or improve cognition (Forbes et al., 2015).

One of the concerns in the area has been how to engage people in exercises that they would find meaningful and fun. Guzman's work has attempted to achieve this via the use of dance (Guzman et al., 2016), and achieved benefits on a range of mood and psychosocial factors. The largest body of work to date has been The Seattle Protocol programme (Teri et al., 2008). This is a series of systematic, evidence-based approaches focusing on the importance of making regular exercise a pleasant activity for both the participants and their caregivers.

Multisensory therapy

Multisensory approaches usually involve using an activity room that has been designed to provide several types of sensory stimulation, such as light, texture, smell, and sound. The use of these resources is tailored to the individual person and therefore all of the forms of stimulation are not necessarily used in one session. Some of the reported benefits for those

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

with more advanced dementia include a reduction in aggressive behaviours, apathy, and depression and an increase in interaction and signs of wellbeing (van Weert et al., 2005a; van Weert et al., 2005b). However, individuals differ in their response to this treatment, with some studies failing to find an effect and some obtaining a negative one. The latter findings highlight the need for individualized assessments and planning (Hope, 1998).

It is also possible to bring sensory experiences into the daily lives of PWD through the use of interesting and stimulating decorations, colour schemes, and textures in the environment, and the selection of personal care items, such as scented toiletries (Wenbourn, 2003). Chung and Lai (2002) reported that, overall, the findings were inconclusive. However, more recently, Verkaik and colleagues (2005) suggest that multisensory approaches are particularly effective in the treatment of apathy and depression both in 24-hour care and in the community.

Alternative preventative psychological strategies

Aromatherapy

The two main essential oils used in aromatherapy for dementia are extracted from lavender and lemon balm, and can either be inhaled or applied via massage. Early controlled trials showed significant improvements in agitation symptoms with excellent compliance and tolerability (Holmes et al., 2002; Ballard et al., 2002), but both these studies have flaws and therefore the findings must be treated with caution. More recent studies have found rather mixed results (Fujii et al., 2008; Yang et al., 2015), similar to that arrived at by Forrester and colleagues (2014).

Light therapy

Light plays a big role in maintaining our circadian rhythms and light therapy can be used to reset these rhythms when they are disrupted. The use of light therapy for Alzheimer's disease, and related dementias, has been shown to help with sleep disorders and agitation, which may or may not be related to tiredness. The benefits can be experienced by both PWD and their carers, with both experiencing more sleep (Figueiro et al., 2015). Burns and colleagues (2009) found that dementia patients who sat in front of a bright light (10,000 lux) for two hours each morning slept an average of 40 minutes longer and slept more deeply than usual. A control group who sat in front of a 100-lux light slept only about eight minutes longer. This tendency was most evident in the winter months.

Riemersma-van der Lek and colleagues (2008) reported that light therapy alone had a modest benefit in improving some cognitive and non-cognitive symptoms of dementia. However, the best effects were observed when it was used alongside the administration of melatonin. The notion being that both treatments were synchronizers of the circadian system.

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Forbes and colleagues (2014), however, recommend caution. They suggest there still is insufficient evidence to recommend light therapy for improving the wellbeing of people with dementia.

Music therapy

The poor quality of studies on music therapy has been noted (Vink et al., 2009), but nevertheless, it has long been accepted within the scientific literature that music can have a profound effect on people's mood and wellbeing (Sherratt et al., 2004). Music is also considered useful in reducing unwanted behaviour and improving communication, particularly when tailored to people's taste. Remington and colleagues (2002) showed increased levels of wellbeing and reduced agitation via using calm music and hand massage. Significant effects were found between music alone and the no-music conditions.

A sustained music therapy programme over 30 weeks has also demonstrated a reduction in BtC scores, in particular, reductions in agitation, delusions, anxiety, apathy, irritability, aberrant motor activity, and night-time behaviour disturbances, with improvements maintained at one-month follow up (Raglio et al., 2008). There have also been reported improvements in depressive symptoms through participation in reminiscence-focused music groups (Ashida, 2002) and improvements in communication and irritability when engaged in structured playing of music (Suzuki et al., 2004). Further, it is worth mentioning Sally Magnusson's work, and her charitable organization Playlist for Life. Sally's account of her discovery of the power of music in relation to her mother's dementia is both illuminating and inspiring (Magnusson, 2014). As with all strategies, caution is required when using this approach, as music can cue problematic memories too (e.g. music of the 1940s reminding people of wartime losses).

Art therapy

Art therapy (drama, model making, drawing, and painting) is a treatment in which people have the opportunity to explore new skills (Mottram, 2003) and thereby enhance their self-esteem. In the case of PWD, art therapy has been shown to provide meaningful stimulation, improve social interaction, and raise levels of self-esteem (Killick and Allan, 1999). While many anecdotal studies suggest that this may be an activity that promotes wellbeing, there is limited evidence of its impact on specific conditions or of longer-term benefit when sessions stop.

Animal-assisted activities

Animals introduced into nursing homes as regular visitors or as care home pets have been shown to have positive effects, including reducing blood pressure, agitation, strain, tension, loneliness, and increasing life expectancy (Churchill et al., 1999). Short-term interactions with dogs have been shown to increase social interaction with, and between, older people with mental impairment (Greer et al., 2001). These forms of social

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

contact have also proven beneficial in the treatment of BtC (Zisselman et al., 1996). The use of a fish tank in a dining area has been shown to reduce aggression and enhance the nutritional intake of home residents with dementia (Edwards, 2004). Looking after hens has also been shown to have benefits (Cook et al., 2013), with a large grant being awarded to Equal Arts UK to roll out its HenPower project. It aims to provide care homes with the support required to host hen-keeping-related activities onsite as a means to encourage residents to engage in positive social interactions (Rippon and James, 2017). The ethos of the HenPower project is also to support frontline care staff to deliver meaningful activities for the residents related to the hens (caring, nurturing hens, collecting eggs, baking). However, the welfare of human and animal participants needs to be considered in any programme and helpful guidance is now becoming available (Lefebvre et al., 2008).

For situations when live animals are not appropriate, researchers have investigated the ability of robotic animals to provide companionship and increase QoL in nursing home residents. Banks and colleagues (2008) examined the interactions of residents with Sony's robotic dog 'Aibo' and found that Aibo and a live dog reduced agitation and were equally effective in doing so. Similarly, Libin and Cohen-Mansfield (2004) have had promising pilot results with a robotic dog. There is also promising work occurring with the use of a robotic seal 'Paro' (<http://www.parorobots.com/>), although the evidence for this item currently remains limited.

Using dolls and toys

The use of dolls and toys in care settings is not new (Libin and Cohen-Mansfield, 2004), but has only recently been studied in a systematic manner (Alander et al., 2015; Mitchell, 2016). Investigations have involved the introduction of dolls and teddy bears into care homes following a standard format (Mackenzie et al., 2006). Typically, staff are given information and guidelines on their use prior to their introduction (Mackenzie et al., 2007). The findings from these investigations have been favourable for both residents and staff (Mackenzie et al. 2006; James, 2015). However, this approach is controversial and an unresolved debate within the *Journal of Dementia Care* (Mackenzie et al., 2006, 2007) has demonstrated resistance to the technique because it can be viewed as 'patronizing' and promoting 'infantilization'. A full review of the field has recently been undertaken by Mitchell (2016).

Tool box approaches

Some of the above strategies have been presented as stand-alone techniques, but it is evident that often carers combine them and use them in non-standard ways. A good example of this is the various forms of 'tool-box' techniques (Thwaites and Sara, 2008). This widely used approach involves creating an individualized box of items for each person, containing personalized material (e.g. photographs, postcards, camcorder

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

recordings of family scenes or voices, items of clothes, ornaments, relevant maps, aromatherapy oils). Carers, particularly care staff, can use the items in the box to stimulate and communicate with the individual, learning more about the person's history and promoting positive reminiscence.

Summary of preventative approaches

Overall, the evidence base for the preventative approaches is variable. The two main reasons for such an equivocal picture are (i) methodological problems associated with undertaking psychosocial research, and (ii) a lack of clarity related to treatment goals.

Methodological problems

Some of this variance is due to the fact that traditional research methods, especially RCTs, are often inappropriate or unfeasible for non-pharmacological interventions with people with dementia (Cohen-Mansfield, 2016). It is also due to the way in which the interventions are delivered. Owing to their preventative nature, they are frequently delivered to a wide range of residents, each on a different stage on the 3-D continua discussed earlier. They are often delivered to groups of people for short periods of time (e.g. one hour) and undertaken infrequently (e.g. once a week). The interventions tend to be available at times that are convenient for the therapist and the care home, as opposed to the residents. Finally, the people with dementia are often entirely dependent on staff to access the interventions (Lawrence et al., 2012) and there may be residents who would benefit but who are not encouraged to attend. As a result, the interventions are rarely truly person-centred as they are not focused on the needs of the residents. Inevitably, this means that some residents will not benefit from the intervention because it is not meaningful to them or delivered at the right time. If we view the preventative interventions in this way it is probable that many resources (e.g. resident time, staff time, therapist time, money) are spent delivering interventions in a way that is counterproductive to the positive benefits we seek.

Lack of clarity related to treatment goals

In the rush by clinicians to find alternatives to medication, many have sought (unsuccessfully) an approach that was a non-pharmacological panacea—an approach that aided well-being, improved affect, and reduced BtC—the equivalent of a 'magic bullet'. Hence, some of the poor efficacy reflects a lack of clarity in terms of the treatments' specific outcomes. From the current authors' perspective, and our review of the area, we believe that the above treatments were generally good at improving wellbeing, but were less consistently successful at improving cognitions, clinical affective disorders, and/or BtC. And such a conclusion would appear to make theoretical sense because, in general, the treatments' various mechanisms of change were not designed to target these clinical features. For example, very few of the studies ever specified

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

how exactly RO, CST, aromatherapy, or doll therapy, etc., were supposed to reduce vocal aggression, sexual disinhibition, and shouting, or improve cognitive skills.

In conclusion, the mixed results indicate that the approaches do have value for some people and if we could change the way we deliver them we can maximize their value to residents by ensuring that they are delivered to the right people, in the right way, at the right time, for the right purpose. To do this we need to understand the needs of each individual.

Use of formulation-led interventions

This section discusses a number of formulation-led approaches. Here, typically a condition has already been observed (depression, problematic behaviour) and the formulation-led intervention is specifically targeted at its causes. These interventions routinely involve the development of a formulation (i.e. a descriptive account of the problem in relation to the person and her past) to help understand the triggering and maintaining features of the condition (James, 2010). First it describes some standard psychotherapeutic approaches (Cognitive Behaviour Therapy (CBT), Interpersonal Therapy (IPT)) where the use is limited to those with mild impairment (James, 2010). It then covers therapies that can be used with all presentations, even with cases of severe dementia (behaviour therapy (BT) and needs-led frameworks).

The function of the formulation of the standard psychotherapies varies according to the type of therapy. CBT and IPT formulations are designed to help 'clients' gain a better understanding of their problems; this requires the clients to have a degree of insight into their difficulties and the ability to initiate change with respect to their behaviour. In contrast, BT and the needs-led frameworks employ formulations as vehicles to enable carers to gain a better understanding of the PWD's difficulties. This is particularly important because, in cases of severe dementia, it is the carers who are required to carry out the interventions.

Standard psychotherapies

Over the last ten years there has been an increasing interest in using CBT and IPT with older people, including those with cognitive impairment (James, 2010; Miller and Reynolds, 2007). In relation to PWD, these therapies are used in cases of low mood, anxiety, or when the person retains some insight and problem-solving abilities.

Cognitive behavioural therapy (CBT)

CBT examines people's distress within a cycle of thoughts, feelings, physical sensations, and behaviours. Teri and Gallagher-Thompson (1991) reported positive findings from a clinical trial of CBT with people in the early stages of Alzheimer's disease. Single-case and group CBT have also

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

been used by other researchers with some favourable results (Koder, 1998; Kipling et al., 1999; James, 2010).

Interpersonal therapy (IPT)

IPT examines the person's distress within an interpersonal context. People are encouraged to look at how important relationships have changed since they have become distressed, and they are also asked to examine their communication styles to see if they can be improved. Such an approach is particularly relevant for those therapists who see BtC as a communication strategy in a form other people find socially unacceptable. For example, a person with poor verbal skills who is unable to ask for food may snatch something from someone else's hand because she is unable to ask for the item by name.

There is some overlap of IPT with the person-centred work of Kitwood (1997) and Stokes (2000). There is good empirical evidence for this form of treatment with older people (Miller and Reynolds, 2002); it has only recently been applied in the area of dementia (James, 2010; James et al., 2003; Miller and Reynolds, 2007; Miller, 2009). Yet, owing to the demands IPT places on insightfulness and the ability to reflect, its use remains rather limited in treating PWD.

Carer-centred, person-focused approaches

The following approaches can be employed for a range of clinical presentations, even in situations where residents have either poor communication skills and/or poor insight; thus, these methods are suitable for working with people with severe dementia. The key reason for their suitability with this group is that, although the focus of the treatment is directed at the PWD, much of the actual work is done via carers. Working with these interventions therefore requires a systems approach, whereby much of the success depends on supporting the carers to deliver the therapy effectively. For this reason, the approaches are termed 'carer-centred, person-focused' (James and Jackman, 2017).

Behaviour therapy (BT)

Behaviour therapy requires a detailed assessment period in which the triggers, behaviours, and reinforcers (i.e. the ABC model: antecedents, behaviour, and consequences) are identified and their relationships made clear. This process is frequently referred to as a *functional assessment* (Gormley et al., 2001; Moniz-Cook et al., 2012). The therapist will often use a chart or diary to gather information about the manifestations of a behaviour (B) and the sequence of actions leading up to it (A). The reactions to the behaviour (C) are also studied because they frequently serve to either increase or decrease the likelihood of the action occurring again. Such monitoring helps to identify the function of BtC, and the accurate observations are essential in generating better hypotheses. For example, consider the case of Polly, whose continual shouting was initially attributed to arthritic pain. The functional assessment revealed that she

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

only shouted in the presence of men, indicating some fear or anger associated with males. This meant her painkillers could be stopped, which relieved her constipation, and the new data allowed the therapist to focus on her issues with men, enabling her therapists to go on to develop a more appropriate intervention.

Teri and colleagues (2005) developed and conducted an 11-session training programme to teach 41 carers of individuals with dementia how to manage agitated behaviour using functional analysis-based behavioural interventions in their home environment. During sessions, carers worked with a therapist to define problem behaviours, complete and interpret functional analyses, and develop interventions. The review of the training programme presented four case studies to illustrate its effectiveness. The antecedents to the four participants' agitation were found to be:

1. Lack of activity
2. Confrontation over confused statements
3. Inactivity specifically at dusk
4. Lack of social attention due to caregiver competing tasks, respectively.

Consequently, antecedent control interventions were designed specifically for each participant (i.e. providing appropriately tailored activities). For one participant, the interventions resulted in the elimination of verbal and physical aggression, and the numbers of agitated and aggressive behaviours also dropped in the other three participants. Unfortunately, no data were presented and only limited qualitative feedback from the participants was reported as an outcome measure, making it difficult to interpret how successful the interventions actually were.

The efficacy of BT has been demonstrated in the context of dementia in several studies (e.g. Spira and Edelstein, 2006). A rigorous review by Moniz-Cook and colleagues (2012) identified eighteen trials, the majority of which were from family care settings, rather than residential care settings. For the primary outcome of frequency of problematic behaviours, only ten studies (n = 1140 participants) had usable data. They concluded that, while functional analysis showed promise, it is too early to provide an indication of its effectiveness. This is because the evidence rests largely on a handful of studies for which the actual effects are unclear, since the intervention tended to be delivered within broad multicomponent programmes of psychosocial interventions.

Positive behaviour support

A recent addition to field of behaviour therapy is positive behaviour support (PBS). PBS is not a technique or therapy, but a formulation-led intervention that uses applied behavioural analysis (ABA) as its predominant theoretical model. Originating from the learning disability field, where it is seen as best practice for the treatment of challenging behaviour (NICE, 2015), it is gradually being adopted across other

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

specialties, e.g. child, forensic, personality disorders (see Clinical Psychology Forum, 2017). We are currently examining its use for BtC for PWD, and it clearly has much to commend it. However, the application of the ABA feature, which is essential, is somewhat problematic with this specific clinical population owing to problems to do with memory, learning, and insight (James and Reichelt, 2017).

Needs-led therapies

These approaches have often been developed specifically for the treatment of BtC. Currently there are a number of conceptual models that examine cases of BtC in terms of people's needs (Cohen-Mansfield, 2001; James, 2011; Aberdeen, 2015; Dexter-Smith, 2007, 2010). These frameworks typically involve obtaining two types of information: (i) background features (history, premorbid personality and coping style, cognitive status, mental health status, physical health status, environmental and contextual status), and (ii) a comprehensive description of the problematic behaviours—a functional assessment. Putting these two types of information together provides a stronger foundation upon which to accurately identify the person's needs. Bird and colleagues (2007) have provided numerous case examples of the benefits of this methodology. More recently, Bird has undertaken a controlled study that illustrates the efficacy of his work (Bird et al., 2009). Holle and colleagues (2016) carried out a systematic review of individualized formulation-led interventions that identified 14 formulation-led interventions and 37 studies that employed individualized interventions, mainly in the care home sector. The reviewers found positive findings in terms of PWD outcomes in nursing homes, while the evidence for staff outcomes was less promising. The results for the own-home settings were also positive, but the findings related to only one trial.

The present authors currently work in NHS services in which specialist teams employ needs-led models across all the care homes in their localities ($n > 210$ homes, James and Jackman, 2017). The use of specialist teams who work exclusively with people displaying BtC is relatively uncommon, but successful teams exist in the North East of England (CNTW Behaviour Support Services), Dumfries and Galloway (IDEAS team), and in the Northern Health and Social Care Trust, Northern Ireland. These teams are multidisciplinary, with the latter two containing members from four or more professions. Each of the teams employ their own conceptual frameworks (i.e. the Newcastle model, CEASE, CLEAR), but essentially all view BtC as a communication of an unmet need. Each team works with staff to help them develop a formulation of the person's needs and develop a person-centred care plan (James and Moniz-Cook, 2018).

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

Staff training

As demonstrated, staff are a vital piece of the jigsaw in delivering good care in homes. De Vugt and colleagues (2004) showed that some care-giving attitudes and behaviours were associated with incidences of behavioural problems. For example, caregiver impatience, irritation, and anger towards residents were more likely to result in greater resident agitation. In terms of training, the methods of staff education have been varied and involved broad ranging teaching programmes (Burgio et al., 2002) and the use of helpful tools like Dementia Care Mapping (DCM: Kitwood, 1997) and the VIPS care model (Brooker, 2007). These frameworks assess the activity and level of wellbeing from a resident's standpoint, and provide information about caregiver interactions—from which action plans for care improvement can be developed. The DCM tool also acts as an audit of person-centred practice and has been used with positive results in some studies and had a more equivocal impact in others. The fact that it can be both intervention and outcome evaluation creates an obvious confound, but it has good face validity and is well received by practitioners (Brooker, 2007).

In general, evidence shows that staff can be trained to deliver better care (Opie et al., 2002; Schrijnemaekers et al., 2002), but the effects do not tend to generalize across care activities and they tend to fade with time. This was supported in a study by Moniz-Cook and colleagues (2017) that trained staff in the development of person-centred individualized care plans. There was no improvement in the number or frequency of problems, but the homes that received the training did report less difficulty in managing the behaviour. However, these effects were not maintained at one-year follow-up. Programmes that have taken a broader organizational focus in implementing person-centred care in combination with training and mentoring have been shown to have some benefits on medication use in the Focused Intervention Training and Support Programme (Fossey et al., 2006; Fossey and James, 2008; Brooker et al., 2016) and some aspects of QoL in the VIPS model of care (Brooker, 2007) and Enriched Opportunities Programme (Brooker, 2011). Individual care home groups have also implemented their own programmes of organizational and cultural change; for example, the PEARL programme (Baker, 2009) uses a cycle of audit, training, and organizational change to achieve clearly defined standards of care. The most comprehensive review of the area from a UK perspective comes from Surr and colleagues (2016) in the 'What Works' Project. In a sophisticated breakdown of aims and targets, the researchers examined the nature of the training required to achieve good outcomes for both clients and staff.

In terms of client outcomes, their preliminary findings suggest the following;

- One should use face-to-face delivery, and engage in discussion and activities that support the application of learning to clinical work.

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

- The training material should be delivered by an experienced trainer who can respond to clinically relevant questions.
- The training should last over one hour, preferably longer.
- The training sessions should be designed for a specific type of service/setting (ward, care home, type of clients).

In contrast, to achieve improved staff outcomes the requirements are:

- Training of a long duration (8+ hrs total, broken down over time), and
- The use of a structured tool or manual to assist with the application of the learning (e.g. FITs, Fossey and James, 2008).

We endorse the 'What works' findings, and once again await the more detailed information that will come from the forthcoming publication of the study. In particular, it is likely that the role of ongoing supervision will be shown to be important in developing and maintaining staff skills and learning.

Discussion

The evidence strongly suggests that individual case-specific formulations, which identify the needs of the individual and lead to the development of person centred care plans, is needed in order to deliver effective psychosocial interventions in care homes (Moniz-Cook and James, 2017; James and Moniz-Cook, 2018). Having reviewed many of the treatments currently available, it is worth highlighting the commonalities between the various interventions. From our perspective, and an examination of the *modus operandi* of many of the treatments, it appears that good communication skills and an ability to interact positively are key to success. This is because many residents in care homes find it an isolating experience due to a combination of the losses experienced (social networks, familiar environment, routines) and cognitive problems (memory and orientation) resulting from dementia. Therefore, when a staff member or therapist engages with a resident using activities, photographs, music, an animal, doll, massage, etc., the individual's level of interpersonal contact rises considerably. For many residents this results in an increase in mood and wellbeing.

More specifically, we believe that the various treatments that were successful either met or enhanced one of the following fundamental needs: physical comfort and freedom from pain; perception of safety; positive touch; love and belonging; esteem; control over environment and possessions (freedom); fun; and occupation and exploration (James and Jackman, 2017). The successful interventions also tended to utilize verbal and non-verbal memories, often in multisensory formats. Yet, fundamentally their success depended on *how* the interventions were delivered rather than the actual *structural* features of the intervention (for example, whether it was RO, dolls, or aromatherapy). Indeed, we

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

suggest that the relevance of *how things are delivered* rather than *what was delivered* also accounts for much of the inconsistency in the literature.

Related to the notion of 'how to' is the current focus on the enhancement of staff communication skills. The ability of each member of staff to encourage, negotiate, and de-escalate during everyday interactions is key to the wellbeing of residents, and crucial in preventing BtC and maintaining the safety of others. Two of the most comprehensive programmes in the UK currently are PACTM (Snow, 2012) and CAIT (Communication and Interaction Training; James, 2015; James and Jackman, 2017).

This chapter has also shown that there is a general move towards more person-centred and staff-centred foci of care. Through the use of such perspectives, greater attempts are now made to understand the individual's experience of his/her problem within an intrapsychic, interpersonal, and organizational context (Bond and Corner, 2001). In a large survey of three different types of Japanese care facilities, Onishi and colleagues (2006) found that the incidences and forms of problematic behaviours differed across settings. The carers' abilities to cope with the behaviours also varied. From their findings, the researchers suggested that such systemic knowledge of the resilience of such settings was crucial in determining the appropriateness of placements and transfers. Therefore, it is important to recognize how the context of PWDs' relationships with family and caregivers affects both the individual with dementia and their caregivers. Such a view emphasizes the need to work with all of the systems involved in the resident's care (families, professional carers, organizations, etc.). Indeed, care staff and families are integral to the treatment strategies and are essential in obtaining valid and reliable information and constructing appropriate formulations and interventions.

Conclusion

People living in care homes present with a variety of complex needs. A host of non-pharmacological interventions exist but the evidence base for them is variable; where the evidence is strong, the interventions are rarely implemented widely in care home settings (Lawrence et al., 2012). Individualized formulation-led approaches are evidence based and offer the best way to meet the varied and complex needs of care home residents. However, the fact that care homes in the UK tend to be large environments looking after a number of people makes this a challenge. The care homes primarily sit within the private sector, but local authorities and the NHS fund a large proportion of placements. The current financial pressures on local authorities and the NHS have reduced the fees paid to care homes, which, in turn, reduces the resources they have available. Providing adequate care to such a vulnerable section of the community is resource intensive. If, as a society, we are to provide people in care homes with the care and treatment they

Non-pharmacological interventions in care homes, with particular emphasis on the treatment of people with dementia

deserve, it is essential that we continue to identify the active ingredients of successful interventions to ensure we develop care plans that match unmet needs, personal abilities, preference, and the environment (Cohen-Mansfield, 2016). This will give us the best chance of providing care that is both cost effective and meets the needs of residents.

Principles of service provision in old age psychiatry

Chapter: Principles of service provision in old age psychiatry

Author(s): Tom Dening and Kuruvilla George

DOI: 10.1093/med/9780198807292.003.0020

Introduction

Support for mental health in older people can be considered as having two main components. The first of these is the general question of how mental health needs in this section of the population are to be met, which includes public health, primary care and other general health and social care services. The other area is the organization of specialist mental health services for older people. Hopefully, too, there is some co-ordination between these two components, so that older people have appropriate access to services that meet their needs.

The nature and extent of mental health services for older people is highly variable, not only across the different countries of the world, but also within individual jurisdictions. In many countries, separate old age psychiatry services do not exist; nonetheless, even a generic mental health service will need to plan how it responds to the particular needs of older people, especially those with dementia, depression and/or medical

Principles of service provision in old age psychiatry

comorbidity. Ageing populations are a truly global issue, so how mental health services respond to older people is increasingly important.

Where dedicated old age psychiatry services do exist, there are sometimes variations in the scope of their work, and there are frequent changes in how they are configured, for example, due to changes in health service structures or funding. Sometimes these changes are so radical as to include the disappearance of the service as a separate entity, even though the expectation is instead for an *increased* demand for specialist services because of the increasing numbers of older people.

Therefore, this chapter focuses on the principles that underlie services, rather than on the detail, partly because the situation will vary in different parts of the world but also partly because the way services are organized will continue to change, rendering anything too detailed obsolete in a short space of time. Furthermore, several other chapters in this book cover specific aspects of service delivery and these will be referred to where appropriate. This chapter also largely focuses on the UK—specifically England. However, many of the general issues are global and also, as the UK has been one of the leaders in developing service models for old age psychiatry, it is likely that what happens there will be of interest to readers internationally.

History

It is generally accepted that old age psychiatry originated in the UK. The earliest traces of the specialty are to be found in the early 1940s (Hilton, 2005b). Before the Second World War, there was virtually no interest in older people's mental or physical health issues, most conditions being assumed to be degenerative, 'senile', and not amenable to treatment. By the early 1940s, there were large numbers of older people with mental disorders in hospitals like the Royal Edinburgh Hospital and Tooting Bec in London. Felix Post, first working in Edinburgh, and encouraged by Professor Henderson, published one of the first clinical studies of mental disorders in old age (Post, 1944). Aubrey Lewis, in London, was also highly influential, for example addressing the Annual Meeting of the Royal Medico-Psychological Association in 1945 (Lewis, 1946) and being active through the Mental Health Standing Advisory Committee of the new National Health Service (Hilton, 2005b).

Several accounts are available of further developments of old age psychiatry (e.g. Hilton et al., 2010). Important advances included pioneering clinical studies, especially Post (1962), his seminal textbook (1965), and Martin Roth (1955). These provided evidence that not all mental disorders could be ascribed to senility and opened the possibility of offering effective treatments for certain disorders, especially affective states. Services dedicated to older people began to open in a patchy fashion across the UK (e.g. Arie, 1970). The common interests of psychiatrists working in this area led first to the formation of an informal gathering, followed by an official Group within the Royal College of

Principles of service provision in old age psychiatry

Psychiatrists in 1973, and then a full Specialist Section in 1978. Old age psychiatry was recognized by the UK Department of Health as a separate specialty in 1989 (Hilton, 2016). Numbers of consultant old age psychiatrist posts have continued to rise, the most recent estimate for England being almost 700 (Royal College of Psychiatrists, 2017a), though 12% of these were unfilled at the point of census.

For several years, the development of old age psychiatry proceeded apart from that of geriatric medicine, despite the obvious overlap in clientele. The reasons for this were complex, often including personal factors and differing expectations and cultures (Hilton, 2014). More common ground was reached by a joint Royal Colleges document on the care of older people with mental illness (Royal College of Psychiatrists/Royal College of Physicians, 1998). Neurology was a relatively late entrant into the field as for many years British neurology paid little attention to cognitive disorders. This has changed dramatically since the 1980s and advances in brain imaging and neuropsychology. Policy also lagged behind the developing clinical services, and until the publication of *Services for Mental Illness Related to Old Age* (Department of Health and Social Security, 1972), there had been no conceptual progress for over 20 years (Hilton, 2005a).

Developments in other countries have been influenced to varying degrees by the UK experience. Patterns of service reflect national factors such as the nature of the healthcare system, the degree to which old age psychiatrists are generalists or dementia specialists, and the level of resources in the individual country. Snowden and Arie (2005) described service developments and also the establishment of national and international organizations for old age psychiatry. Founded in 1982, the International Psychogeriatric Association (IPA) has been particularly influential. The World Psychiatric Association (WPA) (Camus et al., 2003) found that 40 out of 48 countries responding provided some specific mental health services for older people, and 13 of these countries recognized old age psychiatry as a separate specialty.

Principles and values

One of the strengths of old age psychiatry, besides its consideration of epidemiological factors, has been a keen interest in the values underlying its practice. For example, Arie and Jolley (1982) identified five principles: flexibility; responsiveness and availability; unhierarchical use of staff; domiciliary assessment; and willingness to collaborate with other services and agencies. This list has been amended in various places, but the most general statements of values are to be found in series of consensus statements, jointly issued by the World Health Organization (WHO) and the Geriatric Psychiatry Section of the WPA.

These bodies produced five consensus statements concerning: psychiatry of older people; organization of care; education (these three subsequently compiled as a single statement; WHO, 1999); reducing stigma and

Principles of service provision in old age psychiatry

discrimination against older people with mental disorders (WHO, 2002); and ethical practice (Katona et al., 2009). Of these, the consensus statement focused on organization of services has probably been most influential and it is the most relevant to this chapter. As well as setting out seven underlying principles (forming the acronym CARITAS; Comprehensive, Accessible, Responsive, Individualized, Transdisciplinary, Accountable, and Systemic), the document describes the various types of care that may be provided and the components of specialist services. The consensus statement on ethical practice (Katona et al., 2009) discusses the needs for the application of high ethical standards in clinical practice, especially in relation to mental capacity and decision-making.

Values in relation to dementia were set out by the National Dementia Declaration for England, produced by the Dementia Action Alliance, a partnership with 41 signatories representing government, professional bodies, and voluntary and independent sector organizations. The Declaration set out a set of desired outcomes for people with dementia, which have now been updated and expanded as a set of Dementia Statements (Dementia Action Alliance, 2017; see Chapter 15 for a fuller account). The main focus is on people with dementia, to enable them to make their own choices and decisions wherever possible, though it also acknowledges carers as equal partners. The Statements call on individuals and organizations to sign up in order to further the delivery of national dementia policy and these outcomes in particular.

Policy

United Kingdom

Space precludes a discussion of the whole policy framework of relevance to older people. Obviously, this group is particularly affected by reforms to health services and changes in social care policy and funding. In the wider economy, the current debate over pensions will affect the material prosperity of the next generations as they grow older, with people likely to continue working longer. Some more relevant issues, e.g. the roles of public bodies in regulating services and promoting best practice, are discussed later in this chapter. In England, there is no single strand of policies relating to older people's mental health. There is instead a separation between dementia, on the one hand, and other mental disorders, which are considered across the entire age range, on the other. This dates from the publication of separate National Service Frameworks (NSFs) for Mental Health (Department of Health (DH), 1999) and Older People (DH, 2001). The first covered mental health up to age 65, and the second incorporated mental health issues in older people, emphasizing dementia and depression, along with physical illnesses like stroke. Subsequently, because of concerns about possible age discrimination, mental health policy was extended across the age range.

Principles of service provision in old age psychiatry

Mental health policy in England is currently set out in *The Five Year Forward View for Mental Health* (NHS England, 2016). It focuses on: services available seven days a week, especially crisis services; an integrated approach to physical and mental health care; mental health promotion and prevention; and looking forward, in terms of research and improved management of clinical data. As regards older people, there is a welcome emphasis on the importance of recognizing and treating depression. There is specific mention that patients in old age medical settings should have access to expertise in old age psychiatry. However, the *Five Year Forward View* is ambiguous about the separate existence of old age psychiatry: 'Older people should be able to access services that meet their needs—bespoke older adult services should be the preferred model until general adult mental health services can be shown to provide age-appropriate care.'

As regards dementia policy for England, the *National Dementia Strategy* (Department of Health, 2009) was an important step featuring 17 objectives, including improved public awareness, early diagnosis and intervention, improved quality of care in various settings, research, and implementation. This was followed by the then Prime Minister, David Cameron, taking a personal interest and issuing the *Prime Minister's Challenge on Dementia* (Department of Health, 2012). The *Challenge* had three main areas: improvements in health and care; creating dementia-friendly communities; and research. An updated version was published extending up to 2020 (DH, 2015). Among other things, the revised version placed more emphasis on the area of post-diagnostic support and made some specific commitments in relation to dementia research.

The other devolved nations of the UK—Scotland, Wales, and Northern Ireland—all have similar initiatives to those in England (see Scottish Government, 2017; Welsh Government, 2017; Department of Health, Social Services and Public Safety, 2011).

Other countries

At the time of writing, there are around 20 other European countries with a national dementia strategy, with several others in draft (Alzheimer Europe, 2017). Through its Glasgow declaration (Alzheimer Europe, 2014), Alzheimer Europe and the individual national dementia organizations have called for a Europe-wide dementia strategy, though this has not so far been forthcoming. Elsewhere in the world, Australia was probably the first country with a national dementia strategy, launched in 2005. The current version covers the period up to 2019 (Australian Government, 2015). In the US, the National Plan to Address Alzheimer's Disease was recently updated (US Department of Health and Human Services, 2017). It covers all forms of dementia, not just Alzheimer's disease and, while it is national in scope, it is not Federal, so initiatives are quite variable across regions. At the time of writing the newest national dementia plan was that of Chile (November 2017).

Principles of service provision in old age psychiatry

As would be expected, given the scale of dementia worldwide, there have been several international initiatives in recent years. These include several excellent and influential annual reports on different aspects of dementia (e.g. prevalence, economics) from Alzheimer's Disease International (ADI) (see <https://www.alz.co.uk/research/world-report>). The WHO and ADI jointly published *Dementia: A Public Health Priority* (ADI and WHO, 2012) as a call to action for governments. In 2013, the G8 group of nations held a summit for health ministers on the theme of dementia (see https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/265869/2901668_G8_DementiaSummitDeclaration_acc.pdf). Following this, the WHO has published a global action plan on dementia (WHO, 2017a), along with a practical set of guidance, *Integrated Care for Older People* (WHO, 2017b) for preventing and managing functional decline in later life, which makes evidence-based recommendations for simple practical measures that can impact upon health even in low-income countries (LICs).

Services in low- and middle-income countries (LMICs)

There are gross disparities in resources and funding for healthcare between and within developed and developing countries. LICs lack the economic and human capital to contemplate the widespread introduction of specialist services. Instead, the focus must be on developing primary medical care services (Snowdon, 2007). Long-term care facilities are also rare in developing countries where traditional family care arrangements continue to be the main focus of care. Older people tend to live in multigenerational households and families are the main caregivers for relatives with dementia. This is certainly the case in the two most populous countries of the world, China and India (Shaji et al., 2002). Within individual countries there are often also inequities between the services available to rich and poor people, as well as between urban and rural dwellers. The affluent often have access to excellent specialist centres but this is not the case for the masses. Services in disadvantaged areas are often limited to acute care with little in the way of ongoing support or care in the community.

As resources will always be a challenge in low- and middle-income countries (LMICs), integrated psychogeriatric models should be encouraged rather than specialist services. This would mean integrating psychogeriatric services with other mental health services including outreach services in primary care settings (Wang et al., 2013). Services need to have realistic goals, they should be based on careful mapping of all local resources that may be supportive of older people, and they can work through general health workers with suitable brief training (Denning and Shaji, 2005).

This requires improvement of education and training for medical students and general practitioners about mental health of older persons. One approach in China has been to train nominated dementia doctors as

Principles of service provision in old age psychiatry

physicians to support primary care (Chen, L.K., et al., 2014). Dementia support doctors facilitate multidisciplinary cooperation and give lectures about dementia to primary care physicians and educate people in the community. Through these approaches they were able to increase the numbers of medical and care professionals specializing in dementia and to establish systems to provide them necessary education.

Recognizing and treating common mental disorders in old age should be part of the training curriculum of all health personnel in LMICs. This has been done to a limited degree but not nationally in countries like China, India, and some South East Asian countries. There is a need to develop locally relevant and adapted training materials. Again, this has been undertaken with some success in a few LMICs. There are examples of excellent work in this area.

The WHO South East Asia Regional Office published a list of minimum actions for individual nations to take in response to the mental health needs of their older populations (de Mendonça Lima et al., 2010) (see Box 20.1). Services in LMICs are discussed further in Chapter 21.

Box 20.1 Actions for mental healthcare for older persons

- 1** Mental health (MH) problems for older people are managed within primary care.
- 2** Ensure availability of essential psychotropic drugs to old persons.
- 3** MH care for older people is delivered in the community by personnel specifically trained and working in adapted structures. MH care services should promote mental health and the early identification of MH problems in old age. Avoid the use of inappropriate institutional settings. A specialist old age psychiatry service should be available for at least advice and some referrals.
- 4** Educate the public and support non-governmental organizations in public education on specific topics concerning old people.
- 5** Involve communities, families, and consumers, e.g. promote the formation of self-help groups to support individual patients, together with families and caregivers. Such initiatives require funding.
- 6** Ensure that the MH programmes, policies, and budgets sufficiently take into account the needs of old people.
- 7** Train primary health care workers in psychiatry of older persons and ensure that psychiatry of old age is taught in graduate and postgraduate courses dealing with health care of older persons.

Principles of service provision in old age psychiatry

- 8 Develop programs to prepare people for retirement and develop support for non-governmental organizations working in this area.
- 9 Monitor community MH of older persons by including mental disorders in older persons in basic health information systems and by conducting local and national surveys.
- 10 Support research about prevalence, course, outcome and impact of mental disorders in old people living in LMICs.

The nature and scope of old age psychiatry services

This chapter is mainly concerned with specialist services for older people with mental health problems. The boundaries of this activity are rather imprecise, and most interactions with older people and mental disorders will be in social care settings, such as day centres and home care services, or in primary care, where most common disorders, such as depression, frequently present. The contributions of primary care and social care are discussed in Chapter 22 and Chapter 25, respectively. Another important point of contact is in general hospitals (see Chapter 24, which discusses liaison psychiatry for older people).

There are also variations as to the boundaries of specialist services. In some countries, especially if old age psychiatry is not a recognized specialty, this work may be undertaken by general psychiatrists, geriatric physicians, or neurologists. For example, in the US, dementia is largely regarded as a neurological disorder, so that most diagnostic work is undertaken by neurologists, and dementia research lies within the remit of the National Institute of Neurological Disorders and Stroke. Where designated old age mental health services do exist, some limit themselves to dementia, while others accept a full range of mental health conditions. Some services operate as 'all-age' teams for all patients over the age of 18, but have some practitioners within the team who specialize in seeing older patients—in effect operating as an old-age team within a generic service.

The term used for the specialty can also vary. In the UK, 'psychogeriatrics' has largely been superseded by 'old age psychiatry', as its practitioners have emphasized their links with the rest of psychiatry, rather than with geriatric physicians (though there is still debate about the best term to cover this field). In the US, the relevant specialty is 'geriatric psychiatry', though this is often a rather different activity from UK old age psychiatry, as the integral links with community teams are not always present to the same degree, and the diagnosis and medical

Principles of service provision in old age psychiatry

treatment of dementia is more the concern of neurologists. Geriatric psychiatry in the US has been criticized for moving away from the principles of comprehensive, interdisciplinary assessment and therapy, and tending to abandon frail, very old people in favour of those nearer 65 with less-complex needs (Blazer, 2000).

However, despite these problems of terms and boundaries, the following section is mainly about the model of old age psychiatry that has developed from these various influences. There are two accounts to consider: one is the 'traditional' model of old age psychiatry, with its constituent components, and the other includes more recent developments that move away from this simpler model to a more diverse array of services (see Box 20.2). And, given the challenges confronting specialist old age psychiatry services, it is important to consider the evidence whether specific, age-based services provide benefits for patients and families. Draper and Low (2004) summarized a series of systematic reviews of different aspects of services and found good evidence to support multidisciplinary community mental health services, collaborative treatment of depression, and outreach to care homes. However, more up-to-date assessment of the evidence appears to be lacking.

Box 20.2 Components of old age psychiatry services

'Traditional' elements

- Community mental health teams
- Memory assessment services and memory clinics
- Day hospitals
- Respite care
- Support to carers
- In-patient care
- Consultation-liaison psychiatry
- Working with other agencies

Newer topics

- Age-inclusive services
- Primary care mental health services
- Post-diagnostic support
- Integrated care and case management
- Crisis resolution and home treatment
- Outreach to care homes

Principles of service provision in old age psychiatry

Components of old age psychiatry services

Community mental health teams

The English National Service Framework for Older People (DH, 2001a) described a service model for community mental health teams (CMHTs) that reflected agreed norms at that time. Developments since then have been described in a series of studies by Challis and his group in Manchester that trace the changing size and practices of CMHTs (e.g. Tucker et al., 2015; Wilberforce et al., 2015; Verbeek et al., 2018). The core members of the specialist mental health service include consultant old age psychiatrists, community mental health nurses, clinical psychologists, occupational therapists, and social workers. Additional untrained staff, such as health and social care assistants, often make significant contributions (Wilberforce et al., 2017), and adequate administrative support is essential. Agreed working and referral arrangements with other professionals, such as speech and language therapists, physiotherapists, and dieticians, are also required, though these disciplines are not usually members of the team itself. Most CMHTs have this structure, although variations are often seen in practice. Most frequently, one or more professional groups may be lacking—often clinical psychology as there is a lack of practitioners working with older people. There may just be a single consultant psychiatrist for a team, and the consultant may work somewhat detached from the team, perhaps taking separate referrals but also having other commitments elsewhere, e.g. in-patient units.

CMHTs characteristically cover an agreed sector, which may be defined geographically or else by which general practices refer to the team. In the UK, teams usually deal with the full range of mental disorders, not solely dementia. There will be an agreed route of referral, with most referrals in practice coming from primary care, but also from other sources, including social services, residential homes, and sometimes directly from families. Patients appear reluctant to refer themselves, even to teams with open referral policies. Teams are of variable size, often smaller in rural areas. Within a larger team, there is scope for some subdivision of responsibilities or for specialization. For example, each member of the team may be linked to an individual GP surgery or have links with one or more residential or nursing homes in the patch. Or they may develop special roles, such as monitoring patients on antimental drugs.

Leadership in teams is a commonly discussed theme, but there are several aspects to how a team is led. For example, the CMHT will be managed as part of the service to which it belongs; the staff in it will be line managed; they will also have their own professional group hierarchies, which may include supervision of their clinical work; and there may be a designated team leader, whose role will include such matters as chairing the referral allocation meeting. As well as this, consultant psychiatrists provide clinical leadership to the CMHT, which seems to

Principles of service provision in old age psychiatry

comprise a commitment to be involved in the assessment and management of more complicated cases and to act as one of the main conduits between the CMHT and other parts of the service, especially in-patient care.

There is good evidence that CMHTs for older people offer effective interventions. In one of the first evaluations of the impact of a community team, O'Connor et al. (1991) found that early intervention led to *increased* admissions to long-term care within a two-year period for people with dementia living alone. This may have reflected that this group was in fact living in conditions of high risk and relative neglect, though in a more recent study Wilberforce and colleagues (2016) also found that well-integrated CMHTs improved access for patients to other community services but did not reduce rates of institutional admission. Callahan and colleagues (2006) found that an interdisciplinary team working collaboratively with primary care provided significant improvements in the quality of care and in behavioural and psychological symptoms of dementia among primary care patients and their caregivers. Rothera and colleagues (2008) found that a multiagency specialist support team for older people with dementia achieved better outcomes than standard services. Occupational therapy interventions have also been the subject of randomized trials in Europe, with rather conflicting results despite initial promise (Graff et al., 2006; Voigt-Radloff et al., 2011).

However, most RCTs of interventions by CMHTs have concentrated on depression (Draper and Low, 2005). Of these, four out of six reported that the team input was more effective than the control intervention, and these findings have been supported by data from several uncontrolled studies.

There is a good case that assessment and management should take place at home where possible, rather than, say, in outpatient clinics. The advantages of this include being able to take in aspects of the patient's social surroundings in one visit, as well as being highly acceptable to many older people. Case management, in various forms, often known in the UK as the Care Programme Approach (CPA), is an effective way of ensuring that patients are kept in contact with the service. Case management seems to be effective at reducing overall costs and care home admissions for people with dementia living at home (Reilly et al., 2015), but the evidence is variable due to differences in study designs and outcome measures used. It is accepted that specialist teams for older people are more effective at managing depression in older people than general adult mental health teams, though this has not been formally evaluated (Draper and Low, 2005).

As regards the specific role of psychiatry, consultant home visits are probably best targeted at more complex cases requiring diagnosis and the initiation of treatment, but there are few if any recent studies of this practice. Home-based practice lessens the rate of failed appointments and also may cost less than running an outpatient clinic. However, many

Principles of service provision in old age psychiatry

old age psychiatrists hold outpatient clinics in addition to seeing patients at home. Such clinics may be very useful for following up relatively mobile patients, often those with functional disorders, e.g. assisting with managing certain patients on lithium treatment using shared protocols with primary care (Head and Denning, 1998).

Thus, CMHTs for older people are well established in various countries, and there is good evidence to support this style of service. There remain several issues where further research evidence would be helpful. For example, there are no studies that evaluate patient outcomes from specific members of the multidisciplinary team.

Memory assessment services and memory clinics

These specific topics are discussed in Chapter 23. As mentioned earlier in The nature and scope of old age psychiatry services, in many countries patients referred for memory assessment are seen by geriatricians or neurologists, with the role of the psychiatrist being much more to deal with behavioural and psychological problems in people who already have a diagnosis. The English National Dementia Strategy (DH, 2009) placed much emphasis on the importance of early diagnosis and called for the development of new memory assessment services, though it did not specify where these should be located or who should run them. However, in the UK, most memory assessments are performed by old age mental health teams. In recent years, reflecting the increasing numbers of referrals, these have often become nurse-led, with trained nurses undertaking standardized assessments under a variable degree of medical oversight. Nurse-led, as opposed to consultant-led, clinics may attract a lower proportion of referrals with MCI and dementia, especially if they have a self-referral policy (Minstrell et al., 2015).

Memory *clinics* are often, though not necessarily, hospital-based. They were first established in the late 1980s and early 1990s, often by geriatricians and neurologists as well as psychiatrists. They became more widespread and increasingly the domain of old age psychiatry (Lindesay et al., 2002). They are an efficient vehicle for diagnostic assessment and investigation of possible dementia and mild cognitive impairment, and were often set up for research purposes such as recruiting patients to trials of antidementia drugs. However, memory clinics can face some challenging issues, such as waiting lists caused by the complex protocols of some clinics, an overemphasis on medication, and a lack of integration with social care and other community support. From the patient's perspective, the process is often labyrinthine, slow, and confusing (Samsi et al., 2014), so clearly more attention to the patient and carer view is needed when designing services. Following patients up in memory clinics appears no more beneficial than follow-up in primary care (Meeuwssen et al., 2012). Nonetheless, memory clinics can be an effective means of recruiting and monitoring patients in trials of new drugs.

Principles of service provision in old age psychiatry

Thus, memory clinics have tended to broaden their scope, focusing less on academic research and more on early cognitive problems (Ramakers and Verhey, 2011). However, the emphasis is now more on memory *services*, which can be more population based, providing assessments and interventions closer to home. Various models exist, e.g. services based around assessment at home (Banerjee et al., 2007) or in primary care (Greening et al., 2009; Lee et al., 2010), as these seem to achieve high acceptability, high appropriate referral rates, and user satisfaction.

Day hospitals

Day hospitals (often referred to in the US as partial hospitalization programmes) have tended to decline over the last decade or so. Historically they were regarded as a key component of old age psychiatry services (Audini et al., 2001), though their efficacy was often questioned (Fasey, 1994). Day hospitals for older people with medical illnesses offer benefits compared with no treatment, but they are not more effective than alternatives such as home care, and therefore there is no evidence that they are cost effective (Brown et al., 2015). The same is likely to apply to mental health day hospitals for older people.

In the UK, day hospitals are generally distinguished from day centres, the latter being run by social care providers and the voluntary sector, whereas day hospitals are part of the health service. There are therefore differences in funding and staffing arrangements in each type of facility. Day hospitals are more likely to focus on assessment and therapeutic activities (Reilly et al., 2006), and are generally looking to discharge patients elsewhere, either after an agreed period of attendance or once a suitable outcome has been achieved. Day centres do not have the same emphasis on assessment, activities are generally diversionary rather than therapeutic, and indefinite attendance is not usually a problem.

Wilson and Hussain (2008) provided a review of the changing status of day hospitals, which included standards for auditing service quality. Virtually no research has been published since then, which reflects the continuing decline of day hospitals. Many have closed completely, often as a cost-reduction exercise, or else their functions are limited to specific, short-term activities, e.g. post-diagnostic support or the provision of cognitive stimulation therapy.

Respite care

Respite can be regarded as a service (that provides carers with a physical break from their responsibilities) or as an outcome (a psychological break) (O'Shea et al., 2019). It has the limitation that it focuses upon the carer's side of the relationship, with the interests and wishes of the person who has dementia being relatively neglected. O'Shea and colleagues therefore suggest that 'restorative care' would be a more helpful term to employ.

Principles of service provision in old age psychiatry

That having been said, respite care comprises a mixture of activities aimed at giving caregivers temporary opportunities to be away from the patient in order to reduce their stress and to delay or prevent care home or hospital admission. There are broadly three types of respite: short residential placements, day care, and home care. Short-stay respite care is generally provided in residential and nursing homes rather than in hospitals. Respite care may be planned, offered in a crisis, or at the request of the carer.

More recent systematic reviews of 'frail older people' (a category that includes many people with dementia as well as physical health problems) (Mason et al., 2007; Shaw et al., 2009) found evidence of some benefit to carers in terms of decreased burden and improved mental and physical health. There was no reliable evidence that respite either benefits or adversely affects the care recipient, or that it delays entry into residential care. Evidence around respite care for dementia is patchy (Maayan et al., 2014; Vandepitte et al., 2016) but suggests that day care helps caregiver burden; conversely temporary residential admission may cause disruption for both the carer and the person with dementia (PWD); and home-based community respite shows promise but has not been well evaluated. A review of the effects of residential respite care on the behaviour of older people with dementia found variable results, with a modest but short-term reduction in symptoms in some studies (Neville and Byrne, 2007).

However, in practice, many carers regard respite as a priority, especially if it is flexible and readily available (Kampanellou et al., 2017). Carers of people with dementia are more likely to use respite care than carers involved with other long-term conditions (Vecchio et al., 2016) and they often describe high levels of satisfaction with it. When respite care is not used, this seems to be mainly caused by carers' beliefs about adverse outcomes (Phillipson et al., 2013). Respite care may be used by some carers to help them keep the PWD at home for longer, whereas, for others, respite care functions as a stepping stone on the way to long-term care, so it is not surprising that there is no demonstrable effect in delaying admission into residential care. Sometimes, perhaps, respite care is offered when what is really needed is long-term care, in which situation it may be regarded as a form of rationing. Overall, it does appear that providing respite in various forms, in partnership with other agencies, is a legitimate activity for old age psychiatry services.

Support to carers

Old age psychiatry was perhaps one of the first areas where carer issues were first recognized (e.g. Argyle et al., 1985); Chapter 54 provides a more detailed account of this topic. In summary, countless papers have documented how carers of people with dementia seem to have particularly high levels of stress and physical ill health (Gilhooly et al., 2016), together with lower levels of satisfaction with services than other carers. However, the problems of caregiving can be overstated in clinical samples, and a more balanced view is probably more appropriate. Positive

Principles of service provision in old age psychiatry

aspects of caregiving can include a sense of personal accomplishment and gratification, feelings of mutuality in a dyadic relationship, an increase of family cohesion and functionality, and a sense of personal growth and purpose in life (Yu et al., 2017). It is also clear that the previous quality of the relationship with the affected person is an important influence on the experience of caregiving (Quinn et al., 2009).

As a consequence of the importance of carers and their relationship with the PWD, assessments of patients also routinely include assessment of the carers' mental state and coping resources. Indeed, in the UK, carers are legally entitled to their own separate assessments. A carer's needs appear to have two components (McCabe et al., 2016), the first being in relation to the PWD and their care (information about the condition, behaviour changes, access to care) and the second being the carer's own needs (which includes their own health but also their sense of having a life).

Most services provided for patients will also directly or indirectly benefit carers: for instance, treating the patient's symptoms can make life more tolerable for the carer. Many of the services for people with dementia, e.g. day care, respite care, and the management of difficult behaviour, are often aimed primarily at improving matters for the carer. Several systematic reviews have shown that psychosocial interventions for carers of people with dementia can be effective across a range of outcomes (e.g. Selwood et al., 2007; Gilhooly et al., 2016). Perhaps sadly, befriending interventions for carers do not seem to be effective, due mainly to low rates of uptake (Charlesworth et al., 2008).

As well as this, there is considerable interest in supporting carers (especially carers of people with dementia) through educational and other means. At the most basic level, this includes carer support groups, where carers can provide mutual support by sharing experiences and passing on skills they have learned from their own roles. More formal programmes have been developed and evaluated that comprise various elements, such as improving carers' knowledge of mental health problems and teaching exercises to deal more effectively with challenging behaviours; early examples include Mittelman et al. (1996) and Brodaty et al. (1997). The best evidence is for teaching behaviour management strategies in response to the PWD's behaviour, with individual sessions appearing more effective than group interventions (Selwood et al., 2007).

One particular model of working with carers is that of Admiral Nurses. These are specialist mental health nurses working in the field of dementia. The emphasis in their work is on working with family carers, as well as with the PWD. The concept of Admiral Nurses belongs to the charity Dementia UK (<http://www.dementiauk.org/>), which was founded to respond to the unmet needs of family carers. It is a popular model with carers and families as the nurse remains in contact with them throughout the patient's journey. There is a challenge for the model to demonstrate improved outcomes beyond service evaluations and individual case studies (Knight and Denning, 2017), but, more pressingly, as the nurses

Principles of service provision in old age psychiatry

are often funded on a start-up basis, they are vulnerable to cost-saving measures in local services.

Carers also have an important role to play in the formal and informal education of personnel training in old age psychiatry and other professional groups; they can provide a valuable independent perspective in the evaluation of mental health services (Denning and Lawton, 1998). They are often the most passionate and effective lobbyists especially on behalf of people with dementia. Carers are an important force in organizations such as the Alzheimer's Society in England and equivalent organizations elsewhere. They often form the core of public and patient involvement in dementia research and can have an important part to play in setting the research agenda (Kelly et al., 2015).

In-patient care

Across the world, there are varying patterns of in-patient provision for older people. In LMICs, there are often relatively few in-patient mental health beds generally, so in-patient care is a less important contributor to the overall picture. Some countries, notably in eastern Europe, still have large mental hospital populations, in which there may be no specific provision for older people. Elsewhere, there has been a considerable fall in mental health bed numbers as large old-style hospitals have been closed down. In England, for example, mental health bed numbers have fallen from 67,000 to 18,407 in the last 30 years (NHS England, 2019), with no sign of this trend having finished. In other countries, e.g. Australia, bed numbers have been stable in the last few years. For most countries, it is difficult to obtain accurate figures for older people's mental health beds, even if specific provision exists.

There are some significant issues around mental health in-patient care for older people. Wards for older patients are usually separate from those for adults under 65. Wards for mixed ages tend to disadvantage older people, who may be relatively neglected in the face of demands placed by younger, psychotic, and disturbed patients. It is also customary to separate dementia and functional illness, since experience suggests that depressed patients find the presence of patients with dementia and behaviour problems quite difficult to bear. In-patient care for dementia largely caters for patients with particularly difficult behaviour problems. In general, hospitals do not provide long-stay care for people with dementia and, in the UK and elsewhere, this care is usually provided by residential and nursing homes (see Chapter 26).

Published evidence indicates that good links between in-patient units and their respective community teams are beneficial for patients. In the past, it was usual for a consultant psychiatrist to be responsible both for in-patient beds and the corresponding sector of the community, but this is now less common and it is more usual to have a separation between in-patient and community consultants. This can lead to problems in communication and discontinuity of care unless liaison between the

Principles of service provision in old age psychiatry

teams is given suitable priority. Community follow-up, including outpatient attendance and community psychiatric nurse visits, reduces readmission for patients with depression. Longer lengths of stay in hospital are also associated with fewer readmissions, but the relationship between length of stay and other outcomes is less clear. Studies of in-patient treatment suggest quite good treatment outcomes, both for depression and for behavioural and psychological symptoms in dementia (BPSD) (Draper and Low, 2004).

Although joint assessment wards with geriatric medicine were at one time recommended, they are now uncommon. A recent trial of a specialist medical and mental health unit achieved improved patient experience and carer satisfaction but no significant improvements in health outcomes, probably because the patients were very elderly and many were close to the end of their lives (Goldberg et al., 2013). Various factors have contributed to the decline of joint units, but it appears that geriatric physicians are more comfortable with a responsive psychiatric liaison service, and geriatric psychiatrists are satisfied if there is adequate access to medical and diagnostic facilities for their physically unwell patients. It is sometimes somewhat arbitrary as to the bed in which a person is finally placed. Evidence suggests that older patients with dementia in acute hospitals have worse outcomes (Sampson et al., 2009) and patients with depression fare better in mental health care than in general wards (Norquist et al., 1995).

Consultation-liaison psychiatry

Older people in acute hospitals have high levels of psychiatric morbidity, especially dementia and depression. Referrals of patients in general hospital beds generate high volumes of work for old age psychiatry services. This important topic is discussed in Chapter 24. From the point of view of this section, it is worth noting recent developments in this area.

Consultant psychiatrists have always had an important role in diagnosis and advice about treatment in medically complex situations, but in isolation cannot hope to deal with the volume of mental health needs in a large general hospital. In the UK, the report *Who Cares Wins* (Royal College of Psychiatrists, 2005) set out clear recommendations for improved liaison services. Tadros and colleagues (2013) developed the RAID (Rapid Assessment, Interface and Discharge) service and showed that, by reducing lengths of stay in hospital, it could reduce the needs for beds by about 10% with concomitant financial savings. Although RAID was not specifically aimed at older people, most of the impact was upon beds occupied by older people. This model has attracted wide interest and investment in liaison services in the UK.

Relationships to other agencies

There are several key relationships to consider, several of which are discussed in more detail in other chapters of this book. They include working with primary care (Chapter 22), other branches of medicine

Principles of service provision in old age psychiatry

(Chapter 24), social services (Chapter 25), non-government agencies, and residential and nursing homes (Chapter 19 and Chapter 26). End-of-life care, especially in relation to people with dementia, has become an increasingly important area of research and practice in recent years. Palliative care and end-of-life issues involve all of these different agencies (see Chapter 27 and also Chapter 53 for end-of-life issues in dementia).

Age-inclusive services

There is justifiable concern that people should not be discriminated against on the basis of their age. Indeed, age discrimination has now become illegal in the UK through the Equality Act 2010. Part of the reason for this legislation was evidence that older people were denied access to certain health services solely on the grounds of their age (Lievesley, 2009). For example, in the field of mental health, this often included access to psychological treatments. How age equality should be translated into mental health services remains a matter of debate. The two opposing viewpoints are, on the one hand, that age inclusiveness means that a separate specialist service for older people is in itself discriminatory, and, on the other, that the needs of older people are distinct and therefore age equality does not mean scrapping the older people's mental health services as a separate entity.

The authors' view is that the second viewpoint is correct. In some parts of the country, services for older people have indeed been merged with those for younger adults. There may or may not remain a separate service for the assessment and management of dementia. This has been as much a cost saving measure as for the clinical benefit of patients. However, in such general services, it is always likely that the more immediate physical risks posed by younger patients, especially those with psychosis, substance misuse problems, and personality disorders (often in combination), will take up much of the attention of the team to the detriment of older people (Warner and Jenkinson, 2013). Mixed age, 'age-inclusive', in-patient units are often characterized by depressed older people cowering in corners and being generally neglected. Even within community teams, it is difficult to maintain the specific expertise required for supporting older people.

Of course, in present times, most people in their late sixties do not regard themselves as old, especially if they have good physical health and either employment or a viable pension. There may be a case for a more flexible boundary between younger adult services and older people's services, based on need rather than exact chronological age. However, beyond this stage in life, cognitive impairment and/or physical ill health become much more important features, and so the approach to assessment and diagnosis is very different for someone in their eighties or nineties to that for a 30-year-old. There are special skills in either case and it is important that these are maintained and not lost in the pursuit of political correctness. Box 20.3 shows the current criteria for old age psychiatry services developed by the Faculty of the Psychiatry of Old Age (Royal

Principles of service provision in old age psychiatry

College of Psychiatrists, 2015) and the Royal Australian and New Zealand College of Psychiatrists (2015).

Box 20.3 Current criteria for old age psychiatry services

Royal College of Psychiatrists (2015)

- 1 People of any age with a primary dementia.
- 2 People with mental disorder and physical illness or frailty that contributes to, or complicates, the management of their mental illness. This may include people under 65 years of age.
- 3 People with psychological or social difficulties related to the ageing process, or end-of-life issues, or who feel their needs may be best met by a service for older people. This would normally include people over 70 years of age.

Royal Australian and New Zealand College of Psychiatrists (2015)

- 1 People with serious mental disorder, aged 65 or older, newly presenting to local mental health services or who have not been under the care of other local mental health services for a regionally-specified amount of years.
- 2 People with serious mental disorder and significant age-related physical illness or frailty which compounds or complicates the management of the mental disorder.
- 3 People with serious mental disorder and significant psychological or social difficulties related to the ageing process where their needs may best be met by a service for older people.
- 4 People of any age with a primary dementia and serious behavioural and/or psychological symptoms.

© 2015 The Royal College of Psychiatrists and New Zealand College of Psychiatrists

An argument is sometimes presented that services for 'functional' disorders can be provided separately from dementia, and therefore that the functional part of the service can safely be amalgamated with the general adult service. However, this overlooks one of the central diagnostic challenges for old age psychiatry, which is the assessment of states (such as mild cognitive impairment, late onset depression, and depression with a physical illness) where it is not clear whether or not the problem is mainly organic and, if so, to what extent. Many of these cases cannot be easily assigned to 'functional' or 'organic' categories.

Principles of service provision in old age psychiatry

There are numerous challenges to achieving equality in mental health services (National Development Team for Inclusion, 2011). These include such issues as a lack of data on outcomes for older people; poor experience of services, notably in general hospitals; inequity of access to treatments and other services; and low expectations and pessimistic assumptions about outcomes for older people. To bring about improvements requires leadership and a clear vision as to what truly constitutes age equality, making more use of the voices of service users and carers, as well as demonstrating the use of evidence-based practice.

In summary, it matters not so much how the services are organized as that there is a clear philosophy and a genuine commitment to equality of access to appropriate support irrespective of age. However, this does require recognition that older people's issues are different in certain ways and therefore specialist expertise is relevant and necessary. There is a real risk that in 'age-inclusive services', older people may be neglected because of the pressures generated by younger patients, and the leadership of such teams may not have the necessary expertise and understanding of older people's issues.

Primary care mental health services

Most consultations related to mental health take place in primary care and most patients are not, and do not require to be, referred to specialist mental health services. In recent years, there has been much more interest in the actual services that might be offered to people attending primary care, apart from seeing a GP or the practice counsellor. A primary care setting may have advantages over being seen by a specialist mental health team, e.g. familiarity, convenience, a broader focus on physical health matters, availability of blood tests, and prescribing. Primary care mental health is seen as having two components: first-line interventions that are an integral part of general health care; and mental health care, which is provided by primary care professionals who are skilled, able, and supported to provide it (Funk and Ivbijaro, 2008). The latter group may include primary care mental health workers, a relatively new professional group, who in practice are often graduates looking to gain further experience before entering a clinical profession. They tend to work on a generic basis, though obviously some patients will be elderly. It should be noted that educational interventions to improve GPs' diagnostic and management skills in dementia are usually unsuccessful (Iliffe et al., 2015).

In addition, other workers from older people's specialist mental health teams may be based in primary care, for example, community psychiatric nurses, but generally they have remained part of a CMHT in order to prevent professional isolation. In some places, as mentioned earlier, memory clinics may be based in a primary care setting.

Principles of service provision in old age psychiatry

Another important development in the UK has been the programme Improving Access to Psychological Treatments (IAPT) (<<http://www.iapt.nhs.uk/>>), which was established in 2006 and extended to older adults in 2010. IAPT provides cognitive behaviour therapy at two levels of intensity. There is a standard approach, and routine outcome measurement forms part of the package. Although IAPT is not technically a primary care mental health service, as referral is usually required, it sits closer to primary care than traditional mental health services, and clinics are often held in primary care or close at hand. It remains questionable whether older people in fact receive fair access to the service—but when they do, they have outcomes at least as good as younger people (Prina et al., 2014).

Finally, collaboration between primary care and specialist mental health services is clearly important, covering all aspects of the patient's journey from referral to admission, follow-up, and back to primary care. Several important studies from the US have demonstrated the advantages of collaborative care between specialist services and primary care for older people, both those with depression (Unützer et al., 2002; Von Korff et al., 2011) and those with dementia (Callahan et al., 2006, 2011). What is not yet evaluated is whether such collaborative arrangements will confer similar benefits in other health systems with more of a tradition of community-oriented old age psychiatry, and thus trials in other countries are needed.

Post-diagnostic support

Until fairly recently, there has perhaps been more emphasis placed on getting a diagnosis of dementia—referral pathways, diagnostic assessment, the impact of a diagnosis. The recent drive in countries such as the UK to increase the proportion of people with dementia receiving a diagnosis has highlighted the question as to what happens then. Alongside this, resources to CMHTs for older people, who traditionally undertook this role, have been reduced in recent years. The expectation is that patients with dementia, once diagnosed and, if appropriate, commenced on treatment should be discharged from specialist care rather than maintaining indefinite contact with the mental health service. In consequence, there is the prospect of increasing numbers of people being diagnosed with dementia but with little being offered to them.

In response, attention has been placed on the rather nebulous concept of post-diagnostic support. Everyone agrees that it is a good thing and that people should have access to it: see, for example, the Department of Health (2016) joint declaration. However, issues of important detail, such as who will provide it and where the resources will come from, are generally missing from such statements. The Scottish Government (2017) has made most progress in defining and operationalizing post-diagnostic support based on two models from Alzheimer Scotland. These are the Five Pillars for post-diagnostic support (Simmons, 2011) and the Eight Pillars for integrated care co-ordination in moderate to severe dementia

Principles of service provision in old age psychiatry

(Kinnaird, 2012). The components of these two models are listed in Box 20.4. The Scottish Dementia Strategy (Scottish Government, 2017) includes a commitment to a guaranteed minimum of one year's post-diagnostic support, which will be continued for the duration of the person's time living with dementia or until their needs change and they require a greater degree of care coordination. It remains to be seen whether this promise can be met, in terms of the available resources and also whether the assigned link workers will have the ability to access the necessary services (Moir and Miller, 2015). Such general services are usually based around a model of Alzheimer's disease and may be less appropriate for the needs of people with other types of dementia.

Box 20.4 Alzheimer Scotland Pillars of post-diagnostic support

Five Pillars: To support people after diagnosis

- 1 Help to understand the illness and manage its symptoms
- 2 Support to stay connected to the community
- 3 Peer support from other people with dementia and their families and carers
- 4 Help to plan for future decision-making
- 5 Support to plan the shape of the person's future care from their own perspective

Eight Pillars: Community support for living at home

- 1 Dementia Practice Coordinator
- 2 Therapeutic interventions to tackle symptoms of the illness
- 3 General health care and treatment
- 4 Mental health care and treatment
- 5 Personalized support
- 6 Support for carers
- 7 Environment
- 8 Community connections

Source: data from Simmons, H. (2011). Getting Post Diagnostic Support (PDS) right for people with dementia; Adapted from Kinnaird L. (2012). Delivering Integrated Dementia Care: The 8 Pillars model of community support. Alzheimer Scotland, Edinburgh.

Hopefully, any major initiatives in post-diagnostic support will be supported by research into how effective and cost-effective they are. One relevant study, a randomized controlled trial of an eight-week manualized intervention aimed at supporting the mental health of family carers (Livingston et al., 2014), showed clinical and cost-effectiveness and merits further work on its implementation (Lord et al., 2017).

Principles of service provision in old age psychiatry

Despite any shortcomings of what is currently on offer, it is clear that giving people a diagnosis of dementia is not an end in itself, and it is what happens subsequently that makes a real difference to their lives and those of their families. PWDs and their families place great value upon having access to professionals with dementia expertise, potentially over an extended period. Currently this is often frustrated by organizational boundaries and funding issues. It should be more of a priority.

Integrated care and care management

Mental disorders in later life are complex, as they may extend over several years, frequently co-exist alongside physical health problems, and may require input at different times from a range of different practitioners and agencies. Therefore, attention is needed to specify what input may be regarded at what stage and also how the various inputs will be coordinated, otherwise people will not receive the help that they need at the appropriate time, and there may be neglect or unnecessary duplication of effort. Most of the work in this area has been done around dementia, so the rest of this section focuses on dementia, but similar issues apply to the management of other conditions, such as depression and enduring mental illness.

Integrated care pathways (ICPs) are a means of describing the patient's journey with the condition in question, and numerous examples are available for dementia, for example, that provided by NICE (2018b), which is an interactive flowchart displaying an overview pathway with subsidiary pathways for assessment and diagnosis and for management. Although such care pathways appear straightforward, there are many competing terms and definitions. For example, 'critical pathway' is the preferred term in the US and is used as the MeSH heading in the PubMed database; and De Bleser and colleagues (2006) identified 84 different definitions of the concept in the published literature. It is worth noting that using 'integrated' to describe 'care pathway' is a tautology, as a care pathway inevitably requires inputs to be integrated. Schrijvers and colleagues (2012) discussed the advantages and disadvantages of using care pathways. In short, the system is more predictable at the cost of professional autonomy and role satisfaction. A care pathway also enables components of the system to be specified and priced as part of contracts—something that has become increasingly important in modern health care.

As regards pathways for dementia in particular, the problem of ambiguity remains. Samsi and Manthorpe (2014) identified at least four applications of the term: as a means of reducing uncertainty for the PWD and for professionals; to sequence care activities; a guide to consumers; and as a manual for 'walking with' the person. Care pathways may be relevant at various stages of dementia, ranging from the identification of early symptoms to end-of-life care.

Principles of service provision in old age psychiatry

How the pathway is implemented requires some oversight and coordinating activity. For the individual user of the pathway, this is known as care management. Again, this is a deceptively simple concept, but it has several synonyms (care management, care coordination) and numerous definitions (e.g. Lukersmith and colleagues (2016) identified 22 definitions and five competing models of case management). The sheer quantity of terms and models makes reading the relevant literature quite a challenge! Clinical trials of case management in dementia have had variable results, at least partly due to differences in study design and sampling of participants, though there is evidence of benefit for some outcomes in the medium term (Reilly et al., 2015). A Dutch study found that case management was cost effective even if there was no significant difference in clinical outcomes (MacNeil Vroomen et al., 2016). Another study examined primary care-based care managers but was unable to recruit a viable number of patients (Iliffe et al., 2014). In this case, a process evaluation suggested several contextual barriers to success, with the care managers often isolated and unsupported in their roles (Bamford et al., 2014). Successful case management needs to give adequate consideration to the role of the case manager but also to the theoretical and practical framework within which they will operate (for an example from nursing, see: Denning et al., 2017).

Crisis resolution and home treatment

Krisis (κρίσις) is a Greek word that originally meant a decision or a judgment. In English, it may refer to a difficult or dangerous time; a moment at which a decision has to be made; or a point in an illness when the outcome may turn either way, towards recovery or to death (<https://en.oxforddictionaries.com/definition/crisis>). It includes therefore the possibility of improvement or a time of opportunity, though more usually it is the negative aspects of crisis that tend to be stressed, for instance in media headlines.

Crisis theory began to be applied to psychiatry in the 1960s by Caplan and colleagues (e.g. Caplan, 1964). The first published study of a 24-hour crisis resolution team in the UK was an old age psychiatry team (Ratna, 1982), which reported a reduction in hospital admissions and increased proportion of patients remaining at home at follow-up, though it should be borne in mind that the comparison group was a cohort from an unrelated earlier study. During the 1990s, there was a significant expansion of crisis resolution and home treatment teams across general adult psychiatry, but less so for older people's services, and it is only the last decade that implementation has become more widespread in the older age group.

As regards dementia, a commonly used definition of crisis (MacNeil Vroomen et al., 2013) is 'a process where a stressor causes an imbalance requiring an immediate decision to be made which leads to a desired outcome and therefore a resolution of the crisis. If the crisis is not resolved, the cycle continues.' What constitutes a crisis may be seen from

Principles of service provision in old age psychiatry

the perspective of the patient (e.g. falls, comorbid conditions, inability to live independently) or of the informal caregiver (e.g. emotional toll of worsening dementia, caregiver exhaustion or illness, or even death), or of health and social care professionals (e.g. physiological issues like hypothermia, nutrition, etc; psychological and behavioural problems; or concerns about the home environment). To date, there is no satisfactory typology of dementia crises.

In the UK, services have developed in a patchy manner with considerable variations in team composition, hours of working, extent and duration of support offered, whether they are stand-alone or part of a larger team, and whether they work to defined care pathways. This heterogeneity is reflected by the diverse titles that teams undertaking crisis work may have, e.g. Dementia and Intensive Support Team, Mental Health Service for Older People, Memory Assessment Service (MAS), Mental Health Intensive Recovery, Dementia Crisis Support Team, Dementia Rapid Response Team, and Intensive Recovery Intervention Service (Streater et al., 2017). Most commonly, the team exists as part of a CMHT, or as a separate home treatment team, or as part of a memory assessment service. A more rational and systematic approach is described in Victoria, Australia, with the development of Intensive Community Teams within the aged mental health system (George and Giri, 2011). Teams undertake a range of interventions, which may include any of the following:

- Identifying and working with supportive friends or neighbours;
- Environmental adaptations, e.g. assistive technology or equipment;
- Providing or guiding towards purposeful activity;
- Family carer education and support;
- 24-hour access to healthcare professionals;
- Care planning;
- Attention to physical health;
- Developing relevant, flexible care packages;
- Access to respite care or other forms of residential care when needed.

There are still relatively few studies of crisis teams for older people, most of which have a cohort design and use questionable comparison groups (Toot et al., 2011; Streater et al., 2017). There is a suggestion that crisis teams may reduce the need for hospitalization but confidence in this finding is limited by factors such as study design and possible publication bias. Future research is obviously required as to which models of may be most effective, though a bigger question is whether more energy should be spent on providing effective, ongoing, and supportive care that minimizes the risk of crises occurring.

Principles of service provision in old age psychiatry

Support to care homes

Care home residents have high levels of dementia and other mental health problems, as well as physical comorbidity (Matthews and Denning, 2002; Gordon et al., 2014). Chapter 26 discusses in greater detail both how care home staff may struggle with residents who show difficult behaviour and how depression in residents may be easily overlooked. There are several studies over the last 20 years suggesting benefits from various mental health interventions, describing how mental health staff, either on an individual basis or as dedicated outreach teams, can operate (for a review, see: Thompsell, 2011). Challis and colleagues (2014) found that a small number of published studies of dementia outreach reported positive outcomes for residents with depression, but outcomes for dementia were less certain, apart from some reductions in prescribing antipsychotic drugs. However, at least anecdotally, such teams are often successful, valued by care homes and by GPs, but they are often vulnerable to funding reductions. Goodman and colleagues (2017, p. 119) found that the provision of adequate specialist dementia support was highly valued not only by care homes, but also by other health professionals in contact with residents.

In Australia, Dementia Support Australia (<https://www.dementia.com.au/>) is a federally funded initiative offering two services: the Dementia Care Behaviour Management Advisory Service (DCBMAS) and Severe Behaviour Response Teams (SBRT). These work across all settings but much of their work is with care homes and other aged care settings. In a UK-wide survey, Challis and colleagues (2014) also reported on the highly variable nature of provision specifically for care homes. Some CMHTs provided no dedicated staff time for this function, whereas some services include a specialist outreach team. Where a service was provided, the common elements were usually: working to a specific multidisciplinary service model; holding regular meetings with care home staff and/or GP; preparation of tailored resident care plans; and/or training and education of care home staff. As there is currently great emphasis on reducing hospital admissions from care homes, it is likely that care home outreach is likely to remain an important area of work for old age mental health in the foreseeable future.

Equality issues

The UK Equality Act 2010 makes it illegal to discriminate against a person on the grounds of what are referred to as protected characteristics. These include age, sex, disability, sexual orientation including gender reassignment, race, religion or belief, and marriage or civil partnership. Age has been considered above, but the other characteristics are also important, in addition to which certain other groups may also be at risk of unequal access to services.

Principles of service provision in old age psychiatry

Gender

Women live longer than men, the ratio of women to men increasing with advanced age, though recent increases in life expectancy are slightly larger in men (Jagger et al., 2016) and women spend a higher proportion of their extra years of life in a state of dependency (Kingston et al., 2017) —in some regards men are catching up. Women are more likely to be bereaved and to live alone. Depression is more common in women at all ages. Worldwide, the prevalence of dementia is higher in women and women constitute at least two-thirds of the carers for people with dementia (Corfield, 2017). The majority of older people presenting to health and social care are women, so this area may legitimately be regarded as a feminist issue.

In contrast, older men are in a declining section of the population and may have difficulty finding male company and support in facilities like day centres. They are more likely to be supported by a co-resident carer, which greatly reduces their risk of moving into institutional care (Banerjee et al., 2003). However, suicide rates are higher among older men (see Chapter 40) and men have an increased risk of death after a diagnosis of dementia (hazard ratio 1.56 compared to women; Garcia-Ptacek et al., 2014).

Ethnicity

Just about all countries of the world have significant numbers of people from different ethnic and cultural backgrounds. Developed countries often have large numbers of people who have immigrated from elsewhere for various reasons, e.g. looking for work, to escape persecution. In general, minority ethnic groups have a younger age profile than the majority population, but, even so, significant numbers of older people may be involved. In England and Wales, for example, in 2011, there were 416,000 older people of non-White ethnic origin (4.5%) out of a total of 9.2 million over 65s (<https://www.nomisweb.co.uk/census/2011/lc2101ew>). Of these, just over half (57%) were of Asian/Asian British ethnicity and 28% were Black/African/Caribbean/Black British.

Minority ethnic groups vary greatly in their access to material and social resources. However, there are frequent instances in the literature of factors, e.g. social and economic disadvantage, limited opportunities in education and employment, poor health, poor access to formal services, which can then lead to higher rates of dementia (Mayeda et al., 2016), often occurring at younger ages, with limited access to care and support. In addition, there may be cultural attitudes towards mental illness, dementia, and formal services (general practices, hospitals, and care homes) that make people reluctant to seek help (e.g. Berwald et al., 2016). Failure to recognize dementia as an illness about which something can be done creates significant barriers to obtaining services (Mukadam et al., 2011) but, however, negative cultural assumptions can be tactfully challenged and even in situations where a family wishes to care for their

Principles of service provision in old age psychiatry

relative at home they will often need information, emotional support and sometimes additional care input.

In a meta-synthesis of qualitative studies, Kenning and colleagues (2017) identified two groups of barriers—those arising from the inadequacies of available information and relevant services, and those due to cultural factors. These two areas helpfully suggest where attention is required in order to achieve better outcomes. Setting information about dementia and related topics in an appropriate cultural framework is an important starting point (e.g. Dyall, 2014; see also Fig. 20.1). Botsford and Denning (2015) have provided some recent examples of good practice, though it should be said that robust research showing that initiatives have led to better outcomes is currently in short supply.

Fig. 20.1

Sexuality

Lesbian, gay, bisexual, transgender, and other (LGBT+) older people may face significant challenges, as social attitudes towards same-sex relationships have been much less tolerant in the past. Transgender individuals face uncertainty given that it is relatively recent for there to be significant numbers of people who have undergone gender reassignment (Witten, 2014). Gay and lesbian partners are not necessarily recognized as the next of kin by statutory services and this

Principles of service provision in old age psychiatry

may cause considerable distress, though the recognition of civil partnerships and marriage in many countries will ease this situation for some. In general, LGBT+ people will have fewer children to act as potential carers, so they may be more likely to enter care homes as dementia progresses (Peel et al., 2016). Issues around discrimination or disclosure remain problematic and affect the uptake of services by LGBT+ older people and carers (Addis et al., 2009; Price, 2010).

Peel and McDaid (2015) conducted focus groups around the issues of dementia for LGBT people and identified four main themes that form a useful basis for considering how professionals and services might think about responding. These themes, which were accompanied by matching recommendations, were: personal reflections on experiences of LGBT people with dementia; the identities of LGBT people with dementia; negative experiences with health and social care professionals; and provision of LGBT appropriate support and care home services. Few older people's services are targeted towards the needs of this group and with, in some instances, smaller social networks than their heterosexual peers, LGBT+ older people may need help to access statutory services, despite their low levels of trust and confidence in these services. The LGBT+ charity Stonewall provides a guide for staff working in this area (Taylor, 2017). Sexuality in later life is further discussed in Chapter 50.

Spirituality, religion, and ageing

Religiousness and spirituality have often been ignored by many mental health professionals. This area has often been neglected in clinical practice, leaving a gap to be filled by pastoral care workers, clergy, imams, rabbis, shamans, gurus, and other religious teachers. In recent years, a growing body of work in gerontology has suggested that professionals should be more aware of how the aging process motivates many people to wrestle with questions about life's meaning and purpose, including religious and spiritual experiences (e.g. McFadden, 2008; Nelson-Becker, 2017).

The situation is changing with more books and journal articles being published on this topic. Professional organizations have supported the formation of groups with particular interests in spirituality, religion, and aging (Royal College of Psychiatrists, 2013; Moreira-Almeida et al., 2016). As an example, North American studies show high levels of religious belief and practice in hospitalized older adults (Koenig, 1998). Religion may also have a salutary effect on a range of physical illnesses, including cardiovascular disease, hypertension, stroke, and various cancers (Koenig, 1998). It may therefore modify the otherwise unfavourable impact that chronic physical illnesses are known to have on the presentation and prognosis of depression. This has significant implications for the assessment, treatment, and prognosis of geriatric depression (Payman et al., 2008). Mental health practitioners working

Principles of service provision in old age psychiatry

with older persons should know how to assess, engage, and address the spiritual and religious needs of their clients.

Residents of rural areas

Rural areas present particular challenges to older people's mental health services, but they are important as often the proportion of older people in rural communities is higher than elsewhere. In some parts of the world, rural areas are extremely remote or at great distances from centres of population. Although the massive growth of urban areas across the world means that the *proportion* of people living in rural areas is falling, the actual *numbers* are still increasing. In 2016, 46% of the global population lived in rural areas (compared to 66% in 1960) but the number rose from 2 billion to 3.4 billion over the same period (<https://data.worldbank.org/indicator/SP.RUR.TOTL>). During this time, the proportion of rural dwellers aged over 65 continued to increase. In addition, particularly in large countries, some populations are not only rural, but also distinctly remote and isolated.

Studies of rural health and social care consistently highlight certain themes, such as poor access to assessment and diagnostic services, sparse public facilities such as daytime activities and paid caregivers, and difficulties with isolation compounded by poor and expensive transport (Marshall et al., 2018). It may be difficult to attract skilled practitioners to work in such areas and they may be at risk of professional isolation when they do. Reliance on families to provide care is likely to be higher and this too may be problematic if younger generations have migrated to urban areas in search of work (Chen, S., et al., 2014). All of these issues will affect people with dementia and other mental health problems, and their families. Other obstacles, such as denial of illness and uncooperative or absent family members, seem to be more frequent in rural settings (Teel, 2004), and rural carers may also be reluctant to use the services available (Ervin and Reid, 2015).

A few studies have examined the circumstances of rural older people, mainly with dementia, in relation to the care they receive. However, most of these reiterate the same difficulties with providing services and there is a relative lack of research on the experience of families or people with dementia themselves (Innes et al., 2011). A Canadian study (Bedard et al., 2004) found that rural caregivers did not experience higher levels of burden even though rural patients had a higher level of behaviour disturbance. In North Wales, carers received most essential services even though levels of services were low, but the main problems were a lack of crisis support and a reluctance to accept long-term care when it was needed (Wenger et al., 2002). Rural caregivers draw upon available social support and often their religious faith, engaging in joint activities where possible (Branger et al., 2016).

Principles of service provision in old age psychiatry

Rural healthcare requires opportunistic and novel approaches to providing services. Working towards 'dementia friendly' rural communities is an important approach (Wiersma and Denton, 2016). The whole system needs to contribute, not just a limited domain such as the aged care service (Lindeman et al., 2014). Any rural dementia outreach service needs to be flexible and responsive in its approach (Clancy, 2015). The organization of primary care is crucial as it is likely to be the hub for contact with outside specialists (Wakerman et al., 2008). For primary care physicians, the main concerns are the distance from specialist expertise and lack of local services, weighed against the possible benefits of being immersed in the local community (Kosteniuk et al., 2014). There remains relatively little research as to what is most useful, and it mainly comprises small descriptive studies (Morgan et al., 2011). The use of technology and telecommunications has obvious potential (e.g. Morgan et al., 2014), though older people are often suspicious of new arrangements based on claims of technical efficiency (King and Farmer, 2009). Instead, they value local services with a personal emphasis and continuity. We need a better understanding of how families living with dementia go about their everyday lives and how they manage within their familiar places and spaces (Marshall, 2018). The way forward seems to be making more use of generic services or everyday environments, e.g. pubs, churches, supermarkets, and hairdressers, to provide flexible and effective support to patients and carers.

Older prisoners

There are significant and increasing numbers of older people among the inmates of prisons and special hospitals. In England and Wales, for example, the numbers of prisoners aged over 60 increased by 120% between 2002 and 2013 to reach a total of 3400, around 4% of all prisoners (House of Commons Justice Committee, 2013). Almost half of older prisoners have some form of mental disorder (Hayes et al., 2012), usually depression, and all forms of mental disorder including dementia are over-represented compared with the rest of the population (Di Lorito et al., 2018a). Identification and treatment of mental disorders in prisoners can be readily overlooked in older prisoners, as they are less disruptive. Many prisoners are in unsuitable conditions with high levels of unmet physical and mental health needs (Di Lorito et al., 2018b) and there are only limited facilities to support them after release. The same applies to special hospital patients who may remain detained longer than necessary because there are no alternatives. Aspects of crime in relation to old age psychiatry are discussed further in Chapter 56.

Intellectual disabilities

Article 25 of the UN Convention on the Rights of Persons with Disabilities (UN, 2006) relates to health care and states that people with disabilities should have the same fair access to health care as the rest of the population as well as having the health needs related to their disability catered for. This has obvious relevance to people with learning disabilities

Principles of service provision in old age psychiatry

as, for example, they have higher rates of early-onset dementia than the general population (see Chapter 47 for discussion of dementia and other mental health problems), and they may also be excluded from consideration by mainstream health and social facilities.

In general, specialist services for people with learning disabilities cover the whole age range, and people who develop dementia continue to be served by facilities with expertise in learning disabilities. Good practice should comprise several areas of activity, including: accurate information about the local population that can inform planning; information and advice for older people with learning disabilities and their families; suitable accommodation and support; encouragement to remain active and maintain social relationships; support with health; and good end-of-life care (Turner and Bernard, 2014). Both service provision and research in this area needs to take into account the voices of people with learning disabilities (Innes et al., 2012). An international meeting on intellectual disabilities and dementia held in Glasgow in 2016 considered three broad topics: human rights and personal resources; individualized services and clinical supports; and advocacy, public impact and policy (Watchman et al., 2017). England and Wales have access to published guidance on care and support of older people with learning disabilities (NICE, 2018a). More attention is also required for people with autism spectrum disorders, whether or not they have a learning disability (Piven and Rabins, 2011). In future, there will need to be more closely defined working arrangements between primary care, learning disabilities services, and older people's mental health services.

Very old people

People over the age of 80 are the fastest growing age group in the world population (United Nations Population Division, 2020). The number is expected to increase by almost six times from 2000 to 2050 to nearly 400 million, by which time 70% of over 80s will be living in LMICs. The ageing of the world population has also seen increases in longevity: by 2050 the number of centenarians will have grown by a factor of 18 since 2000, to an estimated number of 3.2 million. About one million of these will live in Japan, which has claims to be the world's oldest population. Definitions of the 'oldest old' or 'very old people' are variable and the thresholds have increased over time with growing numbers of people living (well) beyond 80. Extreme old age has a universal fascination so it is unsurprising that there are multiple cohort studies of centenarians across the world (Brodaty et al., 2016).

With great age, the patterns of common illnesses change. Circulatory diseases become an increasingly common cause of death, but the age-specific incidence and mortality rates of most cancers decline beyond age 90. With regard to mental health, centenarians scored lower on cognitive tests and were more likely to feel useless and that life was routine and not exciting (Martin et al., 1992), and they were more likely to report a lack of social resources compared to people in their 80s (Randall et al.,

Principles of service provision in old age psychiatry

2010). Variable estimates of the prevalence of dementia in centenarians have been reported, due to such factors as small sample sizes, incomplete ascertainment of the population, exclusion of people in care homes, and relatives sometimes declining to give proxy consent (Brodaty et al., 2016). Longitudinal studies to measure the incidence of dementia are hampered by the high level of attrition due not only to mortality but sometimes by moves to institutional care. There is also a conceptual issue that is usually ignored, which is to question whether the concept of dementia is robust at this age. Given that clinical criteria for dementia are based on decline of cognitive and functional abilities compared with normal values, it is perhaps not well defined what constitutes 'normal' for anyone over 100. Whether there is a survivor effect at extreme old age, with the prevalence and incidence of dementia falling due to selective survival, remains controversial. However, cohort studies of centenarians suggest that decline continues to develop with greater age (Miller et al., 2010).

Within the everyday practice of old age psychiatry, over recent years there has been a noticeable increase in the age of many of the patients referred, with consequent increases in medical comorbidity, physical disability, and complex social care needs. This underscores the importance of providing mental health services for very old people that are comprehensive, interdisciplinary, and allied to provision of physical healthcare, and for the policy and research agendas to address the needs of this group (Denning and Gabe, 2000).

Vulnerable people and safeguarding

The mistreatment of older people is considered in more detail in Chapter 55. From the perspective of old age psychiatry services, there are perhaps two main issues. One of these is a concern with the frequency of abuse of older patients that can occur in institutional settings, including hospitals. There is a sad catalogue of hospital inquiries, which highlight similar themes, such as geographical isolation, low staffing levels, lack of training, lack of nursing leadership, and lack of clinical governance. In England, regulation of health and social care services has been brought together under the Care Quality Commission (CQC), which monitors performance against a set of essential care standards. Safeguarding procedures are led by local authority social services departments. There is also a national Disclosure and Barring Service that provides checks for employers about prospective employees who may be required to work with vulnerable groups, which include mainly children and older people.

The other issue for old age psychiatry services is to participate as part of the multiagency, interdisciplinary response to cases that arise in all settings. This may include various roles, such as psychiatric assessment of the victim and/or the perpetrator, assessments of mental capacity (especially when financial abuse is suspected), and participating in vulnerable people's procedures. Health professionals have an important part to play in detecting and reporting suspected abuse (Cooper and Livingston, 2014). To date, it is mainly physical abuse and neglect that

Principles of service provision in old age psychiatry

have been highlighted. Financial abuse is less often detected and professionals probably need to develop more awareness of its possible occurrence (Manthorpe et al., 2012). In any case of suspected or confirmed abuse, it is necessary to follow due process, including good documentation and communication, but so far evidence for the efficacy of abuse interventions to protect older people is unsatisfactory (Baker et al., 2016).

Improving and maintaining old age psychiatry services

Quality assurance

Quality relates to the care and treatment provided to an individual and to the overall provision of services to a population. Much work in improving quality is about reducing variation in clinical practice so that patients can expect a consistent approach across the whole service. This involves consideration of the whole care pathway or 'the patient's journey'. Examples of this in older people's mental health include:

- 1. Referral criteria.** Ensuring that the service sees those patients who are in most need within a reasonable time scale requires collaboration with referrers, especially primary care. Agreeing thresholds not only for referral but also for discharge from a specialist service is an important way of controlling the caseloads of team members. There may need to be agreed arrangements for the transfer of patients who have been with services for younger adults.
- 2. Standardized assessments.** Many organizations now use standard protocols, for example for memory assessments. These often incorporate, or are augmented by, some of the many standard rating scales that are now available for more specific purposes, such as assessment of cognition and of mood (compiled by Burns et al., 2004).
- 3. Guidelines and protocols for treatment.** Clinical guidelines are systematically developed statements to assist clinicians and patients in making decisions about appropriate treatment for specific conditions. Protocols are written plans specifying the procedures to be followed in providing care for a particular condition. ICPs are locally agreed summaries of practice, based on the best available evidence, for a specific condition or patient group. A care pathway may therefore be the application of a guideline in a practical situation. Guidelines and protocols may cover the whole management of a condition or they may emphasize specific aspects of treatment, e.g. the use of antimentia drugs or psychological treatments. Examples include the NICE dementia pathways (NICE, 2018b).
- 4. Care management.** As mental health problems in old age often require input from a range of professionals and from different agencies, ways of recording, storing, and sharing information are extremely important in ensuring a quality service. In the UK, this is provided through the CPA, which uses standard documentation and

provides a comprehensive record that can be regularly updated and shared with patients and carers. Integrating different systems of care management (and different IT systems) has been the biggest challenge to successful joint working between health and social services.

5. Outcomes. In theory at least, measuring outcomes should be the gold standard for quality, as outcomes should have more direct relevance to patients than do the proxy alternatives of structure and process that are usually measured. However, outcome measurement can be a challenge in old age psychiatry, where often 'bad' outcomes such as death or institutionalization may actually follow episodes of very high-quality care. Routine measurement of outcomes, especially using the HoNOS 65+ (Burns et al., 1999), has become more widespread, particularly as clinical clusters derived from HoNOS 65+ are used as the basis for a tariff-based funding system in mental health. An alternative approach is to use measures completed by patients or proxies (patient-rated outcome measures or PROMs), which are often used alongside patient-rated experience measures (PREMs, discussed in following section).

6. Evaluation of services. Research plays a part in this, but health services research may be complex and costly. RCTs are relatively rare and are designed to address specific research questions rather than assess overall service quality. Instead, a range of approaches are used, of which clinical audit and surveys are probably the most important. Clinical audit is a tool to measure the way in which things are being done assessed against agreed standards, leading to a cycle of making the necessary changes and then re-auditing. The selection of topics for audit may be either 'top-down' (imposed) or 'bottom-up' (chosen) and this may create tensions. There may be limited administrative resources to support the work and the evidence that audit leads to better outcomes for patients is sometimes quite thin. Audits may be local or across organizations.

Effectiveness, safety, and patient experience

Clinical effectiveness is concerned with the extent to which a service follows best practice. In England, the most important source of guidance is the National Institute for Health and Care Excellence (NICE), which produces clinical guidelines on important conditions such as dementia and depression, as well as technical appraisals of new treatments (drugs, therapies, operative procedures, etc.). There is current guidance on dementia (NICE, 2018b) and also a technical appraisal for antidementia drugs (NICE, 2011/2018).

Other aspects of ensuring best practice include clinical audit and medicines management. Audits may be local, but there are also national audits, some of which are mandatory, e.g. the National Confidential Inquiry into Suicide and Homicide by People with a Mental Illness (Appleby et al., 2018). The Royal College of Psychiatrists has established

Principles of service provision in old age psychiatry

a College Centre for Quality Improvement (CCQI), which currently runs over twenty service quality and accreditation projects across mental health, covering the full range of in-patient services and community teams (<http://www.rcpsych.ac.uk/workinpsychiatry/qualityimprovement/ccqipprojects.aspx>). The most relevant of these to old age psychiatry are the Memory Services National Accreditation Programme (MSNAP); the Quality Network for Older People's Mental Services (for mental health in-patients), and the Quality Mark for Elder Friendly Wards (in acute hospitals). Other relevant accreditation projects include crisis teams, ECT, and liaison psychiatry. Each of these has a set of agreed standards and provides inspection visits, feedback, and accreditation for participating services. The CCQI also runs national audits, including one on dementia in general hospitals (Royal College of Psychiatrists, 2017b). Another, the Prescribing Observatory for Mental Health (POMH-UK), benchmarks prescribing practice across member Trusts in order to improve standards and consistency. These have included an audit of the use of antipsychotic drugs in dementia (Barnes et al., 2012).

There are numerous indicators relevant to patient safety, including suicide data, incident rates and incident reporting, and information about falls. Workforce information, e.g. staff satisfaction, sickness rates, and the proportion of temporary staff working in a team, is also highly relevant to patient safety. In recent years there has been more attention paid to safeguarding vulnerable adults, which is of obvious relevance too. Organizations, such as NHS Trusts, that run mental health services will have in place a structure for healthcare governance to report at board level on issues related to quality. There will be board-level responsibility for quality and governance including the Trust's annual quality account.

Patient experience is best directly measured by obtaining feedback from people using the service. This may include questionnaire surveys, but also information from complaints and patient enquiries gives an important indication of the issues that concern patients and families. In old age mental health, carers often act as proxies for patients, especially for people with dementia, but it is important to recognize that the interests of patients and carers do not necessarily coincide (Denning and Lawton, 1998). Other objective measures, such as environmental inspections, length of stay; delayed discharges (for in-patients) and clinical outcomes are also important.

Regulation

The regulatory framework for NHS Trusts in England is provided by two public bodies, NHS Improvement and the Care Quality Commission (CQC). However, the CQC has the main role in relation to quality. It is the regulator not only of NHS services but also of the whole of adult social care (community and residential services), as well as having a remit for compliance with the Mental Health Act. CQC has a framework of 13 fundamental standards that apply to health and social care, covering a full range of issues, from treating people with dignity and respect to

Principles of service provision in old age psychiatry

environmental and staffing issues. Organizations are inspected against these standards and required to amend any failures or concerns that are raised. CQC reports are public documents, as are the quality reports produced by Trusts.

Another important part of the regulatory framework is the Quality and Outcomes Framework that operates in general practice and forms part of the basis for payments to GPs and practices. This sets out a series of indicators across 25 major clinical areas that GPs are expected to meet to obtain the requisite payments. Two areas are relevant to old age psychiatry. There are three indicators for dementia, around maintaining a dementia register, performing appropriate investigations for possible dementia, and keeping patients with dementia under review. The indicators for depression apply to all ages but are concerned with diagnosis, assessment of severity, and review. The introduction of this framework has influenced GP behaviour and encourages GPs to seek a diagnosis for people with possible dementia.

Future challenges

Population change

Probably the biggest single challenge to services for old people across the world is posed by demographic change and the ageing population. This takes different forms in different countries. At present, the developed countries of Europe, Japan, and the US have the highest percentages of people aged 65 and over in their populations. Over the next 20–30 years, numbers of older people will continue to increase, but the increase will be especially in very old people, those aged 85 and above. In contrast, LMICs have lower percentages of old people, but in general their populations are ageing at a faster rate. That is, numbers of people aged over 65 will increase by a greater proportion than in Europe and the US. Moreover, as certain countries (e.g. China, India, and Indonesia) have very large total populations, the absolute numbers of older people in these countries will grow very rapidly.

It is estimated that there are currently around 47 million people in the world with dementia (Prince et al., 2015), a figure predicted to double every 20 years to 115 million by 2050. Already, almost 60% of people with dementia live in LMICs and this proportion will grow to 70% by 2050. The worldwide costs of dementia (US \$818 billion in 2015) amount to more than 1% of global GDP, leading to the often-quoted observation that, if dementia care were a country, it would be the world's eighteenth largest economy (Prince et al., 2015) or, if it were a company, it would be by far the world's largest. Most people with dementia, probably three-quarters of the total number, have not received a diagnosis (<https://www.alz.co.uk/research/statistics>).

An ageing population will be associated with not only more cases of dementia, but also with increased levels of other forms of illness and

Principles of service provision in old age psychiatry

disability, and comorbidity of physical and mental disorders. At the same time, an increasing proportion of older people will affect the national economy, especially if the working-age population is not expanding. This has both economic and manpower effects on the resources that are available for health and social services available to older people. There will, of course, be changes in retirement ages and pensions, which may serve to keep people working for longer.

In the light of these changes, every country should be developing a dementia strategy and putting in place systems that will improve access to diagnosis, information, and help. Information on current dementia plans can be found at <https://www.alz.co.uk/dementia-plans>. Although most of these are currently from Europe or some of the wealthier countries elsewhere in the world, it should be possible, even in the poorest countries, to introduce a coherent strategy using simple interventions based in primary care.

Scientific advances

It is impossible to predict what scientific discoveries may influence the future course of mental disorders in old age. At present, no single development seems likely to have a startling impact upon conditions such as Alzheimer's disease. Better general health may improve dementia and depression, too, though this is difficult to demonstrate. The future availability of pre-symptomatic diagnosis of dementia would have an impact upon the demand for services. Clinicians will become adept at using currently available treatments more efficiently. For example, perhaps Alzheimer's disease may respond better to a combination of several treatments, rather than a single drug such as a cholinesterase inhibitor. It will, however, be difficult to do RCTs to investigate combined treatments as large numbers of patients will be required. In the treatment of depression and psychotic illnesses, improved use of newer antidepressant, mood stabilizing, and antipsychotic drugs, together with use of combined treatments, may bring better outcomes with fewer side effects for many patients.

Dementia has been identified as a global priority for research, though the money spent on it remains relatively limited compared to the amounts spent on cancer and heart disease. In the last few years, there has been progress to increase the numbers of people with dementia participating in research. This includes establishing registers of patients with dementia and ascertaining their willingness to participate in research at the outset, together with the further development of clinical and research networks. There are several international initiatives aimed at creating larger collaborative studies and collecting large databases of potential participants, who have been clinically characterized, e.g. by scans or biomarkers. These include the European Prevention of Alzheimer's Consortium (EPAD); the MRC Dementias Platform UK (DPUK); and the Global Alzheimer's Disease Foundation (GAD). In the UK, the National Institute of Health Research hosts Join Dementia Research (JDR; <http://>

Principles of service provision in old age psychiatry

news.joindementiaresearch.nihr.ac.uk/), a public service where any individual (with dementia or not) can sign up to be contacted about suitable studies, and researchers can use the resource to aid recruitment. At present, about 30,000 people have signed up to JDR, of whom about one-fifth are people living with dementia.

Research into psychosocial aspects of dementia and the lives of older people is also crucial, since the likelihood of curative biological treatments still seems distant. Research is also needed into other mental disorders, such as late life depression, psychosis, and substance misuse. The experience of the millions of people who have dementia *now* needs to be addressed and their needs assessed and met. Thus, at least for the time being, that older people will be most helped by the more effective provision of services. Simple routes of referrals, prompt and efficient assessments, access to specialized treatment when needed, care and support at home wherever possible, all backed up by effective care coordination, are all elements of good services that are supported by evidence. In keeping with trends across the whole of medicine (and, indeed, society in general), the prediction is that the voice of patients and carers as consumers will become more powerful, which, in turn, will influence the type of services available, how they are provided, and the agenda for research.

The impact of technology

Technology has many applications relevant to the lives of older people, and there is burgeoning interest in technology as applied to dementia. There are various ways of classifying technology in relation to dementia, for example, by the type of device (e.g. simple health alarms and memory aids, devices using sensors, and devices using remote technology such as mobile phones or iPads) or by the intended purpose (e.g. to aid cognition or improve mood or whether to enhance safety). A useful approach, which approximately corresponds to the stages of mild, moderate and severe dementia, is based on technology that is (respectively) used *by* the PWD, used *with* them, or used *for* them (Gibson et al., 2016). Examples in these three categories might include, first, independently using an electronic calendar to prompt about appointments; second, the use of personalized memory archives or music playlists; and, third, sensors to monitor movement around the home or to detect falls. The term 'assistive technology' (AT) is often used to emphasize the importance of maintaining function and independence when possible. The term includes the process of assessment and choice as well as any actual devices. AT may also be usefully regarded in three categories: AT that is supplied by public social services following an assessment; 'off the shelf' AT that is usually purchased privately, most commonly by the adult children of the PWD; and 'do it yourself' AT, which is the use of everyday household products modified by the person's families in the absence of any specific alternative AT product (Gibson et al., 2015).

Principles of service provision in old age psychiatry

Meiland and colleagues (2017) reviewed issues around the provision of technologies to support people with dementia living at home and reported several challenges that should be addressed. These include more involvement of end users (people with dementia) in developing products and assessing their usability; better studies of outcomes of using technologies; improved databases of available technologies to improve uptake and deployment; and more consideration of potential ethical issues. There is a distinct lack of well-conducted trials to evaluate the usefulness of various kinds of AT, for example, products to support memory function (van der Roest et al., 2017).

As well as through AT, the quality of services can also be improved in various other ways, e.g. improved online access to information for users and carers. Technology can provide contact with services across long distances, e.g. in rural areas (Bradford et al., 2016). Finally, the potential of electronic care records is yet to be fully realized in many countries (though there are exceptions, such as Finland) as systems in public services may be inflexible or incompatible between organizations. However, advances are possible, e.g. identifying retrospective cohorts from routine health records (Baker et al., 2017) or using free text word searching functions to explore clinical topics, such as drug side effects (Iqbal et al., 2017). In the future, we can also expect that individuals will take a much more active role in their healthcare by taking more ownership of their record. This could transform the current relationship between consumers and providers of services, although it may also raise important issues regarding information governance and confidentiality.

Specialist training in old age psychiatry

The development of specialist curricula and training programmes in old age psychiatry has closely followed the development of clinical services. Formal criteria for old age psychiatry training were first adopted in the UK in 1989, followed by programmes in the US, Canada, and Australasia. In Europe by 2012, there were 11 countries with geriatric psychiatry training programmes (Toot et al., 2012) and ten of these also had specialist continuing professional development for consultants.

The European Association of Geriatric Psychiatry, with the WHO and the WPA Section of Psychiatry of the Elderly, published a consensus curriculum of skill-based objectives for specialist training in old age psychiatry (Gustafson et al., 2003). The curriculum comprised 22 areas of competence and learning objectives. These included clinical skills, such as recognition of mental health problems, history taking, and physical examination; relevant areas of knowledge, including ageing and the mental disorders of old age; treatment, management, and care; and the organization of services. There were some rather specific domains, including end-of-life issues and the abuse of older people. The last few competencies were general topics, such as prevention, teaching, knowledge management, and research. The curriculum is perhaps in need of review: for example, competencies are not operationally defined and

Principles of service provision in old age psychiatry

the curriculum does not provide much guidance as to how they should be assessed. Nonetheless, it has been influential in helping countries set up their own programmes.

Details and requirements for training vary between countries. For example, the entry point into specialization in old age psychiatry in the UK is after three years of core psychiatry training, and consists of a further three years, of which at least two must be in old age psychiatry. In the US, doctors acquire the certificate in psychiatry of the American Board of Psychiatry and Neurology and then undertake an additional year of geriatric psychiatry before sitting the exam for the additional certificate, though there are calls for this additional year to be incorporated in the three years of general psychiatric training in order to improve recruitment in geriatric psychiatry (Kirwin et al., 2016).

In general, however, there has been a trend towards old age psychiatry/geriatric psychiatry both becoming more central to the core curriculum of psychiatric training and acquiring its own identity as a specialty. A good example is provided by Canada, where geriatric psychiatry has recently become required as part of core training for psychiatry, and in 2009 geriatric psychiatry became a recognized subspecialty within the Royal College of Physicians and Surgeons of Canada (Andrew and Shea, 2010). Probably the most detailed curriculum is that developed by the UK Royal College of Psychiatrists (2010, updated 2017, see Fig. 20.2), which covers the competencies required and the relevant assessments for both core and specialist training within psychiatry and old age psychiatry, respectively.

Principles of service provision in old age psychiatry

There are perhaps three big challenges in this area. One is that the curricula usually just relate to old age *psychiatry* and not other mental health professions, for whom training arrangements and competencies are far less developed. A second issue is that there needs to be specific attention on developing clinical researchers in old age psychiatry so that the clinical aspects of mental disorders in old age continue to receive adequate attention alongside basic biological and epidemiological research (Bartels et al., 2010). In England, the National Institute of Health Research (NIHR) has initiated a programme of academic clinical fellowships that offer doctors a proportion of research time while they complete their specialty training, with the aim that they then move on to a higher degree or research fellowship. These posts can be in any specialty, but there is certainly interest in providing posts in old age psychiatry and dementia research. The third challenge is that recruitment can be difficult, since professionals in training may find working with older patients less attractive than with other groups or they are deterred if the sub-specialty training is longer. Research consistently finds that having good experiences working with older people during or before medical school training or other training posts are associated with doctors choosing to work in the specialty (Lieff et al., 2003; Rej et al., 2015). What is probably also required is more flexibility allowing psychiatrists to move into old age psychiatry at a later stage of their career, rather than forcing them to choose irrevocably at too early a stage.

Conclusion

Increasing numbers of older people across the world pose a major challenge to health and social care services, including those involved in mental health. Old age psychiatry has become a mature specialty and there is a considerable evidence base for many of the things that it has to offer. However, there is a paradox in that, at the time that it would seem to be most needed, it also seems to be under threat. Nonetheless, in whatever way services are configured in the future, we will still need well-trained, skilled practitioners who are able to assess and manage conditions such as dementia and depression in older people. Anyone who has these competencies or is in the process of acquiring them should feel confident that they have a major part to play.

Psychiatric presentations among older people living in low- and middle-income countries

Chapter:

Psychiatric presentations among older people living in low- and middle-income countries

Author(s): K. S Jacob and Cleusa P. Ferri

DOI: 10.1093/med/9780198807292.003.0021

Introduction

The introduction of operational diagnostic criteria and categories in the Diagnostic and Statistical Manuals of Mental Disorders (DSM) (DSM III, IIIR, IV, 5) (American Psychiatric Association, 1980; 1987; 1994; 2013) and in the International Classification of Diseases-10 (ICD-10) (World Health Organization, 1992) have seen the universalization of psychiatric diagnoses and their use across countries and cultures. This strategy has been also employed for the diagnosis of older people with mental illness. Yet, the use of symptom counts to define psychiatric syndromes without context results in clinical heterogeneity within diagnostic categories, which is often magnified when used in low- and middle-income countries (LMICs) with their diverse environmental milieu. This chapter highlights the different contexts prevalent in LMICs, their impact these contexts

Psychiatric presentations among older people living in low- and middle-income countries

have on psychiatric diagnosis, and the management of different condition across regions.

Population ageing

The ageing of populations, considered the most significant transformation of the twenty-first century (United Nations, 2015) has been documented across regions, countries and cultures. The total number of persons aged 60 or above is expected to double by 2050 and triple by 2100, rising from 962 million in 2017 to 2.1 billion by 2050, and 3.1 billion by 2100. The great majority of this increase will take place in LMICs: 65% of the increase among older people between 2017 and 2050 will occur in Asia; Africa will contribute 14%, Latin America and the Caribbean 11%, and the remaining 10% will occur in other regions (United Nations, 2017).

The ageing of populations affects diverse aspects of society including labour and financial markets, goods and service sectors like housing, transportation, and social security, family structures, and intergenerational relationships (UN, 2017 report) However, the ageing phenomenon is not a homogenous or uniform process. The differences in base populations and rates of growth and longevity mean that there will be wide variations between regions. The projected increase in older people living in LMICs coupled with limitations in resources in these regions adds complexity and urgency (Ferri and Jacob, 2017). This chapter discusses the issues related to the assessment, diagnosis, and care of older people living with psychiatric disorders in LMICs. It highlights the complexity of the issues, the impact of varied contexts, and the major differences in approaches needed for diagnosis and management.

Dementia

The ageing of populations has also highlighted the importance of age-associated cognitive impairments, including dementia, in older people across regions, countries, and cultures. The number of people living with dementia has been increasing and is estimated to reach 75 million by 2030, with the majority living in LMICs (Alzheimer's Disease International, 2015).

DSM-5 recommends that major neurocognitive disorder (termed dementia in earlier editions) is diagnosed in the presence of significant cognitive decline from a previous level of functioning in one or more cognitive domains, which include complex attention, executive function, learning and memory, language, perceptual-motor, and social cognition (APA, 2013). These deficits interfere with independence in everyday activities and evidence of decline is based on information from a knowledgeable informant/clinician and preferably documented by neuropsychological testing. These cognitive deficits do not occur exclusively in the context of delirium and are not better explained by another mental disorder (e.g. major depression, schizophrenia).

Psychiatric presentations among older people living in low- and middle-income countries

DSM-5 recommends the use of neuropsychological testing or, in its absence, another quantified clinical assessment to document impairment in cognitive performance (APA, 2013). It recommends comparison with population norms appropriate to the patient's age, educational attainment, and cultural background. It suggests a diagnosis of major neurocognitive disorder for performance more than two standard deviations below the population norm or less than the third percentile. Nevertheless, DSM-5 also acknowledges that neuropsychological testing is not available in all settings, that neuropsychological thresholds are sensitive to the specific test(s) and norms employed, as well as to test conditions, sensory limitations, and inter-current illness. It also suggests specific 'bedside' assessments to objectively document current performance in settings where such testing is unavailable or not feasible. The absence of population norms in many LMICs complicates issues (Jacob, 2014a,b).

Prevalence

Estimates of the total numbers and proportion of older people living with dementia across regions and countries show an increasing trend. However, differences between populations have been documented. Population-based studies on dementia prevalence have been done around the globe. Prevalences seem to be lower in India (1.36% to 3.50%) compared to the high-income country (HIC) data (5.9% to 9.4%) (Chandra et al., 1998; Ferri et al., 2005). A systematic review of the global prevalence of dementia showed that age-standardized prevalence varied from 2.1% in sub-Saharan Africa to 8.5% in Latin America (Prince et al., 2013). Systematic reviews have also documented the high prevalence of undetected dementia, particularly across LMICs (Lang et al., 2017).

True differences in population prevalence exist and are attributed to differing genetic and environmental factors, life expectancy, duration of disease, and age-specific incidence. However, variations in prevalence data may also be due to the use of different data collection procedures (one stage/two stage), assessment schedules, diagnostic criteria, and cultural conceptions of the condition (Ferri and Jacob, 2017).

Diagnosis

It has been well recognized that low or absent education impacts cognitive assessment in general (Cherbuin et al., 2008) and in LMICs in particular (Lopes, 2012; Noroozian et al., 2014). The 10/66 Dementia Research Group examined the impact of education and age on performance in dementia assessments and developed strategies for adjusting for these (Prince et al., 2003; 2004). They employed a standardized methodology to assess the prevalence of dementia in many LMICs (e.g. Latin American countries, China, and India) in order to produce data, which is comparable across regions (Prince et al., 2004). However, a detailed analysis of data from Vellore, India, which was part of the consortium, demonstrated wide variations in prevalence depending

Psychiatric presentations among older people living in low- and middle-income countries

on the diagnostic criteria used. The prevalence of dementia was 63.4%, 21.2%, 10.6%, and 0.8% with the Geriatric Mental State (using AGE-CAT), the original 10/66 diagnostic algorithm, the education adjusted 10/66 algorithm, and according to Diagnostic and Statistical Manual IV (DSM-IV) criteria, respectively (Jacob et al., 2007b). Investigations from Africa comparing DSM-IV criteria with 10/66 criteria have also demonstrated significant differences (Paddick et al., 2013, 2015). The 10/66 Dementia Research Group has also acknowledged the wide variation found in prevalences based on specific diagnostic criteria (Llibre Rodriguez et al., 2008).

Information variance (e.g. different informants, interview schedules) is a common reason for observed differences in prevalence; variations in diagnostic criteria also contribute to massive differences in the threshold for the condition, and the number and the type of patients identified (Jacob et al., 2007a; Jacob, 2014b). While there is general agreement on the major criteria for the diagnosis of dementia, minor variations in information and criteria can result in wide variations in the patients identified and pose a major problem for cross-national comparisons.

The diagnosis of dementia is also complicated by the fact that newer criteria differ from standards used in the past. DSM-5 has made significant changes to its diagnostic criteria for dementia (now termed major neurocognitive disorder) (APA, 2013). It has expanded cognitive domains, which now also include complex attention and social cognition. The clinical interview schedules and instruments used to diagnose dementia do not routinely assess these domains and/or include them in their diagnostic algorithms. Clinical information and the results of neuropsychological tests are also necessary for a definitive diagnosis of neurocognitive disorders. DSM-5 also demands a comparison of the person's individual performance in neuropsychological tests with population norms, adjusted for age, education, and cultural background. As mentioned, the absence of population norms and the lack of resources to conduct detailed neuropsychological tests in LMIC hamper cross-site comparisons (Ferri and Jacob, 2017; Jacob 2014b). In addition, the clinical continuum of age-related cognitive decline, mild cognitive impairment (minor neurocognitive disorder), and dementia make the task of dichotomous demarcation, to identify dementia, difficult (Jacob et al., 2007b; Jacob, 2012b, 2014b).

The impact of cognitive decline on a person's daily function is also dependent on their milieu, which includes family expectations of their behaviour and involvement in family life, socioeconomic circumstances, level of social support, cultural roles, and social responsibilities. Consequently, variations in the milieu will affect the impact of impaired functioning, resulting in differential measured disability and handicap. In addition, cognitive impairment is more difficult to identify in settings where memory loss is considered part of normal aging, in contexts where older people face fewer cognitive demands in everyday life (e.g. joint families common in some LMICs) and where low education poses

Psychiatric presentations among older people living in low- and middle-income countries

significant challenges to cognitive assessments (Patel and Prince, 2001; Jacob et al., 2007b).

Screening instruments and strategies

Several instruments have been employed to screen patients for dementia in the community (Milne et al., 2008). Many screening instruments designed and developed in HICs have attempted to reduce the impact of education level, ethnicity, and culture. However, the use of items, which are region and culture specific (e.g. the recall of information including dates, paper-and-pencil tests, details related to finance and travel) makes it difficult for people without cognitive impairment in LMICs to fare well in these tests (Jacob, 2014b).

Because of the high rates of underdiagnosis worldwide, there is currently a strong call to increase diagnosis rates (Jacob, 2016). However, there are several challenges to be overcome regarding any potential screening programme to help increase identification (Stanley, 2009; Chambers et al., 2017). These include that: (i) many instruments, including the commonly used Mini-Mental Status Examination, are influenced by education and by culture, making them inappropriate for use in societies with low literacy (Mitchell, 2009); (ii) the education and culture free screening tests, which employ activities of daily living rather than paper and pencil tests, do not systematically test multiple cognitive domains; (iii) even screening instruments with good sensitivity and specificity, when used in situations of low prevalence (e.g. community and primary care) result in high false positive rates and low positive predictive values as these are dependent on prevalence (and incorrect identification of people with dementia can have long-term consequences including stigma, loss of employment, and autonomy); (iv) health systems might not have the capacity to increase screening. Therefore, at the moment, screening should only be employed in people with symptoms of cognitive impairment, rather than using it in the general population, where prevalence is much lower, making these instruments perform poorly and result in misclassification.

A recent systematic review and meta-analysis concluded that while numerous tools for assessment of cognitive impairment in low-literacy settings have been developed, and tools developed for use in HICs have also been validated in low-literacy settings, most tools have been inadequately validated (Paddick et al., 2017). They conclude that at present no screening test can be recommended for use (Paddick et al., 2017).

The changes in the DSM-5 standards for dementia (APA, 2013), the expansion of cognitive domains, and the need for the establishment of local norms mandate a review of previously validated and routinely employed screening tools. A recent study attempting to validate existing instruments (e.g. MMSE, Vellore Screening Instruments for Dementia (VSID)) reported different screening thresholds dissimilar from those

Psychiatric presentations among older people living in low- and middle-income countries

originally recommended for these instruments; it also recorded different indices of efficacy, i.e. sensitivity and specificity (Varghese et al., 2018). These findings demand a recalibration of all existing instruments for use with the new DSM-5 standards. They also suggest the need to recalculate cut-offs/thresholds for screening.

Most of the available screening instruments were developed long before the advent of the DSM-5 standards. The MMSE uses simple screening questions to evaluate comprehension, reading, writing, orientation, and drawing abilities, which were the gold standard for diagnosis of dementia in the 1970s (Folstein et al., 1975). VSID employs activities of daily living related to the DSM-IV diagnostic criteria/domains (memory impairment, agnosia, aphasia, apraxia, and loss of executive function) (APA, 1994) against which they were validated (Stanley et al., 2009). Essentially all screening instruments, when initially designed, take the available gold standard of diagnosis and attempt to simplify the diagnostic process and employ proxy questions/tasks to identify similar dysfunction (Díaz-Orueta et al., 2017). Consequently, major changes in gold standards mandate the need to redesign screening instruments. The increased scope of the DSM-5 symptom criteria for diagnosis of neurocognitive disorders demands the need for a reappraisal of screening and confirmatory strategies. There is a definite need to develop screening instruments which evaluate all dimensions of cognitive impairment included in the DSM-5 criteria, which then have to be validated against the new standard in large populations.

Yet, screening instruments and strategies, even those with good sensitivity and specificity, do not perform well in situations with a low prevalence of the condition (Chambers et al., 2017). Predictive values are prevalence dependent and screening all people, when the prevalence of dementia/mild cognitive impairment is low, is bound to result in high false positive rates. Even good screens for dementia will necessarily have to be judiciously used, as they will perform poorly if employed in community and population surveys (Stanley et al., 2009). However, their predictive values will improve when used to screen people who complain of cognitive problems and those whose caregivers report such difficulties.

Correlates

Many factors associated with dementia in HICs have also been documented in LMICs. These include: increased mortality (Prince et al., 2012a; Wang et al., 2010), female sex (Ochayi and Thacher, 2006; Cheng et al., 2014), advanced age (Ochayi and Thacher, 2006; Prince et al., 2012a), hypertension (Ogunniyi et al., 2011), diabetes mellitus (Salas et al., 2016), APOE ϵ 4 genotype (Rodriguez et al., 2014), smoking (Ferri et al., 2011), low fish and meat consumption (Albanese et al., 2009), traumatic brain injury (Khan et al., 2015), sleep complaints (Mazzotti et al., 2012), frailty (At et al., 2015; Llibre Rodriguez et al., 2018), neuropsychiatric symptoms (Acosta et al., 2017), incontinence, hearing impairment, mobility impairment, and under-nutrition (Prince et al.,

Psychiatric presentations among older people living in low- and middle-income countries

2011b), weight loss (Albanese et al., 2013b), smaller arm and waist circumferences (Taylor et al., 2012) and shorter leg length and skull circumference indicative of lower early-life nutrition (Prince et al., 2011a), and contemporaneous low blood pressure (Albanese et al., 2013a).

Disability

Disability among older people has been measured across LMICs (Sousa et al., 2010). A 10/66 Dementia Research Group study demonstrated that dementia and other biomedical determinants (e.g. stroke, limb impairment, arthritis, eyesight problems, gastrointestinal disorders) were the leading cause of disability among older people (Sousa et al., 2009). However, a reanalysis of 10/66 data from India, which included environmental variables in the multivariable model, identified many social and economic factors as significantly contributing to disability (Duba et al., 2012). These included advanced age, illiteracy, hunger, poor nutrition, and the cost of travel to primary health facilities. There is a need to focus on local contexts and modifiable risk factors to design appropriate public health policies and interventions for older people in LMIC (Llibre Jde et al., 2011).

Mild cognitive impairment

Mild cognitive impairment (MCI; minor neurocognitive disorder) is diagnosed in the presence of cognitive decline from a previous level of functioning in one or more cognitive domains included in the DSM-5 (APA, 2013). These deficits interfere with independence in everyday activities, based on information from a knowledgeable informant or documented by neuropsychological testing. Furthermore, the deficits do not occur exclusively in the context of delirium and are not better explained by another mental disorder (e.g. major depression, schizophrenia). The recommended norms for minor neurocognitive disorder are fixed between the third and sixteenth percentile or between 1–2 standard deviations. DSM-5 recommends the use of neuropsychological testing or in its absence, another quantified clinical assessment to document impairment in cognitive performance (APA, 2013). It recommends comparison with population norms appropriate to the patient's age, educational attainment, and cultural background. Nevertheless, DSM-5 also acknowledges that neuropsychological testing is not available in all settings, that neuropsychological thresholds are sensitive to the specific test(s) and norms employed, as well as to test conditions, sensory limitations and inter-current illness. It also suggests specific 'bedside' assessments to objectively document current performance in settings where such testing is unavailable or not feasible. As described for dementia, the absence of population norms in many LMICs complicates issues (Jacob, 2014b).

Psychiatric presentations among older people living in low- and middle-income countries

MCI has been reported from across LMICs (Nie et al., 2011; Baiyewu et al., 2012; Wang et al., 2015; Villareal et al., 2016). MCI was examined in Latin America, China, and India using 10/66 standardized methodology and algorithms (Sosa et al., 2012). The crude prevalence of amnesic MCI (aMCI) ranged from 0.8% in China to 4.3% in India. Country differences changed little (range 0.6%–4.6%) after standardization for age, gender, and education level. Pooled estimates suggested that MCI was significantly associated with male gender and fewer assets but was not associated with age or education.

Mild cognitive impairment may be more difficult to identify in settings where memory loss is considered part of normal aging, in contexts where older people face fewer cognitive demands in everyday life (e.g. joint families common in some LMICs), and where low education poses significant challenges to cognitive assessments (Patel and Prince, 2001; Jacob et al., 2007b).

Delirium

Delirium is characterized by a disturbance in attention and awareness (reduced orientation to the environment), often of short duration, and with an abrupt onset. Disturbance of cognition (e.g. memory deficits, disorientation, language, visuospatial ability, or perception) may also be present (APA, 2013). Its close association with medical illness is reflected in incidence and prevalence estimates that vary widely depending on clinical setting. Substance withdrawal, medication-induced delirium, and delirium with multiple aetiologies are also common. The prevalence of delirium in hospital settings is high compared to that present in the general population and in community locations.

Instruments to recognize delirium have been validated and used in LMICs (Shyamsundar et al., 2009; George et al., 2011). While delirium, as a clinical presentation, has been identified across LMICs (and often in the medical context and hospital settings; see Säll et al., 2009; Lahariya et al., 2014; Tanaka et al., 2015; Xing et al., 2017), most of the studies on the subject do not focus on older people. A systematic review identified only two studies of delirium among older people from Africa (Paddick et al., 2015). Regional variations in aetiology and medical comorbidities that cause delirium, and variations in the manifestation of the clinical syndrome, demand further study.

Psychosis

Psychosis is also a common presentation among older people. The later onset of psychosis often mandates a careful clinical examination and investigations to rule out underlying causal medical, endocrine, and neurological conditions. Late-onset psychosis is often characterized by a predominance of psychosis with preservation of affect and social functioning. The relationship of such psychosis to schizophrenia diagnosed prior to mid-life remains unclear. Studies on late-onset

Psychiatric presentations among older people living in low- and middle-income countries

psychosis form a small minority of all research efforts related to psychosis in general, and particularly in LMIC settings.

Socioeconomic and cultural factors play an important role in clinical presentations. Ideas that appear to be delusional in a particular culture (e.g. witchcraft) may be common in another. Linguistic variation in narrative styles across cultures mandate culturally sensitive assessments. Evaluating pseudo-hallucinations and overvalued ideas requires cultural competence on part of clinicians. Soares and colleagues (2015) examined psychotic symptoms in a Brazilian community sample and documented its correlation with lower cognitive scores, lower education, and lower socioeconomic status, as well as higher medical comorbidity. A study from Nepal recorded much lower rates of older people hospitalized in psychiatric facilities, compared to HIC rates and to younger people from the area, suggesting poor delivery of care to this group (Aich et al., 2012).

At least one behavioural and psychological symptom of dementia was reported in 70.9% of the participants in the population studies of the 10/66 Dementia Research Group undertaken in Latin America, China, and India, with schizophreniform/paranoid psychosis diagnosed in 10.9% of the sample (Ferri et al., 2004).

Depression and anxiety

Depression and anxiety with onset in late life are common and documented across LMICs. The World Health Organization's 'Study on global AGEing and adult health (SAGE)' documents a cross-national prevalence of late-life depression of 4.7% (95% CI: 1.9%–11.9%) (Brinda et al., 2016b). Female gender, illiteracy, poverty, indebtedness, past informal-sector occupation, bereavement, angina, and stroke had significant positive associations, whereas pension support and health insurance showed significant negative associations with late-life depression.

These disorders also commonly co-occur with dementia in older people. Depression (45.3%), apathy (37.7%), appetite change (24.5%), irritability (22.6%), delusions (22.6%), anxiety (18.9%), and agitation (17.0%) have been reported among older people in Nigeria, particularly those with cognitive impairment (Baiyewu et al., 2012). While at least one behavioural and psychological symptom of dementia (BPSD) was reported in 70.9% of the participants of the 10/66 population studies, depression syndromes (43.8%) were most common (Jacob, 2012a) followed by anxiety neurosis (14.2%) (Ferri et al., 2004).

The prevalence of co-occurring anxiety and depression syndromes ranged between 0.9% and 4.2% across 10/66 data collection sites. Gender, socioeconomic status, urbanicity, and physical comorbidities were associated with the different comorbid states and these disorders were linked to higher disability scores (Prina et al., 2011a). However, age- and gender-standardized prevalence of anxiety varied greatly across 10/66

Psychiatric presentations among older people living in low- and middle-income countries

sites, ranging from 0.1% in rural China to 9.6% in urban Peru. Age, gender, socioeconomic status, and comorbid physical illnesses were all associated with a GMS/AGECAT diagnosis of anxiety, as was disability (Prina et al., 2011b). Much of the evidence suggests the need to manage psychosocial and economic contexts in addition to medical comorbidity among older people in order to reduce symptoms of depression and anxiety in late life.

Substance use

It is now recognized that misuse and addiction to alcohol, prescription medication, and illicit drugs, although not often studied among older people, is an invisible epidemic in many countries. The increasing size of the older cohorts poses particular challenges. Physiological changes with aging and age-related factors have led to the setting up of lower recommended limits of alcohol use among older people. Under-reporting of use and the use of prescription and over-the-counter medication is also common among older people.

Alcohol use has been documented among older people living in LMICs (Kim et al., 2007; Zhou et al., 2014; Martinez et al., 2014). Nadkarni and colleagues (2011) documented the significant presence of harmful alcohol use among older people living in the Dominican Republic and its adverse impact on family and carers, which was not accounted by disability but explained by behavioural problems. Zhou and colleagues (2014) reported on the risk of alcohol and tobacco use and its association with dementia among older people living in China. A high degree of concordance of smoking and drinking habits has been documented among older couples living in Latin America, which was explained by the size of their social networks rather than by their socioeconomic circumstances (Machado et al., 2017). Similarly, medication overuse has been documented across LMICs (Find et al., 2015; Kamuhabwa and Lugina, 2010). While substance misuse and dependence are often managed as an individual issue requiring specific treatment and psychological intervention, there is much to be said for the use of public health approaches to reduce their use in LMICs (World Health Organization, 2014; 2017).

Suicide

Higher suicide rates have been traditionally reported among older people. Suicide has also been associated with mental illness. Completed suicides, suicidal attempts, and ideation have been recorded across LMICs. Borges and colleagues (2015) found a lifetime prevalence of suicide ideation of 13.5% and a two-week prevalence of 4.2% in a community sample of older people in Mexico. The common factors associated with both these outcomes were having a large number of physical disorders, depression and anxiety, and screening positive for psychosis.

Psychiatric presentations among older people living in low- and middle-income countries

Very high annual suicide rates of 189 per 100,000 for people over 55 years of age have been reported from India (Abraham et al., 2005). The age-specific suicide rate for men and women increased with age. Hanging (52%) and poisoning with organophosphorus compounds (39%) were the commonest methods employed for committing suicide. Significantly, more women chose drowning or burning as suicide methods than men, who were more likely to choose poisoning or hanging.

Suicide, a common cause of death in many LMICs, has often been viewed through a medical/psychiatric lens (Jacob, 2017b). However, recent studies have documented low rates of mental illness and higher rates of contextual stress. A systematic review that examined the association between suicide and poverty in LMIC documented a positive association (Iemmi et al., 2016). It also acknowledged a positive association between non-fatal suicidal ideation, behavioural symptoms, and poverty and argued for the potential benefit of addressing economic poverty within suicide prevention strategies, with particular attention to both chronic poverty and acute economic events. Recent studies from India (Manoranjitham et al., 2010) and from China (Zhang et al., 2010; Li et al., 2008) have also shown that the majority of the people who kill themselves are distressed secondary to their psychosocial context and only a small minority have severe mental illness. While people with severe mental illnesses do complete suicide, their contribution to population rates is much less significant than that seen in HICs. The absence of a social security net, which seems to be crucial in managing psychosocial and economic distress, may explain the differing rates of suicide and the rates of serious mental disorders among those who kill themselves in high-income and emerging economies.

While individual interventions and psychiatric inputs can prevent suicide in people identified to be at risk, their impact on population rates of suicide is yet to be demonstrated. Consequently, public health approaches have also been advocated. For example, ingestion of pesticides is a common method of suicide in settings where these are readily available and kept in accessible domestic locations (Abraham et al., 2005). It has led to research, encouraged by manufacturers of pesticides, which focused on evidence that providing safer methods of storage (e.g. a double locked box) (Hawton et al., 2009) and the use of pesticide banks (i.e. a secured central storage facility) (Vijayakumar et al., 2013) to reduce impulsive suicide attempts and fatalities. Nevertheless, such focus belies the fact that extremely lethal pesticides banned in HICs are sold by multinational corporations and are freely available in most LMICs. These strategies shift the responsibility for suicide from large businesses, which refuse to change practices in order to maximize profits, to individuals. While selective approaches like the banning of lethal WHO Class I organophosphorus insecticide in Sri Lanka has reduced hospital admissions, the use of Class II compounds means continued deaths by pesticide self-poisoning (Eddleston et al., 2012).

Psychiatric presentations among older people living in low- and middle-income countries

While interventions have shown a reduction in method-specific or site-specific rates, there is no firm evidence to suggest an overall reduction in suicide (Jacob, 2017b). The reductions in suicide reported in some countries have more to do with secular trends and improvements in living standards than specific suicide prevention programmes. Social determinants of health and mental health demand public health interventions in order to reduce inequity and provide social justice, which in turn may prevent suicide among vulnerable people.

Suicide, when viewed through a medical/psychiatric lens, medicalizes social and personal distress and suggests individual and medication-based treatments. There is a definitive need to examine suicide in LMICs from a public health perspective and argue for the need for population-based social and economic interventions. (Jacob, 2017b).

Carer burden and health expenditure

The costs of psychiatric problems among older people and carer burden have been studied in LMICs. A recent study (Ferretti, 2018) on the costs of dementia in Brazil showed that 56.6% of total dementia costs was attributable to informal care costs. In this study, progression of the disease, which was associated to caregiver burden, had a significant influence on the economic impact of the disease. The impact of dementia on the mental health of relatives and carers of older people living in LMICs has also been documented. Depression and high strain scores have been recorded among carers of people with dementia in the 10/66 Dementia Research Group studies (Prince, et al., 2012b; Brinda et al., 2014). Women carers reported more strain than men; carer strain was associated with the presence of behavioural and psychological symptoms of dementia (BPSD), severe dementia, higher disability, incontinence, need for care, and time spent caring. There was tentative evidence for a protective effect of having additional informal or paid support.

Inequitable service access and the cost of care for older people also contributes to carer burden. Increasing out-of-pocket health expenditure among older people has been documented and worsens the inequitable access to essential health services in LMICs (Brinda et al., 2012). Male gender, poor sanitation, diabetes, tuberculosis, malaria, respiratory ailments, gastrointestinal diseases, dementia, depression, and disability were associated with higher out-of-pocket expenditure. Illiteracy, tuberculosis, diabetes, and dementia increased the risk for catastrophic health expenditure, while pension schemes protected against it. Income inequalities were associated with inequities in education, disease prevalence, and access to safe water, sanitation, and nutrition. It highlights the need for equitable health services and policies, focusing on both medical and social determinants. Socioeconomic disparities in health and health care are major concerns in many LMICs (Brinda et al., 2016a,b). The achievement of health equity demands strategies beyond

Psychiatric presentations among older people living in low- and middle-income countries

health policies, to include pro-poor, social welfare policies among older people.

Health systems

Health systems play a significant role in the care of older people and impact health care delivery. Dementia, for example, is under-recognized, under-disclosed, under-treated, and under-managed, particularly in LMICs (Ferri and Jacob, 2017; Lang et al., 2017). The WHO (1990) and the 10/66 Dementia Research Group (ADI, 2016; Shaji et al., 2002) recommend the strategy of employing community health workers to identify mental illnesses in general, and dementia in particular, in resource-poor settings. However, in India the use of community health workers to identify people with dementia in the population resulted in a very high false positive rate (Jacob et al., 2007a).

The reasons for the failure of the strategy include the fact that disorders with low prevalence at the community level cannot be diagnosed accurately unless a referral system is in place. A tiered organization (e.g. health worker, public health nurse, physician, psychiatrist/neurologist) that screens, confirms, and refers people at risk up a pathway of care is therefore required for improving the overall accuracy of the system. The failure to put in place such a diagnostic system, which employs health personnel to filter cases at multiple levels, has contributed to the failure of community psychiatry programmes across LMICs (Jacob, 2011) that aimed to identify and manage mental disorders including dementia. There is a definite need to put in place a tiered network if screening and management programs are to be successful (Jacob et al., 2007a).

Health services in LMICs are beset by multiple and complex problems, including poor infrastructure, overburdened systems, inappropriate training for health professionals, professional apathy, limited finances, impoverished environments, and low morale of primary health-care staff. The problems are compounded by substantial differences in primary and tertiary care approaches to mental health and illness and include differences in settings, patient profiles, and physician perspectives (Jacob, 2014a; Jacob and Patel, 2014). It is important to acknowledge the complex realities of primary care in LMICs when advocating for the introduction of mental health care into primary care.

Care

Care of older people with psychiatric problems is complex, particularly in resource-poor settings. The progression of the disease alters care needs over time in people living with dementia; other psychiatric presentations may also require continual assessment and a continuously tailored management approach to deal with the clinical changes and changed contexts (ADI, 2016). While health care models that focus on task-shifting and task sharing have been discussed in HICs, the challenges are even

Psychiatric presentations among older people living in low- and middle-income countries

more complex with the limited resources found in LMICs (Ferri and Jacob, 2017).

The identification of the critical role of local and social determinants in respect of disability, and the paucity of medical interventions to reverse the pathology of dementia, mandate the need for psychosocial support, accommodation, and nursing care as the mainstays of management (ADI, 2016). In reality, reduced public health expenditure, the absence of social security and the limited access to universal health care in most LMICs, as well as the lack of formal and institutional care for dementia, place a huge burden on relatives and carers (Ferri and Jacob, 2017) and result in increasing out-of-pocket expenditure (Jacob, 2017a). While informal care and family support are crucial, organized services for older people living in LMICs will reduce the costs and burden of care. However, overburdened and under-resourced public health systems, low staff morale, poor training, and limited expertise in mental health result in poor care for older people. There is a need to integrate social and health intervention programmes to provide optimal care for older people (Alzheimer's Disease International, 2016).

Need for a contextual understanding

The mental health issues facing older people in LMICs and the different approaches this chapter describes need to be considered taking into account their day-to-day lives and the particular characteristics of the local settings. The success of programmes in HICs and their replication in successful projects in LMIC do not necessarily mean that they can be scaled up and be effective when rolled out to larger populations. The distinctive context of care for older people in LMICs requires tailored solutions to the problems they face. Context and local knowledge are critical to understanding health and illness and structures of care (Jacob, 2017c).

Direct comparisons between LMICs and HICs of context, presentations, burden, and services may not be appropriate. Medical and non-medical approaches and public health strategies should all be employed to relieve the suffering related to mental distress and illness among older people. The issues call for a shared perspective, which should be negotiated not only with people with mental illness, but their families and local communities as well.
